¹ CHAPTER 1 Laboratory Diagnosis of Viral and Rickettsial Infections and Epidemiology of Infectious Disease

James F. Evermann

Rance K. Sellon

Jane E. Sykes

Clinical diagnosis of viral and rickettsial infections is of utmost importance as the range of clinical inquiry expands. Veterinarians are under increasing pressure to assist with and develop testing strategies to accurately determine the infection status of dogs and cats. Clinical inquiry generates information that not only clarifies the disease status of an animal but also determines whether an infectious microbe is present. Once its presence is confirmed, additional considerations include the infectious agent's potential to be shed and infect other susceptible animals and humans, its potential to be carried as an asymptomatic infection, and its risk of causing disease (Table 1-1).

Various technologies exist for detecting viral and rickettsial infections of dogs and cats. In some cases, diagnosing disease is the veterinarian's paramount goal so that the correct course of action can be determined (e.g., diagnosing canine distemper virus [CDV] in a dog with neurologic symptoms). In other situations, it may be important to determine the *infection* status of a dog, such as during a prebreeding screen for canine herpesvirus (CHV) and *Brucella canis*. As testing strategies have evolved, so have applications of different assays to address these issues.¹² Such assays include the more recent use of serologic assays to monitor immune competence and the evaluation of serum antibody titers to assess frequency of vaccination boosters.⁴⁷ Other areas important to companion animal veterinarians include clinical epidemiology as it relates to multiple animal households, population-based preventative veterinary medicine in humane facilities,^{13,21,37} interspecies spread of infections between dogs and cats, and zoonotic potential of infections.^{4,25}

1.1 DIAGNOSIS OF DISEASE VERSUS DETECTION OF INFECTION

Clinicians use diagnostic testing for two main reasons: (1) to diagnose an acute or chronic infectious disease process and (2) to detect a preclinical infection when susceptible animals or humans may be vulnerable to disease or shedding of infection.^{1,7,32} As expectations of preventative medicine have increased, so has the demand for early detection of infectious diseases.^{11,12,40} Although the majority of diagnostic assays have been designed to assist in making a disease diagnosis (e.g., the canine parvovirus [CPV] antigen enzyme-linked immunosorbent assay [ELISA] for fecal samples), more clinicians are using nucleic acid detection assays that use the polymerase chain reaction (PCR) for amplification of minute quantities of microbial RNA or DNA (see Molecular Diagnostics). This technology has uncovered the latent phases of herpesviral and retroviral infections, such as CHV, feline leukemia virus (FeLV), and feline immunodeficiency virus (FIV) infections.^{1,12,21,32} It has also allowed clinicians to recognize the importance of carrier animals in the population, which harbor low levels of certain microbes as infections, such as CDV as upper respiratory infections and canine coronavirus as gastrointestinal infections.^{13,36} Early detection of infections has added a new dimension to diagnostic testing and has assisted the veterinarian in making decisions at the individual level (e.g., whether to give medication or vaccinate a particular animal) or at a population level (whether to segregate or depopulate).^{17,20,40}

Diagnostic tests in nonclinical areas of veterinary practice are used in surveillance, monitoring or screening for unusual clinical presentations, estimating infection prevalence in a practice area, and performing risk factor

Infectious Diseases of the Dog and Cat, 3rd Edition

analysis.^{20,22,41} Preclinical testing of animals is also being performed more frequently before show, sale, adoption, breeding, or placement in high-risk human environments (such as children's classrooms and convalescent care centers), which may require an animal to be certified not only as “disease free” but also as “infection free.”^{4,12,16}

1.2 DIAGNOSTIC ASSAY INTERPRETATION

Although the goal of a diagnostic assay is 100% accuracy, it is important to recognize that laboratory tests have varying degrees of sensitivity and specificity^{20,39,41} (Fig. 1-1). *Test sensitivity* is the likelihood that an animal known to have a particular disease or infection with a particular microbe will be identified with a positive test result. A test with high sensitivity has few false-negative results.⁴¹ The limits of test sensitivity can extend to an animal with a preclinical infection (i.e., an animal with a latent infection, that is an asymptomatic carrier, or that is in the incubatory phase of disease), therefore the values vary for either disease or infection. One assay may yield false-positive results for disease but true-positive results for infection, such as a PCR for CPV (Fig. 1-2). Conversely, the CPV antigen ELISA is an excellent way to detect CPV-associated disease but not sensitive enough to detect CPV in an asymptomatic carrier.

Test specificity is the likelihood that an animal known to be free of disease, infection, or both will have a negative test result. A highly specific test has few false-positive results. Knowing the specificity of a diagnostic test is very important because more false-positive results occur with a test of low specificity.⁴¹

Table 1-1 Interpretation of Laboratory Analysis of a Suspect Case of Canine Parvoviral Enteritis

CLINICAL INQUIRY	TEST	LEVEL OF INTERPRETATION
Is the dog infected with CPV?	ELISA for antigen	Yes/no
When was the dog exposed?	IgM serology	7–10 days
Is the CPV a new strain or variant?	Virus isolation, neutralization with monoclonal antibody	Strains 2, 2a, or 2b
Are other infectious agents present?	EM, virus isolation	Rotavirus, coronavirus, calicivirus
	ELISA for antigen	Rotavirus
	Bacteriology	<i>Salmonella</i> sp., <i>Campylobacter</i> sp., <i>Escherichia coli</i>
	Parasitology	<i>Giardia</i> sp.
Is the dog protected?	IgG serology, HI serology	≥1:100 (IgG) or ≥1:80 (HI)
Is the dog shedding low levels of virus subclinically?	Nucleic acid-based (PCR) assays	Yes/no
What are the risks of infection in susceptible dogs and cats?	IgG serology, risk analysis	≥1:100 (IgG)
What are the risks of disease in susceptible dogs and cats?	IgG serology, concurrent CCV infection, risk analysis	≥1:100 (IgG)
CPV, Canine parvovirus; CCV, canine coronavirus; EM, electron microscopy; HI, hemagglutination-inhibition; PCR, polymerase chain reaction; ELISA, enzyme-linked immunosorbent assay.		
A case in which canine parvoviral enteritis was suspected or being monitored based on clinical signs or at-risk category. Interpretation depends on the level of clinical inquiry and types of laboratory tests used.		

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 1-1 Calculation of sensitivity, specificity, and predictive values using a two-by-two table.

		INFECTION (DISEASE)		
		Present	Absent	
ASSAY	Positive	a True Positive (TP)	b False Positive (FP)	a + b
	Negative	c False Negative (FN)	d True Negative (TN)	c + d
		a + c	b + d	
Sensitivity	$= \frac{a}{a + c} = TP$		Prevalence	$= \frac{a + c}{a + b + c + d}$
Specificity	$= \frac{d}{b + d} = TN$		Accuracy	$= \frac{a + d}{a + b + c + d}$
Positive predictive value	$= \frac{a}{a + b}$		Negative predictive value	$= \frac{d}{c + d}$

Because an assay may not be able to distinguish an animal that is a preclinical carrier of infection status from an animal with the actual disease, a test's predictive value is very important to the veterinarian (see [Fig. 1-1](#)).⁴¹ Classically, a positive predictive value is the probability that an animal with a positive test result has the disease. A negative predictive value is the probability that an animal with a negative test result does not have the disease. The predictive values depend on the prevalence of the disease in the regional population.

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 1-2 The various levels of assay sensitivity, with canine parvovirus (CPV-2) as an example. Note the five different assays (A through E) and the assays that would be of greatest value for clinical diagnosis versus subclinical detection of infection.

1.3 SAMPLE SELECTION AND PRESERVATION

Laboratory diagnosis of viral and rickettsial infections requires proper sample selection, collection, and submission.⁴² A disease-causing organism is best detected when an animal is in the acute phase of the disease.^{32,44} During this phase the microbe is in its highest concentrations in areas such as body fluids, excretions, secretions, and blood. Postmortem samples may be valuable in the management of other animals in the susceptible population; however, the degree of diagnostic accuracy is generally reduced because of protein and nucleic acid degradation of live microbes or their antigens or genomes.^{1,11,32} Fresh samples should be promptly refrigerated for short-term shipment (24 to 36 hours) to a laboratory close to the clinic or by overnight carrier service. For long-term shipments (2 to 4 days), samples should be frozen and shipped on wet ice to the laboratory. Tissues for histopathology and immunohistochemistry (IHC) should be promptly fixed in buffered formalin. Serology may be of diagnostic value if acute and convalescent sera samples are available for IgG analysis or single samples are available for IgM analysis.^{23,49} Table 1-2 and Appendix 5 list collection samples used to make a laboratory diagnosis of viral and rickettsial diseases. As mentioned, of equal importance is specimen preservation and shipment to the testing laboratory. As more diagnostic test kits become available for use in clinics, long-term sample preservation becomes less important than appropriate sample collection. Table 1-3 gives guidelines for specimen collection, processing, and shipment for laboratory diagnosis. Because of the changing nature of diagnostic assays and the ability to detect some infections earlier, it is recommended that the laboratory be contacted for updated guidelines on sample collection, processing, and shipment.

Infectious Diseases of the Dog and Cat, 3rd Edition

1.4 LABORATORY ANALYSIS

1.4.1 Viral Infections

Table 1-3 presents the five primary methods used in diagnostic virology.^{11,32,44} Veterinary hospitals have the ability to perform in their clinics ELISA assays for detection of FeLV and CPV antigens and FIV antibody. Specialized laboratories should be consulted for more in-depth analysis of specimens from a particular case if the number of clinically ill animals significantly increases, unusual clinical signs are found, or new variants of preexisting viruses such as CPV and CDV are suspected. Veterinarians should be on the alert for first-line detection of emerging infections in primary and secondary hosts.¹³ The main methods of viral detection are electron microscopy (EM); immunologic detection of viral-coded proteins through immunofluorescence, ELISA, and immunoperoxidase-IHC; virus isolation in cell cultures or embryonating eggs; serologic assays that detect antibodies to specific viral-coded proteins; and nucleic acid-based detection using PCR for amplification of viral nucleic acid.⁴² Isolation and PCR are the techniques of choice for detection of unknown or new strains of viruses and rickettsia.³² See the respective chapters (Chapters 3 to 32) for additional information on viral infections of dogs and cats.

Table 1-2 Sample Collection for Laboratory Diagnosis of Viral and Rickettsial Diseases

SITES OR CLINICAL SIGNS	ANTEMORTEM SAMPLES ^a	POSTMORTEM SAMPLES ^b
Respiratory and ocular tissues	Nasal, ocular, pharyngeal swabs; conjunctival scraping; serum; whole blood ^c ; transtracheal wash	Selected tissues ^d and bronchiolar lymph nodes
Gastrointestinal tract	Feces, vomitus, serum, whole blood ^c	Selected small intestine sections, intestinal contents, mesenteric lymph nodes
Skin and mucous membranes	Vesicle fluid, swabs, scrapings of lesions, serum, whole blood ^c	Selected tissues ^d and regional lymph nodes
Central nervous system ^{a,e}	Cerebrospinal fluid, serum, whole blood ^c , feces	Selected brain sections
Genitourinary tract	Urogenital swabs, vaginal mucus, urine, serum, whole blood ^c	Selected sections from placenta, fetal lung, liver, kidney, and spleen
Immunosuppression, hematologic abnormalities, blood dyscrasias	Whole blood ^c , serum, bone marrow	Selected tissues ^d and lymph nodes

Modified from Murphy F, Gibbs EPJ, Horzinek MC, et al. 1999. *Veterinary virology*, 3rd ed, pp 193–224. New York, Academic Press.

a Samples should be kept moist and chilled.

b Fresh samples should be fixed (in 10% buffered formalin) for histologic and immunohistochemistry analysis.

c Sample should be collected in ethylenediaminetetraacetic acid (EDTA) and kept refrigerated.

d Hematogenous organs: lung, liver, kidney, bone marrow, and spleen.

e An animal with neurologic signs should be handled with extreme caution; before further diagnostic testing is performed, a public health laboratory should state the animal is free of rabies virus (see Chapter 22).

Infectious Diseases of the Dog and Cat, 3rd Edition

1.4.2 Rickettsial Infections

Rickettsiae are small, obligate, intracellular gram-negative bacteria that are often included with viruses in diagnostic discussions because common methods are used to diagnose them.^{16,23,26} Rickettsiae generally require living cells for propagation and are usually cultured in embryonating chicken eggs or in cell culture. Because of their fastidious nature, serology has been extremely valuable in the diagnosis of rickettsial infections.^{3,23} More recently, PCR assays have been used for detection of some rickettsial infections.^{2,14,16,38} Rickettsiae of veterinary importance and commonly used diagnostic assays are listed in [Table 1-4](#). See the respective chapters ([Chapters 27 to 30](#)) for additional information on rickettsial and chlamydial infections of dogs and cats.

1.4.3 Recognition of Newly Emerging Viral and Rickettsial Infections

The observation of unusual clinical manifestations in dogs and cats can serve as an initial clue that an infection is emerging from a new disease-producing agent.¹³ Emerging infections may be caused by interspecies spread of infectious microorganisms such as the transmission of feline calicivirus to dogs, West Nile virus (WNV) from insects to accidental dead-end hosts (e.g., dogs, horses, humans), and *Rickettsia felis* from cat fleas to dogs and humans.^{5,13,38} Emerging infections may also be caused by intraspecies mutations in which the microorganism becomes more virulent within a host species or in an immunocompromised host.¹³ Detection strategies initially using culture and broad-based PCR identify these microorganisms. This is followed by the development of new serologic assays, which enables surveillance and eventual control.^{32,40}

3

4

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 1-3 Specimen Collection, Processing, and Shipment for Diagnosis of Viral and Rickettsial Diseases

PROCEDURE AND SPECIMEN	COLLECTION AND PROCESSING	SHIPMENT
Organism isolation, nucleic acid-based testing, ELISA for antigen <i>Specimens:</i> Tissue, excretions, secretions	Collect aseptically to prevent bacterial contamination, and store at $\leq 10^{\circ}\text{C}$ to prevent inactivation; do not freeze or fix.	Use whole blood, ^a tissue biopsy, feces, swabs, ^b commercial transport media, or sterile minimal essential medium 10% FBS with penicillin (100 U/ml) and gentamicin (50 mg/ml) to inhibit bacterial growth; double bag for shipment; pack on wet ice to last 48–72 hr.
Serology <i>Specimens:</i> Serum, cerebrospinal fluid, synovial fluid	Collect aseptically to prevent contamination, and handle gently to prevent hemolysis; remove needle from syringe before dispensing; allow to clot at room temperature; rim clot and centrifuge at 650 g for 20 min; pipette serum fraction into clean tube; although paired samples (10–14 days apart) are preferred, single samples may be diagnostic (e.g., CDV IgM).	Refrigerate until shipping; double bag for shipment; use leak-proof vial.
Histology, immunohistochemistry <i>Specimens:</i> Tissue Direct FA testing	Collect aseptically to prevent contamination, 5 mm thick; fix in 10% buffered formalin (10 \times volume). Make tissue impression on clean, dry microscope slide and air dry; fix in alcohol for cytology or in acetone for direct FA. ^c	Double bag for shipment; ship in leak-proof container with adequate fixative. Pack on wet ice and ship as for isolation; smears can be shipped unrefrigerated.
<i>Specimens:</i> Tissue, tissue impression Electron microscopy <i>Specimens:</i> Tissue Feces or body fluids	Collect aseptically, 1 \times 2 mm thick; fix in 2%–4% glutaraldehyde (10 \times volume) for 24 hr at 20° C. Collect fresh; do not freeze or fix.	Double bag for shipment; ship in leak-proof container with adequate fixative. Refrigerate until shipping; double bag for shipment; pack on wet ice to last 48–72 hr.
<i>ELISA</i> , Enzyme-linked immunosorbent assay; <i>FA</i> , fluorescent antibody; <i>FBS</i> , fetal bovine serum; <i>CDV</i> , canine distemper virus		
a Collected in ethylenediaminetetraacetic acid (EDTA) and kept refrigerated.		
b Use Culturettes (Becton Dickinson, Cockeysville, Md).		
c Use Michel's fixative to preserve tissue specimens for antibody testing by indirect FA. For antigen detection, other fixatives may be used.		

1.5 SERODIAGNOSIS AND SEROSURVEILLANCE

Serology, the measure of antibodies in serum or other body secretions or excretions, has maintained a valuable presence in the diagnosis of viral and rickettsial infections.⁴² Its value is due in part to the development of more specific assays that incorporate purified antigen substrates for capturing specific antibodies and to increased sensitivity from Western blot and ELISA technology. Serologic assays are the foundation for serodiagnosis and serosurveillance. Serodiagnosis is the use of a serologic assay to assist in the diagnosis of current disease,³² such as the use of IgM (early antibody) assay with indirect fluorescent antibody to detect acute CDV-associated disease. Serosurveillance is the use of a serologic assay for determining whether an individual animal has been infected or exposed to an infection, or if multiple animal serums are analyzed, the prevalence of infection in a population.

Infectious Diseases of the Dog and Cat, 3rd Edition

Serosurveillance has expanded during the past decade and can now be used to assess an individual animal's level of protection against certain infections and determine the need for booster vaccination (see Serologic Testing, [Chapter 100](#)).^{30,31} Dogs with CDV titers of defined levels are generally considered protected against CDV-induced disease. However, additional studies must be conducted by laboratories to determine whether this antibody level can be used with multiple breeds of dogs under varying degrees of CDV challenge. Comparisons can also be made by sending duplicate samples to laboratories that have completed this reference standardization.

4

Formalin fixation

1.6 MOLECULAR DIAGNOSTICS

Nucleic acid-based assays such as PCR have been developed for the detection of viral and rickettsial infections such as CDV, FeLV, feline rhinotracheitis virus, WNV, and *Ehrlichia canis*.^{*} Partly because of the higher costs associated with establishing and maintaining PCR assays, selected laboratories have adopted multilayered testing techniques in which animals may be screened initially by a less expensive assay such as serology or antigen ELISA. If initial tests results are positive, PCR may help clarify issues such as the quantity of microbial shedding. Similarly, if screening assays are negative, then questions regarding latent conditions (such as FeLV in a valuable kitten) may arise, so PCR analysis could be recommended because of its increased sensitivity.^{8,27}

PCR can also be used to assess animals in the acute stages of disease, which are likely to have low antibody titers or have antigen levels too low to permit early detection by ELISA.^{39,40} PCR is not confounded by the presence of vaccination-induced or maternal antibodies, which may interfere with interpretation of serologic results. Tissues submitted for histologic examination may have characteristic pathologic lesions but not contain enough infectious agents or antigens to be detectable by virus isolation or IHC.⁴⁰ Occasionally, definitive documentation of the presence of some agents may be impaired because of the existence of similar but nonpathogenic organisms in the sample (e.g., coronavirus-like particles in feces prepared for EM). Molecular diagnostics have the potential to overcome these shortcomings.

The application of techniques to detect nucleic acids by PCR and reverse transcriptase (RT) PCR (RT-PCR) is increasingly useful in veterinary clinics.⁴⁰ PCR detects DNA and thus is appropriate for documenting the presence of DNA viruses and rickettsial organisms (Fig. 1-3). RT-PCR detects RNA—either messenger RNA (mRNA) or ribosomal RNA (rRNA)—after the enzyme RT has made a copy of DNA (cDNA) complementary to the RNA sequence. RT-PCR is appropriate for detection of RNA viruses such as feline caliciviruses (FCV). RT-PCR can also be used to detect organism-specific RNA of any infectious agent, including DNA viruses and rickettsial agents.

Infectious Diseases of the Dog and Cat, 3rd Edition

Because RNA is usually quickly degraded in living organisms, the detection of RNA is more suggestive than DNA of active infection. Therefore RT-PCR may be advantageous because it does not detect DNA in animals recovering from viral and rickettsial infections.⁴⁰

The strength of PCR and RT-PCR as tools in the diagnosis of infectious disease is their increased sensitivity compared with the other diagnostic assays listed in [Table 1-4](#). Studies that have examined the sensitivity of PCR and RT-PCR have been performed primarily in experimentally infected animals, but some reports on naturally occurring disease support the conclusion that these molecular assays are more sensitive than most routine diagnostic tests.⁴⁰ Sensitivity is inherent in these assays, which amplify a few copies of nucleic acid (e.g., in an animal with a very few infectious microorganisms) to millions of copies that are readily detectable. Detection of the amplified product is usually accomplished by gel electrophoresis or nucleic acid hybridization techniques. RT-PCR using rRNA as the template has been suggested as being even more sensitive than PCR because rickettsial organisms typically have more copies of rRNA than DNA, increasing the number of templates and therefore the number of amplified sequences. Specificity of the assays may also be increased by the sequence of the primers—short DNA segments that are complementary to specific DNA sequences in the target microorganisms.^{39,40}

Fig 1-3 The principles of nucleic acid extraction, amplification by PCR, separation and identification by gel electrophoresis, and dot blot or microarray hybridization with specific oligonucleotide probes. Dot blot: PC, Positive control; NC, Negative control. Blots A and D show a negative result for viral or rickettsial nucleic acid, and blots B, C, and E show a positive result.

Infectious Diseases of the Dog and Cat, 3rd Edition

PCR and RT-PCR also provide the clinician the ability to make retrospective diagnoses of viral and rickettsial infections because the assays can be performed on archived samples (tissue blocks, frozen serum, blood, or other fluid samples).^{40,43} Viral or rickettsial infection may not be a clinician's chief consideration but may become suspect after histopathology on biopsies or necropsy tissues. The PCR and RT-PCR can prove useful in such instances because DNA and occasionally RNA can be extracted from samples for the assays (Fig. 1-4).

Fig 1-4 Gel electrophoresis (2% agarose) of PCR-amplified CDV from archival canine brain (formalin fixed, paraffin embedded). Lane 1 is the molecular marker control; lanes 2, 3, 4, and 5 show positive reactions for CDV; lane 6 is the negative control; and lane 7 is the water-only negative control. A, 500-Base-pair band; B and C, expected PCR products specific for CDV. (From Stanton JB, Poet S, Frasca Jr S, et al. Development of a semi-nested reverse transcription polymerase chain reaction assay for the retrospective diagnosis of canine distemper virus, *J Vet Diagn Pract* 14:47-52.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Another advantage of PCR and RT-PCR in the diagnosis of viral and rickettsial infections (and infections of other etiologies) is that primers can be designed to detect broad groups of organisms (e.g., all members of the genus *Ehrlichia*) rather than single species.¹⁰ Such an approach was used to indicate that a clinical illness in certain dogs was caused by *Ehrlichia ruminantium* even though their symptoms were consistent with infection by *Ehrlichia canis*, and their *E. canis* serologic and PCR results were negative.² Although more study is needed to define *E. ruminantium* as a cause of clinical disease in dogs, the approach indicates the power of the nucleic acid-based assays to detect agents that are not yet described as pathogens but are related to known pathogens.²²

As useful as PCR and RT-PCR can be for diagnosing infectious disease, like other assays they have their limitations (Table 1-5).^{39,40} The greatest strength of the assays—their sensitivity—is also one of their weaknesses; contamination of the reactions with mere traces of DNA or RNA molecules can create false-positive results. Accredited laboratories follow quality control measures to prevent contamination of the reactions and use controls in the assays designed to help detect potential contamination. False-positive results may also result if an animal has been very recently vaccinated with modified live virus vaccines against the infection being evaluated. Compared with DNA, RNA is a less stable molecule and subject to degradation, thus RT-PCR results could be falsely negative if the RNA in the sample has denatured during storage or handling.

Unfortunately PCR and RT-PCR methods do not definitively document the presence of viable organisms, thus positive results need to be assessed in light of other available information about the patient (Fig. 1-5). History, clinical signs, physical examination, and results of diagnostic testing should also link the presence of a given microbe in a patient with the clinical illness before concluding that the result of a PCR or RT-PCR is diagnostic of the disease.^{17,45,48}

Fig 1-5 Graphic presentation of feline herpesvirus (FHV) shedding after an experimental inoculation (oronasal and ocular); shedding is measured by virus isolation in CrFK cells (virus titer) and PCR amplification of FHV-specific DNA sequences by cycle threshold (ct). Note the presence of infectious virus peaks 1 to 2 days postinfection, which are sustained until days 18 to 19 after infection and are undetectable by day 26. The presence of FHV-specific DNA was detected until more than 80 days after infection. (From Vogtlin A, Fraefel C, Albini S, et al. 2002. Quantification of feline herpesvirus 1 DNA in ocular fluid samples of clinically diseased cats by real-time Tag man PCR. *J Clin Microbiol* 40:519-523.)

1.7 CLINICAL EPIDEMIOLOGY

Epidemiology is the study of the distribution and frequency of an event within a defined population, as well as the factors governing the occurrence of the event within the population.³⁷ An understanding of epidemiologic features of a particular infectious disease facilitates the identification of outbreaks or decreases of the disease's occurrence and increases understanding of the spectrum of signs observed; it is essential for development, implementation, and monitoring of prevention and control strategies. For example, worldwide, rabies virus is maintained in nature in wild and feral animal reservoirs; however, the dog is the most important source of rabies virus infection in people.^{7,25} Widespread vaccination of the dog population has reduced the incidence of human rabies in the United States, and most human cases are now associated with rabies virus variants of wild animals, especially bats.²⁵

The terms *incidence* and *prevalence* are often used to describe the frequency of a disease's occurrence in a population, and it is important to differentiate between them. *Incidence* refers to the number of new cases occurring in a population over a defined sequential time.⁴¹ *Prevalence* refers to the number of current cases of a disease within a population at a given point in time. If a disease has an acute course, such as CPV enteritis, its incidence is generally greater than its prevalence. In contrast, the prevalence of a disease such as FIV infection is greater than its incidence because cats may live for years after becoming infected.

Accurate descriptions of the epidemiology of a disease require precise definition of the population being sampled.^{15,22,41} For example, the incidence of FeLV infection is considerably higher in young cats than older cats because older cats develop an age-related resistance to infection with this pathogen. The incidence of FeLV-related myeloproliferative *disease* is lower than the incidence of FeLV *infection* because the majority of infected cats develop subclinical infections without developing FeLV-related disease. Accurate epidemiologic descriptions of infection and disease require data gathered from diagnostic assays with high sensitivity and specificity. Use of an assay that generates numerous false-negative results (i.e., an assay with low sensitivity) causes numerous cases to be excluded from a survey. In contrast, use of assays that generate numerous false-positive results (i.e., assays with low specificity) cause incorporation of irrelevant cases. Both of these situations lead to erroneous conclusions regarding the epidemiology of infections and diseases.⁴¹ When the prevalence of infection is low, the test used must also have a high positive predictive value (see Diagnostic Assay Interpretation in this chapter).

The epidemiology of infectious disease depends on factors associated with the microorganism itself (microbial ecology) and factors associated with the host. Important microorganism factors include the ability of the microorganism to survive in the environment, the ability of the microorganism to infect the primary host and secondary host (interspecies transmission) and cause disease, the resistance of the microorganism to antimicrobial drugs, and the microorganism's ability to evade host immune defenses (i.e., escape mutants).^{12,13,17,41} Numerous host factors have the potential to influence exposure and disease. Age and immune status are considered the most critical of these factors.

Epidemiology also encompasses the analysis of contact patterns in the population. For example, the incidence of feline infectious peritonitis (FIP) in catteries can reach 5%, whereas in single- or two-cat households it is 0.02%.³⁵ 7
This increased incidence in catteries reflects heightened levels of infectious virus in the environment, increased viral 8
replication from acquired immune suppression (caused by concurrent infections and stress of crowding), as well as host cat genetic factors (see Immunodeficiencies and Infectious Diseases, [Chapter 95](#)). To replicate successfully, a highly infectious virus that causes a strong protective immune response needs a steady influx of susceptible hosts.

Infectious Diseases of the Dog and Cat, 3rd Edition

For example, the ability of CPV-2 to persist well in the environment allows the virus to encounter susceptible canine and feline hosts.^{13,33} In contrast, pathogens that persist within the host for months or years depend less on frequent contact with susceptible individuals. *E. canis* establishes a chronic, subclinical infection in dogs, providing a reservoir for infection of new ticks that feed on the infected host.¹⁶ Analysis of contact patterns also provides insight into the origin of a pathogen (Fig. 1-6). For example, a recent outbreak of feline hemorrhagic disease caused by FCV was traced back to a shelter kitten with upper respiratory tract disease that was brought into a veterinary hospital in Southern California.^{34,37}

After identifying factors that might contribute to an animal's susceptibility to infection or disease, the importance of those factors in the animal's risk is often presented in terms of a relative risk or an odds ratio.⁴¹ *Relative risk* is the ratio of the rate of disease or infection in animals exposed to the risk factor to animals not exposed to the risk factor (Fig. 1-7). Relative risk is determined through analysis of a cohort, in which groups of animals with defined exposure factors are monitored prospectively for the development of infection or disease. *Odds ratios*, which approximate the relative risk, are determined through retrospective, case-control studies (see Fig. 1-7). A relative risk or odds ratio of greater than 1 implies that the exposure factor is associated with the infection or disease. If the ratio is less than 1, the exposure factor is related to a decreased risk of disease. For example, FeLV and rabies vaccinations in cats have been associated with an increased risk of sarcoma formation at the injection site (see Feline Vaccine Associated Sarcomas, Chapter 100). The relative risk does not provide any information about the proportion of cases resulting from exposure to that risk factor. This proportion can be determined by calculating the *attributable risk*, which accounts for the relative risk and the proportion of the population exposed to the risk factor (see Fig. 1-7). When more than one factor is statistically associated with infection or disease, confounding must be considered. Confounding occurs in situations in which an association with one factor might lead to an apparent association with another factor, such

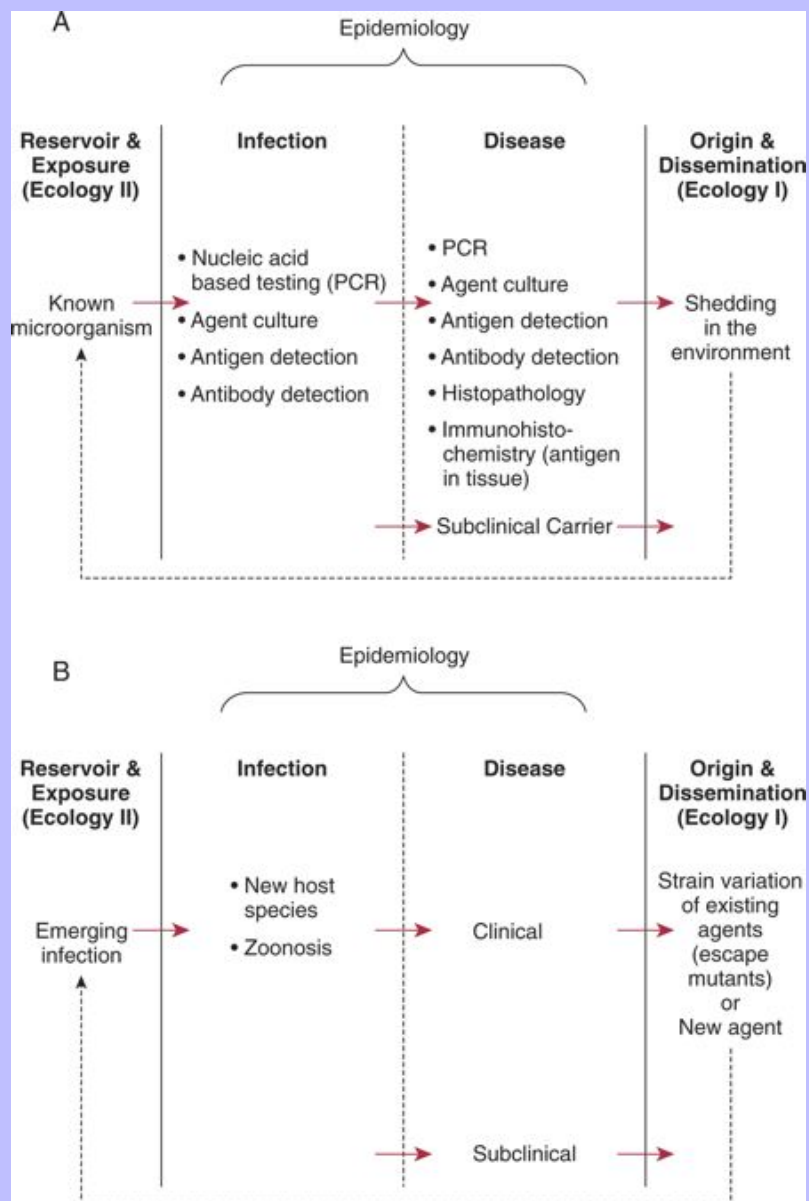

8

9

as a coinfection with a virus and secondary bacteria.²⁴ Use of computer software that performs multiple logistic regression analysis allows the investigator to control for multiple factors and simultaneously determine the effect of individual factors on infection or disease.

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 1-6 **A**, Schematic of the continuum between epidemiologic and ecologic movement of microorganisms. Note how the areas of infection and disease are flanked by origin and dissemination of an infectious agent and the connection with reservoirs and exposure. The various testing strategies are listed for detection of infection and diagnosis of disease. **B**, An example of an emerging infection via strain variation and infection of a new host species, such as occurs with canine calicivirus and *Rickettsia felis*.

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 1-7 Calculation of relative risk, odds ratio, and attributable risk using a two-by-two table.

	Disease (case)	No Disease (control)	
Risk factor present	A	B	A + B
Risk factor absent	C	D	C + D
	A + C	B + D	

Relative risk (RR) = $\frac{A}{A+B} \div \frac{C}{C+D}$

Odds ratio (OR) = $\frac{AD}{BC}$

Attributable risk (AR) % = $P(RR-1) \div [1+P(RR-1)] \times 100$
(P = prevalence of exposure)

Although the pattern of spread can be approximated through comparisons of clinical signs and exposure factors, precise reconstruction of the network through which a pathogen is spread often requires the use of applied molecular diagnostics,^{*} such as the aforementioned PCR and RT-PCR and microarrays, which allow subtyping of viruses and rickettsia.^{46,50} Most methods now rely on analyzing the DNA or RNA of the pathogen by either sequencing a section of the organism's nucleic acid or analyzing DNA banding patterns. DNA banding patterns are most commonly generated using *restriction enzymes*, which are enzymes that always cleave DNA at a certain point within a specific short sequence (an area known as a *restriction site*). For example, the enzyme *Eco* RI cleaves DNA to the right of the guanine (G) residue in the DNA sequence GAATTC. Every time this sequence is present within an organism's DNA, the enzyme cuts the DNA after the guanine, generating numerous DNA fragments. The DNA is then processed in a gel matrix using electrophoresis, which separates the fragments on the basis of size and creates a banding pattern. Two identical isolates would have the same number of restriction sites in the same locations on their DNA, therefore their DNA banding patterns would be identical (see Fig. 1-4). An identical banding pattern would indicate that it is likely both DNA samples came from the same organism. Organisms that differ have *restriction fragment length polymorphisms*, and their DNA banding patterns are different.⁵¹

Numerous other PCR-based molecular typing methods have been developed. PCR-based methods eliminate the requirement for culture before typing, which for viral and rickettsial pathogens may be difficult because of their fastidious growth requirements or public health concerns.^{10,11,38,39,40} The amplified DNA can subsequently be sequenced so that strains can be compared, or the DNA can be treated with restriction enzymes and then subjected to

Infectious Diseases of the Dog and Cat, 3rd Edition

electrophoresis (PCR-RFLP) to generate patterns unique to the strain or species of organism. Other PCR-based typing methods include *repetitive element PCR*, or *rep-PCR*, which uses PCR to amplify regions between known genes that have multiple copies spaced throughout the genome. Amplification of sections of DNA between the repeats generates a range of fragment lengths that is unique to a particular strain. Rep-PCR has been used to type ehrlichial pathogens. *Arbitrarily primed PCR* involves using primers of low specificity that bind to multiple sites in an organism's genome, generating multiple PCR products that can be separated using agarose gel electrophoresis and subsequently used for typing.⁵⁷

Many viruses are being typed using serologic techniques such as virus neutralization, but these methods are gradually being replaced by molecular approaches because they are better able to detect subgenotypes.⁵⁰ For example, PCR-based typing methods are being used increasingly for investigation of the epidemiology of CDV, FCV, and feline enteric coronavirus/FIP.¹ The knowledge of infectious disease ecology and epidemiology has greatly increased because of these methods and is providing evidence for the field of predictive microbiology.⁴⁶ As additional detection methods become available and existing methods become more standardized, the ability to rapidly identify and type microorganisms will improve. This improvement will increase understanding of microbial epidemiology, resulting in more successful control and prevention strategies.

2 CHAPTER 2 Antiviral and Immunomodulatory Chemotherapy

Katrin Hartmann

2.1 ANTIVIRALS

Clinical use of antiviral drugs is still not very common in veterinary medicine, and the number of controlled studies about their usefulness is limited. Unlike with antibacterial therapy, complete elimination of the agent is usually not achieved with antivirals, mainly because viruses are inhibited only during their replicative cycle and are not susceptible to antivirals during their latent or nonreplicative phases. Furthermore, achieving selective interference by antiviral chemotherapy is difficult because viral replication is more dependent on host cell metabolism than is bacterial replication. Treatment of acute viral infections is problematic primarily because diagnosis is often made after the replicative phase of infection is complete. Thus antiviral agents are useful mainly in treating chronic viral infections and in preventing reactivation of latent infections.

Many antiviral drugs that have been experimentally tested never appear on the market because they are too toxic. With the exception of the new feline interferon (IFN)- ω and some immunomodulatory substances, no antiviral drugs are licensed for veterinary medicine, and drugs licensed for humans have to be used in animals. Most antivirals are specifically intended for treatment of human immunodeficiency virus (HIV) infection. Therefore retroviral infection in cats, and more specifically feline immunodeficiency virus (FIV) infection, is the most important indication in veterinary medicine. Many compounds have been shown to be active against FIV, in cell culture and in cats. However, many FIV treatment studies were conducted to screen new compounds in the FIV model to document a potential benefit for HIV-infected patients. Most of these compounds are in an experimental state and will never appear on the market or be accessible to veterinarians, even if some have good efficacy against FIV.

Some of the anti-HIV drugs on the market have been used to treat naturally FIV- or feline leukemia virus (FeLV)-infected cats, and improvement of clinical signs and prolongation of life can be achieved in some of these cats using antiviral therapy. Furthermore, feline herpesvirus (FHV)-1 infection can be treated with antiviral compounds, either systemically or topically (mainly eye infections). Attempts to treat feline infectious peritonitis (FIP) with antiviral compounds have not been successful. In canine viral infections, antiviral chemotherapy plays only a minor role so far. Overall, antiviral drugs that are available and useful for cats and dogs are limited, and few controlled studies have been performed to support their use. In this chapter, only drugs will be addressed that are available on the market and have been used clinically or experimentally against feline or canine viral infections. Other drugs used to treat human infections may be found in the Drug Formulary, [Appendix 8](#).

“True” antivirals are compounds that interfere with one step (or several steps) in the viral replication cycle. Closer scrutiny of the relationship of the virus to the cell reveals several points at which the viral cycle can be interrupted, including adsorption to and penetration of the cell, uncoating of the viral nucleic acid, the various stages of nucleic acid replication, assembly of new viral particles, and release of infectious virions, if the cell is not destroyed ([Table 2-1](#)).

The most common antiretroviral drugs are inhibitors of the reverse transcription inhibiting the retroviral enzyme reverse transcriptase (RT) (e.g., nucleoside analogues). Drugs with a broader spectrum inhibit other viral enzymes such as DNA or RNA polymerases and thus interfere with virus genome replication (e.g., phosphonoformate, acyclovir) or by inhibiting proteinases (e.g., proteinase inhibitors) that are important for the splitting of precursor proteins during viral assembly. Other drugs target the viral entry by binding to specific receptors that the virus uses

Infectious Diseases of the Dog and Cat, 3rd Edition

for adsorption (e.g., bicyclams, a new class that inhibits the CXCR4 receptor, which is important for HIV and FIV entry), by acting as fusion inhibitors preventing the conformational changes of the virus necessary for the fusion process, or by interfering with uncoating (e.g., amantadine). Currently used inhibitors of the viral replication cycle can be divided into five classes of compounds: nucleoside analogues, cycloalkylamine derivatives, phosphonic acid derivatives, trypan red derivatives, and amino acids (Table 2-2).

2.1.1

Nucleoside Analogues

In the event of viral replication, the process of nucleic acid replication, which is extremely rapid relative to most mammalian cells, has proved to be the most vulnerable point of attack. The most clinically useful antiviral agents are nucleoside analogues interacting with this specific step. These nucleoside analogues are derivatives of nucleosides, so-called “antimetabolites.” A nucleoside consists of a nitrogenous base covalently attached to a sugar (ribose in RNA, 2-deoxyribose in DNA); a nucleotide consists of a nitrogenous base, a sugar, and a phosphate group. A nucleic acid (RNA and DNA) contains a chain of nucleotides covalently linked together to form a sugar-phosphate backbone with protruding nitrogenous bases. For integration of these nucleotides (or monophosphates) into the nucleic acid, three phosphate groups have to be bound to the nucleoside first (triphosphates), two of which are removed, releasing energy during elongation of the nucleic acid chain.

Nucleoside analogues are similar molecules to the “true” nucleoside; they have to be equally phosphorylated intracellularly to become active compounds. Because of their structural similarities, they can bind to the active center of enzymes (e.g., RT, other polymerases) and block enzyme activity. Many of these analogues also can be integrated in developing DNA or RNA strands, but because of differences in the molecular structure of the next nucleotide, they cannot be attached. This leads to chain termination or nonfunctional nucleic acids.

Nucleoside analogues can be divided into antimetabolites with “wrong” base (e.g., ribavirin, idoxuridine, trifluridine), antimetabolites with “wrong” sugar (e.g., zidovudine, acyclovir, vidarabine), and antimetabolites with “wrong” base and “wrong” sugar (e.g., didanosine). Nucleoside analogues are not only accepted as false substrates by viral enzymes, but also by cellular enzymes, and this is the major cause of their toxicity. Selectivity, however, results from differences in DNA synthesis of infected and noninfected cells; in noninfected cells, DNA synthesis is intermittent, although it is continuous and fast in infected cells.

10

11

Table 2-1 Effects of Antivirals on Stages of Viral Replication Cycle

STAGE OF REPLICATION	SPECIFIC STAGE AFFECTED	ANTIVIRAL DRUGS
Virus entry	Adsorption	Cycloalkylamine derivatives
	Binding to cellular receptor	
	Penetration	
	Virus cell fusion	
	Uncoating	
Virus replication	Reverse transcription (retroviruses)	Nucleoside analogues
	Integration (retroviruses)	
	Synthesis of viral RNA/DNA	
Synthesis of viral proteins	Translation	Proteinase inhibitors
	Processing	Phosphonoformate acid derivatives
	Splitting of precursor proteins	L-lysine
Release of virus particles	Assembly	Interferons
	Budding	

Infectious Diseases of the Dog and Cat, 3rd Edition

2.1.1.1

Zidovudine

Zidovudine (3'-azido-2',3'-dideoxythymidine [AZT]) was the first drug to be approved for treatment of HIV infection. AZT inhibits replication of retroviruses and has a mild inhibitory effect in the replication of herpesviruses. The inhibitory effect of zidovudine is 100 times higher against HIV-RT than mammalian cell DNA polymerases.⁴³ AZT is the most thoroughly studied antiviral drug in veterinary medicine; it has been used in experimental and in clinical trials in FIV- and in FeLV-infected cats.

The mechanism of AZT of inhibiting nucleoside phosphorylation explains its antiherpesviral activity, as well as its side effects. It is converted to zidovudine triphosphate, which blocks the retroviral RT. AZT inhibits FIV replication in vitro and in vivo⁴³; it reduces plasma viral load, improves the immunologic and clinical status of FIV-infected cats, increases quality of life, and prolongs life expectancy.

In a placebo-controlled trial, AZT improved stomatitis and increased the CD4/CD8 ratio in naturally FIV-infected cats.⁵³⁻⁵⁵ Neurologic abnormalities also tend to respond favorably to treatment with AZT. In some cats with FIV-associated neurologic signs, a marked improvement occurs within the first days of therapy. As is the case in HIV, evidence exists that FIV can become resistant to nucleoside analogues. AZT-resistant mutants of FIV can arise after only 6 months' use. A single-point mutation in the FIV gene was identified that can create resistance to AZT.¹³⁵ In humans, resistance to AZT frequently develops, but the addition of lamivudine to a therapeutic protocol can cause AZT-resistant strains to revert to AZT-sensitive strains. A combination of these two drugs might be a promising approach in FIV-infected cats to prevent resistance development.

AZT is effective against FeLV in vitro.¹⁵¹ It has also been shown to be somewhat effective in treating cats experimentally infected with FeLV when treatment is initiated less than 3 weeks after infection. When treated less than 1 week after challenge, cats were protected from bone marrow infection and persistent viremia.⁴³ In a study in naturally FeLV-infected cats that were treated with AZT and high dose subcutaneous human IFN- α for 6 weeks, however, treatment with AZT or human IFN- α , or both, did not lead to a statistically significant improvement of clinical, laboratory, immunologic, or virologic parameters.⁵⁸ In general, therapeutic efficacy of AZT in FeLV-infected cats seems to be less promising than in FIV-infected cats. For AZT dosage and handling instructions, see the Drug Formulary, [Appendix 8](#).

Pregnancy of FIV-infected queens is a potential indication for AZT treatment if the owner wants the kittens to be delivered, although in utero transmission occurs infrequently in natural FIV infection. During AZT treatment, regular blood cell counts are necessary because nonregenerative anemia is a common side effect, especially if the higher dose is used. A complete blood count should be performed weekly for the first month. If values are stable after the first 4 weeks, a monthly recheck is recommended. Cats with bone marrow suppression should not be treated because of the risk of life-threatening anemia. In cats with concurrent chronic renal failure, the dosage should be reduced to avoid toxicity. Studies in which cats were treated with AZT for 2 years showed that the drug is well tolerated in most FIV-infected cats. Hematocrit declines within 3 weeks of initiating treatment to approximately 60% of baseline but comes back up afterwards in most cases, even without discontinuation of treatment. If hematocrit drops below 20%, discontinuation is recommended, and anemia usually resolves within a few days.⁵⁴ Neutropenia is less frequent than anemia. Neutropenia may be prevented or treated with filgrastim in FeLV- but not in FIV-infected cats, which may lead to increased viral loads. Other side effects in cats, including vomiting or anorexia, rarely develop. One side effect that is sometimes positively noted by owners is the development of a fuller and shiny hair coat. AZT should not be

Infectious Diseases of the Dog and Cat, 3rd Edition

combined with drugs that are myelosuppressive. Concurrent use of nonsteroidal antiinflammatories has to be monitored carefully because it can delay AZT metabolism, result in kidney toxicity, or lead to neutropenia.

2.1.1.2

Stavudine

Stavudine (2',3'-didehydro-2',3'-dideoxythymidine, [d4T]) is a thymidine-based nucleoside analogue and was the fourth drug to receive U.S. Food and Drug Administration (FDA) approval for use against HIV infection.

11

d4T is closely related in mode of action to AZT because both are thymidine analogues. d4T is active against

14

FIV in vitro.^{7,182} Mutants of FIV that are resistant to d4T and cross resistant to several other antivirals, including AZT, didanosine, and foscarnet, have been found. A single-point mutation in the RT-encoding region of the pol gene that is responsible for the resistance was identified.¹⁸² No in vivo data in FIV-infected cats are published. d4T activity against FeLV is unknown.

a In cats with anemia or neutropenia.

2.1.1.3

Stampidine

This experimentally nucleoside RT inhibitor has been used to treat cats that are chronically infected with FIV.¹⁵⁶ A single oral bolus of 50 to 100 mg/kg resulted in a decrease in FIV in peripheral blood mononuclear cells. A 4-week course of 50 to 100 mg/kg was well tolerated, and cumulative doses as high as 8.4 g/kg were given. Further studies may be needed to evaluate the safety and toxicity of this drug.

2.1.1.4

Didanosine

Didanosine (2',3'-dideoxyinosine [ddI]) is also used to treat HIV infection in humans (second anti-HIV drug approved by the FDA). ddI is an inosine analogue, an antimetabolite containing a “wrong” base and a “wrong” sugar molecule. It is intracellularly converted to the active substance dideoxyadenosine triphosphate that competitively inhibits RT. Additionally, ddI is less bone marrow suppressive in humans but is less active against HIV than AZT and is active against FIV³⁹ and FeLV¹⁵¹ in vitro. Controlled in vivo studies confirming the efficacy in cats with retroviral infections are not available to date.

2.1.1.5

Zalcitabine

Similar to AZT, zalcitabine (2',3'-dideoxycytidine [ddC]) was originally developed as an antitumor agent; and 20 years later, its antiretroviral activity was detected. Currently, ddC is used to treat HIV infection in humans (the third drug approved by the FDA). ddC is an analogue of the nucleoside 2'-desoxycytidine. The active compound is the intracellularly produced 2',3'-dideoxycytidine-5'-triphosphate that acts as an RT inhibitor.

In vitro, antiviral efficacy has been demonstrated against FIV,¹⁰³ but no in vivo data exist demonstrating its efficacy in FIV-infected cats. A mutant of FIV that is resistant to ddC was selected in cell culture that showed cross resistance to other antiviral compounds (e.g., ddI, foscarnet).¹⁰³ ddC is effective against FeLV in vitro^{62,119,151} and has been used in experimental studies to treat FeLV-infected cats. It has a very short half-life (clearance and half-life values for ddC in cats are 6.5 ml/min/kg and 54.7 min, respectively)¹¹⁹ and therefore was administered in these studies either via intravenous (IV) bolus dosage or via controlled-release subcutaneous implants. Controlled-release delivery of ddC inhibited de novo FeLV replication and delayed onset of viremia; however, when therapy was discontinued (after 3 weeks), an equivalent incidence and level of viremia were established rapidly.⁶² In a study evaluating the prophylactic antiviral activity against FeLV, ddC was administered by continuous IV infusion for 28 days. Doses of 22 and 15 mg/kg/hr were extremely toxic, causing death in 8 of 10 cats. A dose of 10 mg/kg caused thrombocytopenia, and only 1 of 10 cats receiving 5 or 10 mg/kg remained antigen-negative, although onset of viremia was delayed for several weeks.¹¹⁹

Therefore ddC should not be used in concentrations over 5 mg/kg/hr continuous infusion in feline patients. In humans, ddC is used orally (with greater than 80% bioavailability), but no data exist on oral application in cats.

Infectious Diseases of the Dog and Cat, 3rd Edition

2.1.1.6

Lamivudine

This compound, (2R,cis)-4-amino-1-(2-hydroxymethyl-1,3-oxathiolan-5-yl)-(1H)-pyrimidin-2-one, 3TC, the newest of the approved HIV drugs, is the (-)enantiomer of a dideoxy analogue of cytidine with activity against HIV and hepatitis B virus (HBV). Intracellularly, 3TC is phosphorylated to its active triphosphate metabolite, 3TC triphosphate. The principal mode of its antiretroviral action is the inhibition the RT via DNA chain termination after incorporation into the viral DNA. 3TC triphosphate is also a weak inhibitor of mammalian DNA polymerases α and β and mitochondrial DNA polymerase, which explains its anti-HBV activity. 3TC is often combined with AZT in HIV-infected patients, given that both drugs show a synergistic effect. However, HIV mutants exist that are resistant to both 3TC and AZT.

3TC is active against FIV in vitro.^{4,12} Combination of AZT and 3TC had synergistic anti-FIV activities in primary peripheral blood mononuclear cell cultures.⁴ FIV mutants resistant to 3TC containing a point mutation in the RT gene were selected in vitro and showed cross resistance to AZT.¹³⁵ One in vivo study was performed in experimentally FIV-infected cats that were treated with a high-dose AZT-3TC combination (100 or 150 mg/kg/day for each drug). The combination protected some cats when the treatment was started before experimental infection. However, AZT-3TC treatment had no anti-FIV activity in chronically infected cats. Severe side effects that included fever, anorexia, and marked hematologic changes were observed in some of the cats with such high-dose dual-drug treatment.⁴ Data on the anti-FeLV activity of 3TC are not available.

The pharmacokinetic of 3TC in cats shows considerable similarity to AZT pharmacokinetics in cats and to that of 3TC in humans.⁶⁹ Thus in naturally infected cats, 3TC doses similar to AZT are probably recommended.

2.1.1.7

Ribavirin

Ribavirin (1- β -D-ribofuranosyl-1H-1,2,4-triazole-3-carboxamide [RTCA]) is a broad-spectrum triazole nucleoside that has marked in vitro antiviral activity against a variety of DNA and RNA viruses. The strongest antiviral activity is against RNA respiratory viruses and herpesviruses. RTCA has been effective in HIV infection, Lassa fever (a human adenovirus infection), and in Hantavirus infections.⁴³ Systemic use, however, is limited because of the development of dose-dependant hemolytic anemia in humans. Thus RTCA is currently used by aerosol route to treat only people with respiratory syncytial viral infection. If used as an aerosol, only low concentrations appear in the systemic circulation, and side effects are tolerable.⁴³

RTCA is active against a significant number of feline and canine viruses in vitro, including FIV,¹³⁷ FeLV,⁴³ FHV-1,¹²¹ feline calicivirus (FCV),¹²¹ feline coronavirus (FCoV),^{9,170} Borna disease virus (BDV),¹⁰⁹ and canine parainfluenzavirus (CPiV).¹²¹ In vivo, however, therapeutic concentrations are difficult to achieve because of toxicity, and cats are extremely sensitive to side effects.

In a study investigating its anti-FCV activity in cats, RTCA administered (25 mg/kg orally [PO] every 8 hours for 10 days) beginning either 1 or 4 days after aerosol exposure failed to have any beneficial effect on the clinical course of the disease or to reduce viral excretion. In contrast, enhanced severity of the clinical findings occurred in the treated group.¹²⁰

Infectious Diseases of the Dog and Cat, 3rd Edition

Although active against FCoV in vitro, ribavirin was not effective in treating cats with FIP. RTCA was administered (16.5 mg/kg, PO, intramuscular [IM], or IV, every 24 hours for 10 to 14 days) to specific-pathogen-free (SPF) kittens 18 hours after experimental challenge exposure with a FIP-causing virus. All kittens, including RTCA-treated and untreated kittens, succumbed to FIP. Clinical signs of disease were even more severe in the RTCA-treated kittens, and their mean survival times were shortened.¹⁶⁷

The most common side effect in cats described in several studies (using low doses of 11 mg/kg) is hemolysis that develops as a result of sequestration of the drug in erythrocytes.^{120,166} In addition, there is a dose-related toxic effect on bone marrow, primarily on megakaryocytes (resulting in thrombocytopenia and hemorrhage) and erythroid precursors. In longer treatment or higher doses, the drug suppresses the number of neutrophilic granulocytes. Liver toxicity also occurs. Weiss and co-workers¹⁶⁷ tried to decrease the toxicity of RTCA by incorporating it into lecithin-containing liposomes and giving it at lower doses (5 mg/kg) IV to cats challenged with a FIP-causing virus. The drug, however, was not able to reach therapeutic concentration with this therapeutic regimen.

Overall, side effects have limited the systemic use of RTCA in veterinary practice. It may be used as an aerosol in cats or dogs with respiratory virus infections as it is currently used in people. For further information, see the Drug Formulary, [Appendix 8](#).

2.1.1.8

Acyclovir

Acyclovir (acycloguanosine, 9-[2-hydroxyethoxymethyl] guanine, AZV) is a nucleoside analogue that only interferes with actively replicating but not latent herpesviruses. AZV is given parenterally, orally, and topically in people to treat mucocutaneous and genital herpesviral infections and parenterally against herpesviral encephalitis. Resistance of human herpesviruses to AZV occurs. AZV is the only antiherpesviral drug that has been used systemically in cats.

AZV is effective against FHV-1 infection¹¹²; however, it is less effective against human herpes simplex virus (HSV). AZV was used in several studies in FHV-1-infected cats, but the results of these studies were not conclusive about the antiviral efficacy.^{49,61,111} When AZV is combined with human IFN- α , however, synergistic antiviral effects were found¹⁶⁴ resulting from the different mechanisms of action of the two drugs; AZV inhibits viral DNA polymerase, and IFN- α interacts mainly with translation of viral proteins. The synergy observed also may result from AZV blocking the synthesis of an IFN- α inhibitor produced by the virus.

Oral and IV administration is less frequently recommended. If used topically in eye infections, frequent application (every 4 to 6 hours) is recommended. In cats, AZV should be combined with human IFN- α or feline IFN- ω because these drugs can potentially increase the antiviral effect of AZV.

AZV has a relatively low toxicity because uninfected cells do not activate it. When given in higher doses, when maximal solubility of acyclovir (2.5 mg/ml at 37° C) is exceeded, systemically, however, the drug itself (not the triphosphate) may precipitate in the renal tubules, causing obstructive nephropathy if diuresis is inadequate. In these cases, needle-shaped AZV crystals can be detected in the urine sediment. Urinalysis should be performed regularly in long-term AZV treatment. Renal failure is reversible with adequate rehydration. In a toxicity study in healthy dogs, a shorter high-dose regimen (210 mg/kg/day via constant infusion for 43 hours), which maintained AZV plasma concentrations, was more detrimental to the kidneys

15

16

Infectious Diseases of the Dog and Cat, 3rd Edition

than a longer exposure to a lower dose of the drug given intermittently (15 mg/kg via intermittent infusion every 8 hours for 28 days).⁷¹

Accidental ingestion of AZV in dogs seems to be a problem as it was recently presented in a retrospective study of 105 cases reported to the National Animal Poison Control Center.¹²⁶ The most common signs of toxicity included vomiting, diarrhea, anorexia, and lethargy; polyuria and polydipsia was reported in only one dog.

2.1.1.9

Valacyclovir

Valacyclovir (2-[(2-amino-1,6-dihydro-6-oxo-9H-purin-9-yl)methoxy]ethyl L-valinate hydrochloride, VAZV) is a prodrug for AZV. It is the L-valine ester of AZV and has the same antiviral spectrum but has a much higher (three to five times) oral bioavailability than acyclovir. In humans, it is mainly indicated for treatment of herpes zoster, treatment or suppression of genital herpes, and cytomegalovirus (CMV) prophylaxis in kidney transplant recipients.

In a placebo-controlled, experimental study to determine whether orally administered VAZV can be used safely and effectively, cats with FHV-1 infection were treated with high-dose VAZV (60 mg/kg orally). Cats appeared to be uniquely sensitive to the toxic effects (renal tubular epithelium and hepatocellular necrosis, severe bone marrow suppression), and even high doses appeared not to suppress FHV-1 replication in these acutely infected cats.¹¹³

Pharmacokinetics of VAZV in cats is unknown, but in humans, it is rapidly absorbed orally and hydrolyzed to AZV and L-valine. Its oral bioavailability (as AZV) is 54%. Approximately 50% is excreted in the urine (mainly as AZV) and 50% in the feces. VAZV should probably be used at the same dose as AZV (10 mg/kg every 8 hours) the low bioavailability makes it less effective. Combination with human IFN- α or feline IFN- ω should be considered. Use of higher doses of VAZV is not recommended because of toxicity.

2.1.1.10

Idoxuridine

Idoxuridine (5-iodo-2'-deoxyuridine, [IDU]) was developed in 1954 and was the first clinically used drug for treatment of HSV infection. IDU is a halogenized thymidine analogue that acts as a pyrimidine antagonist after being phosphorylated by cellular enzymes to the active triphosphate, which inhibits DNA synthesis of virus and host. Latent virus infections are unaffected. Its clinical use is topical in human medicine, with the main indication of HSV keratitis and dermatitis. IDU is highly toxic when given systemically; this is mainly because of bone marrow suppression.

IDU is active against FHV-1 in vitro¹¹² and is used topically in cats with ocular FHV-1 infection.^{96,141} Experimentally, systemic use in cats was not effective and caused severe toxicity (e.g., gastrointestinal [GI] disorders, bone marrow suppression).¹⁴⁰ Treatment of systemic canine herpesvirus (CHV) infections with IDU was not successful.¹⁷ Therefore only topical treatment with IDU is recommended in cats with ocular FHV-1 infection. Frequent application (every 4 hours) is important. Prolonged topical use may cause irritation or nonhealing corneal ulcers.

Infectious Diseases of the Dog and Cat, 3rd Edition

2.1.1.11 Trifluridine

Trifluridine (5-trifluoromethyl-2'-deoxyuridine, trifluorothymidine, [TFT]) is a halogenized thymidine analogue similar to IDU that acts as pyrimidine antagonist. TFT is phosphorylated either by viral or by cellular thymidine kinases and inhibits cellular thymidilate synthase, causing a reduction in thymidine building and thus increasing the phosphorylation of TFT. Given that noninfected cells are also inhibited in their DNA synthesis, side effects are comparable to IDU if the drug is given systemically (GI and bone marrow toxicity); thus TFT is used only topically to treat ocular herpesvirus infections.

TFT is active against FHV-1 in vitro¹¹² and is used topically in FHV-1 eye infections.^{96,141} It has a better cornea penetration than IDU. Frequent application (every 4 hours) is necessary.

2.1.1.12 Vidarabine

Vidarabine (9-β-D-arabinofuranosyladenine monohydrate, adenine arabinoside, Ara-A), a purine nucleoside, also inhibits DNA synthesis by incorporating into nucleic acids and inhibiting DNA-synthesizing enzymes. It is effective in vitro against herpesviruses, poxviruses, and retroviruses, but its clinical use in humans has been restricted to treatment of smallpox and HSV keratitis, dermatitis, and encephalitis.⁴³ Ara-A is phosphorylated intracellularly to Ara-A triphosphate that is incorporated into the DNA of virus and host where it terminates elongation. It inhibits DNA polymerase of DNA viruses approximately 40 times more than those of the host.

Ara-A is active against FHV-1 in vitro¹¹² and is used topically in FHV-1 eye infections.^{96,141} Case reports indicate that a beneficial effect may occur in dogs with CHV infection. In one case, Ara-A was given to five littermates (two puppies had died from CHV infection), and all five survived.¹⁷ Ara-A also shows activity against FIP-causing FCoV strains in vitro,⁹ but no data have been found to demonstrate efficacy in vivo.

The major disadvantage of Ara-A is its poor solubility; therefore, if it is given systemically, Ara-A must be administered IV and in large volumes of fluid over extended periods. Ara-A is rapidly deaminated by adenosine deaminase to hypoxanthine arabinoside. Toxic effects include local irritation at infusion sites, nausea, vomiting, and diarrhea. The drug also causes bone marrow suppression, resulting in anemia, neutropenia, and thrombocytopenia. Systemic toxicity restricts its use in veterinary practice mainly to topical ophthalmic treatment, with frequent applications (every 4 hours) being necessary.

2.1.2 Phosphonic Acid Derivatives

The main compound of the phosphonic acid derivatives is foscarnet, the salt of phosphonoformate acid.

2.1.2.1 Foscarnet

Foscarnet (trisodium phosphonoformate hexahydrate [phosphonoformic acid (PFA)]) is a pyrophosphate analogue that inhibits virus-specific DNA and RNA polymerase and RT. It has a wide spectrum of activity against DNA and RNA viruses, including herpesviruses and retroviruses. Some AZV-resistant herpesvirus infections in people have been treated successfully with PFA. It also has been administered to treat HIV infection, especially if co-infection with CMV is present, but significant nephrotoxicity has limited its use.

Infectious Diseases of the Dog and Cat, 3rd Edition

Renal dysfunction is evident in most people after 2 weeks of therapy.⁴³ PFA is only virustatic, and after treatment is stopped, viral replication is activated.

In vitro, PFA has been shown to be active against FIV³⁹ and FeLV.¹⁴⁵ As for HIV, PFA-resistant FIV strains can develop.³⁹ No reliable data exist on its efficacy in cats and dogs in vivo, and its use in veterinary medicine is limited because of toxicity. For dosages, toxicity, and further information on PFA, see the Drug Formulary, [Appendix 8](#).

16

2.1.3 Cycloalkylamine Derivatives

17

Cycloalkylamine derivatives are used in human medicine mainly against influenza virus infections. Amantadine is the most important example of cycloalkylamine derivatives and the only one that has been used in veterinary medicine. Rimantadine, a closely related analogue, has equal or greater efficacy with reduced central nervous system (CNS) side effects but more GI irritation. No experience exists in veterinary medicine. Tromantadin, another related substance, is used locally in human herpesvirus infection, but no data exist in animals.

2.1.3.1 Amantadine

Amantadine (tricyclo[3,3,1,1,3,7]dec-1-ylamine hydrochloride, L-adamantanamine) is a highly stable cyclic amine that acts against enveloped RNA viruses. As an antiviral drug, amantadine is administered mainly for prophylaxis of human influenza and is most efficacious when administered before or during early infection. As a dopaminergic drug, amantadine has been used to treat Parkinson's disease, cocaine dependence, and apathy in multiple sclerosis. It has mild antidepressive effects; however, marked antidepressive effects occur in some patients attributed to antiviral activity against human BDV infection (see [Chapter 21](#)). Some investigators have linked BDV to patients with depressive episodes and psychiatric disorders. Experimental BDV infections of rats show virus-induced behavioral changes and emotional and learning deficits.⁸⁷ Amantadine was effective against BDV in vitro,⁸⁷ and other authors found no effect in cell culture in concentrations that were effective against influenzavirus.⁴⁸ In one study involving patients with BDV receiving amantadine, peripheral viral antigen was cleared, and a significant antidepressive response was described.³⁵

Data on the usefulness of amantadine in dogs and cats are limited. Anecdotal reports exist from cats with BDV infection in Northern Europe that benefit from treatment with amantadine. Potentially beneficial effects might be expected in CPiV outbreaks.

2.1.4 Trypan Red Derivatives

2.1.4.1 Suramin

This 1-(3-benzamido-4-methylbenzamido)naphthalene 4,6,8-trisulfonic acid sym-3'-urea sodium salt, a sulfated naphthylamine and trypan red derivative, is one of the oldest known antimicrobial agents. It is still used in the treatment of African trypanosomiasis (see [Chapter 72](#)) and river blindness (onchocerciasis). It also inhibits angiogenesis, and recent interest has been found in suramin as a therapy for patients with advanced prostate cancer because of its effects on growth factors involved in prostate cancer cell growth. It exerts an inhibitory effect on the RT activity of several retroviruses. Suramin has been used for treating patients with HIV infection; it has, however, only minor clinical value.

Infectious Diseases of the Dog and Cat, 3rd Edition

Suramin was used to treat FeLV-infected cats, although only a limited number of cats have been evaluated. In one study, serum viral infectivity ceased transiently in two cats with naturally acquired FeLV infection during suramin treatment but returned to high levels approximately 14 days after treatment was stopped.¹⁹ In another study, six anemic cats received suramin (10 to 20 mg/kg as 10% solution over 3 minutes every 7 days for 7 to 9 weeks), and within 4 to 14 days, erythropoiesis improved. However, progenitor cells remained infected.¹ No studies on the efficacy of suramin against FIV have been conducted.

Although effective, suramin is associated with a significant number of severe side effects, and the lack of studies involving larger numbers of animals limit its use in veterinary medicine. For further information, see the Drug Formulary, [Appendix 8](#).

2.1.5 Amino Acids

2.1.5.1 L-lysine

This amino acid suppresses clinical manifestation of herpesviral infection.⁴⁷ Oral administration of L-lysine in cats has been adopted from human medicine. Inhibition of FHV-1 in vitro is similar to the data obtained for HSV.⁹⁴ In an experimental placebo-controlled, double-blind study including eight cats, oral administration of L-lysine (500 mg per cat every 12 hours) was well tolerated and resulted in less severe manifestation of conjunctivitis caused by acute FHV-1 infection compared with cats that received placebo.¹⁴² The effects of L-lysine (400 mg PO per cat every 24 hours) on clinical signs and ocular shedding of FHV-1 in latently infected cats was studied after reactivation of a latent infection. Significantly fewer viral shedding episodes were identified after a stress event of rehousing in the treatment group cats compared with the control group cats. Fewer cats and eyes were affected by conjunctivitis, and onset of clinical signs of infection was delayed in cats receiving L-lysine.⁹⁵

In conclusion, L-lysine may be beneficial in cats with FHV-1 infection but should be used as early as possible after infection is established. It also can be recommended as long-term treatment in cats with recurring clinical signs of FHV-1 infection to prevent reactivation of latent infection. For further information, see the Drug Formulary, [Appendix 8](#).

2.2 IMMUNOMODULATORS

In general, immunotherapy includes any form of treatment that alters the immune system. This discussion is limited to nonspecific means of stimulating the immune system in an attempt to restore immunocompetence and control or treat infectious diseases ([Table 2-3](#)). Immunomodulators have been used to treat more than viral diseases for which the first part of this chapter covered. Nonspecific immunotherapy has been used to treat infections caused by facultative intracellular bacteria, viruses, fungal agents, or metazoan parasites for which vaccination or specific forms of chemotherapy are unavailable.

Immunomodulators or immunostimulatory agents or biologic response modifiers are probably the most widely used medications in feline and canine viral infections, especially in FIV and FeLV infections ([Table 2-4](#)). Theories suggest that these agents benefit infected animals by restoring compromised immune function, thereby allowing the patient to control viral burden and recover from associated clinical syndromes. These substances modify the responses of immunocompetent cells through cytokines or other mechanisms. Immunomodulators are used against

Infectious Diseases of the Dog and Cat, 3rd Edition

viruses and other infectious agents. Some of them have an effect on the immune system and a true antiviral activity (e.g., some interferons, acemannan).

2.2.1

Microorganisms

Microorganisms and their extracts have been classically used as nonspecific immunostimulators. Freund's complete adjuvant is a water-in-oil emulsion containing inactivated whole mycobacteria. The antigen is contained in the aqueous phase, and the mycobacteria are in the oil phase. Injection of this mixture induces cell-mediated immune (CMI) response and humoral antibody formation. It produces a severe reaction of local inflammation and large granuloma formation. The adjuvant, which is the active ingredient in Freund's, is N-acetylmuramyl-L-alanyl-D-isoglutamine (muramyl dipeptide). Purified, it can produce a response without side effects. Bacille Calmette-Guérin (BCG) is a nonpathogenic strain of *Mycobacterium bovis* that has been used in treating neoplasia in dogs and cats and in cats infected with FeLV. Ribigen-B and Ribigen-E (Ribi, Immunochem Research, Hamilton, Mass.) are mycobacterial cell wall fractions that are given as adjuvants. Facultative intracellular organisms such as mycobacteria that are immunostimulators have a marked affinity for localizing in and stimulating mononuclear-phagocyte clearance mechanisms.

17

19

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 2-4 Immunomodulators Used in Dogs and Cats

EXAMPLE OR SOURCE	MODE OF ACTION	TYPE OF IMMUNE RESPONSE	DISEASE SPECIFIC	SPECIES SPECIFIC
Microorganisms				
<i>Bacteria</i>				
BCG, Freund's complete adjuvant (muramyl dipeptide)	Cell wall components: enhances phagocytosis and intracellular killing, increases macrophage chemotaxis and T-cell response	Cell mediated Humoral: primarily IgG	No	No
<i>Salmonella</i> , <i>Serratia</i> , <i>Bordetella pertussis</i> , Staphylococcal protein A	Humoral immune interference, T-cell responses	Humoral and cell mediated	No	No
<i>Propionibacterium acnes</i>	Stimulate cytokine release	Cell mediated ¹	No	No
<i>Viruses</i>				
Newcastle disease virus, avian poxvirus	Interferon inducer	Interferon	No	Variable
Cytokines				
Interferons α , β , γ , ω	Antiviral or immunostimulatory	Interferon effect	No	No ^a
Filgrastim (G-CSF)	Stimulates granulocytopoiesis	Granulocyte phagocytes enhanced	Granulocytopenia	No ^a
Sargramostim (GM-CSF)	Stimulates leukopoiesis	All phagocytes enhanced	Leukopenia	No ^a
Insulinlike growth factor	Stimulates lymphoid system	Cell mediated immunity	No	No ^a
Macromolecules That Induce Cytokines				
RNA, poly-IC, poly-AU	Interferon inducer, can enhance cellular and antibody response	Interferon Cell mediated	No	Variable
Acemannan	Carbohydrate polymer stimulates cytokines	Cell mediated	No	No
Small Chemicals				
Organic: vitamin A, fatty acid, lipids, LPS, Freund's incomplete adjuvant, glycosides (Quil A), Liposomes	Delays antigen absorption, alters antigen presentation	Humoral and cellular	No	No
Inorganic: beryllium, alum, silica	Prolongs release of antigen	Humoral: primarily IgE	No	No

BCG, Bacille Calmette-Guérin; IgG, immunoglobulin G; G-CSF, granulocyte colony-stimulation factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; poly IC, polyriboinosinic-polyribocytidylic acid; poly AU, polyadenylic-polyuridylic acid; LPS, lipopolysaccharides; IgE, immunoglobulin E.				

^a Repeated parenteral use of these recombinant products made for people may stimulate antibodies, which make them ineffective and potentially detrimental.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 2-5 Immunomodulators Licensed for Use in Dogs or Cats

PRIVATE PRODUCT	MANUFACTURER	ACTIVE PRINCIPLE	LICENSED INDICATIONS
Acemannan Immunostimulant	Carrington Labs	Complex carbohydrate from Aloe vera	Adjunctive therapy for canine and feline fibrosarcomas
ImmunoRegulin	Immunovet (Vetoquinol)	Killed <i>Propionibacterium acnes</i>	Adjunctive therapy with antibacterials for canine pyoderma
Regressin-V	Vetrepharm	Mycobacterial cell wall fraction	Treatment of canine mammary tumors
Nomagen ^a	Fort Dodge	Mycobacterial cell wall fraction	Treatment of equine sarcoid or bovine ocular carcinoma
Staphage Lysate	Delmont Labs	<i>Staphylococcus aureus</i> components with bacteriophage	Treatment of canine pyoderma
Rubeola virus ^b	Eudaemonic Corp	Inactivated rubeola virus	Treatment of ossifying spondylitis in dogs

a Same as Regressin-V, which is no longer available.

b Conditional license.

An emulsion of the cell wall from a nonpathogenic species of mycobacteria (Regressin-V, Vetrepahrm Inc., Athens, Ga.; Nomagen, Fort Dodge Labs, Fort Dodge, Iowa), which has been modified to decrease toxicity and antigenicity while retaining antineoplastic activity, has been licensed as a CMI stimulant for treating equine sarcoids. It has been recommended for immunotherapy for other neoplasms, such as canine mammary tumors, lymphomas, and sarcomas, although studies demonstrating its efficacy for this purpose are not available at this time (Table 2-5). Various other bacteria, including *Propionibacterium acnes* (*Corynebacterium parvum*) and certain species of *Staphylococcus* and *Salmonella*, have also been proposed as immunostimulants. Immuno Regulin (ImmunoVet Inc, Tampa, Fla.) is a preparation of *P. acnes* that acts as a nonspecific immunostimulant. Clinical studies have involved the treatment of cats with FeLV infection, FHV infection, and canine staphylococcal pyoderma (see the Drug Formulary, Appendix 8).

Modified inactivated, rubeola virus immunomodulator (Eudaemonic Corp., Omaha, Neb.) has been licensed as an immunomodulator to decrease the inflammatory reaction generated by activated T lymphocytes. It has not been adequately evaluated in controlled studies but has received conditional licensing for treatment of navicular disease in horses and ossifying spondylitis in dogs.¹⁶¹

Staphylococcus aureus phage lysate is a sterile preparation containing cell wall components of this bacteria. It has been licensed for the treatment of staphylococcal or polymicrobial pyoderma in dogs. It is thought to act through the stimulation of cytokine production. Local or systemic allergic reactions are potential side effects.

2.2.1.1

Staphylococcal protein A

Staphylococcal protein A (SPA) is a bacterial polypeptide product purified from cell walls of *S. aureus* Cowan I. It may combine with immune complexes at the Fc (non-antigen-binding) region of certain IgG subclasses and stimulate complement activation, as well as induce T-cell activation, natural killer cells stimulation, and IFN- γ production. Antitumor activity has been described.^{13,75}

A variety of SPA sources and treatments have been used in FeLV-infected cats. Interest was first generated when plasma from FeLV-infected lymphoma-bearing cats was passed over SPA or *S. aureus* columns to

Infectious Diseases of the Dog and Cat, 3rd Edition

remove circulating immune complexes and then returned to the cats. More than 100 cats were treated in this manner, generally undergoing treatments twice a week for 10 to 20 weeks. ^{*} In some studies, a high rate of tumor remission and conversion to FeLV-negative status was observed; in others, responses were less dramatic and short-lived. Subsequently, it was determined that SPA and other products may have leached from the filters and columns used for immunosorption and been returned to the cats as contaminants in the treated plasma. ⁵⁰ The possibility that these products exerted a positive immunomodulatory effect caused investigators to treat cats with small doses of SPA. In such a study including kittens with experimental FeLV infection, treatment with SPA (7.3 mg/kg IP twice weekly for 8 weeks) did not correct anemia or improve humoral immune function. In a placebo-controlled study, treatment of ill client-owned FeLV-infected cats with SPA (10 mg/kg intraperitoneally [IP], twice per weekly for up to 10 weeks) did not cause a statistically significant difference in the FeLV status, survival time, or clinical and hematologic parameters when compared with a placebo group, but it caused a significant improvement in the owners' subjective impressions on the health of their pets. When SPA was combined with low dose (30 U/day) oral IFN- α on alternate weekly intervals, the effect was less than with SPA alone. ¹⁰² For further information on use of this drug, see the Drug Formulary, [Appendix 8](#).

* References 26, 33, 68, 83, 84, 138, 163.

2.2.1.2

Propionibacterium acnes

P. acnes, formerly *Corynebacterium parvum* (ImmunoRegulin, ImmunoVet) is available for veterinary use and consists of a killed bacterial product that has been shown to stimulate macrophages resulting in release of various cytokines and IFNs and to enhance T-cell and natural killer cell activity in mice. It was effective in preventing development of rabies in some mice after challenge. ¹⁰⁴ In cats and dogs, it has been used for the treatment of certain tumors (e.g., malignant melanoma). ^{91,152} It was effectively used as adjunct treatment to antibiotic therapy against chronic recurrent canine pyoderma. ¹⁰ As an antiviral, *P. acnes* has been given to cats with FeLV infection, FHV-1 infection, and FIP.

19

P. acnes has been used in FeLV-infected cats, but no prospective studies have been performed. Clinical experience has been documented in roundtable discussions and in two anecdotal reports. ^{80,82} In one report, a practitioner reported treating 76 clinically ill cats with natural FeLV infection with *P. acnes* (0.1 to 0.2 mg/cat IV twice weekly, then every other week for 16 weeks) and supportive care. Although no specific clinical and laboratory evaluations were discussed, 72% of the cats became FeLV test-negative and survived for an unspecified period. In the other report, 700 cats with natural FeLV infection were treated with *P. acnes* (0.2 mg/cat IV every 3 days, then every week for 6 or more weeks) in conjunction with supportive care. Approximately 50% of the cats clinically improved, although conversion to a FeLV-negative status was rare.

20

P. acnes treatment was used in 74 cats with experimentally induced FIP that received either *P. acnes*, high-dose subcutaneous (SC) human IFN- α , a combination, or placebo. ¹⁶⁸ Although *P. acnes* alone was ineffective, some indication showed that a combination of *P. acnes* and high doses of IFN- α was more effective than IFN- α alone in prolonging the mean survival time in the treated cats for a few days.

2.2.1.3

Bacille Calmette-Guérin

BCG (Tice BCG, Organon, West Orange, N.J.) is a cell wall extract of a nonpathogenic strain of *Mycobacterium bovis* that was originally developed in 1908 by Calmette and Guérin as a “vaccine” against tuberculosis in humans. Facultative intracellular organisms such as mycobacteria are immunostimulators that

Infectious Diseases of the Dog and Cat, 3rd Edition

have a marked affinity for localizing in and stimulating mononuclear-phagocyte clearance mechanisms.⁴⁴ Severely immunodeficient animals or those on immunosuppressive therapy might develop infection rather than stimulation by this vaccine. BCG has been used in treating neoplasia in cats and dogs.⁸⁹ Other mycobacterial cell wall preparations, used as adjuvants in vaccines, have been modified (decreasing toxicity and antigenicity while retaining antineoplastic activity) and licensed as CMI stimulants for treating equine sarcoid (Regressin-V, Vetrefarm, Athens, Ga.).

Feline sarcoma virus (FeSV) is a recombinant virus that can develop in a cat after FeLV infection. Kittens experimentally infected with FeSV were inoculated with BCG SC, either at the same time and site as the FeSV inoculation, or at the same site but 1 week after FeSV inoculation, or with a mixture of viable autochthonous neoplastic cells approximately 35 days after FeSV inoculation. The BCG treatment was not able to prevent tumor development or increase survival rate.⁶

2.2.1.4

Serratia marcescens

A commercially available orphan biological extract of *S. marcescens* (BESM) (ImuVert, Cell Technology, Boulder, Colo.) containing DNA and membrane components of *S. marcescens* is used as immunomodulatory substance. *S. marcescens* is a motile facultative anaerobic gram-negative bacillus that occurs naturally in soil and water, as well as the intestines and produces a red pigment at room temperature. It can cause nosocomial infections associated with urinary and respiratory tract infections, endocarditis, osteomyelitis, septicemia, wound and eye infections, and meningitis in humans; systemic infections in cats and dogs are also described.⁵ BESM stimulates normal feline bone marrow-derived macrophages to release maximal concentrations of interleukin (IL)-6, tumor necrosis factor, and IL-1, leading to elevations in rectal temperature and neutrophil counts.³² In one study in dogs, BESM (0.08 mg/kg SC every 24 hours beginning the day after administration of doxorubicin) was effectively used to reduce the duration and severity of doxorubicin-induced myelosuppression.¹¹⁶ In a study with FeLV-infected cats, weekly treatment with BESM, however, failed to prevent or reverse viremia in cats when initiated before or 6 weeks after inoculation with FeLV.³²

2.2.2

Interferons

IFNs are polypeptide molecules produced by vertebrate cells in response to viral infections or certain inert substances, such as double-stranded RNA, and other microbial agents. In people, at least three types can be found: IFN- α (formerly leukocyte IFN), IFN- β (formerly fibroblast IFN), and IFN- γ . IFN- α and IFN- β are structurally similar, being produced in response to viral infection or polyribonucleotide administration. IFN- γ is structurally distinct and is produced by T lymphocytes in response to a specific antigenic stimulus. Human IFNs have been manufactured by recombinant DNA technology and are available commercially. IFNs are not strictly species-specific in their effects, although their biologic activity and toleration are greater in cells of genetically related species. For more information on each human IFN, see the Drug Formulary, [Appendix 8](#).

2.2.2.1

Human IFN- α

Recombinant human (rHu) IFN- α has immunomodulatory and antiviral activity. IFN- α is active against many DNA and RNA viruses, although in vitro sensitivity varies (e.g., myxoviruses are susceptible, whereas adenoviruses are not). In people, high-dose parenteral IFN- α administration has shown some efficacy against influenza viruses, rhinoviruses, herpesviruses, and papillomaviruses. IFN- α has also been shown to inhibit oncogenic transformation induced by retroviruses. It has been licensed for the treatment of people with

Infectious Diseases of the Dog and Cat, 3rd Edition

myelogenous leukemia, papillomatosis, and HIV infection. IFN- α is applied topically, intranasally, ocularly, and intralesionally (e.g., in papillomavirus infections). Human IFN- α has been used in cats with FIV, FeLV, FHV-1, and FCV infections, and with FIP, as well as in papillomatosis in cats and dogs. IFN- α acts as a cytokine having immunomodulatory effects, but it also has direct antiviral effects. It is not virucidal but merely inhibits viral nucleic acid and protein synthesis.

There are two common treatment regimens for use of rHuIFN- in cats, SC injection of high-dose (10^4 to 10^6 IU/kg every 24 hours) IFN- α or oral application of low-dose (1 to 50 IU/kg every 24 hours) IFN- α . When given parenterally to cats (or dogs), it becomes ineffective after 3 to 7 weeks because of development of neutralizing antibodies that limit its activity. In one study, cats that were treated with human IFN- α SC became refractory to therapy after 3 or 7 weeks, respectively, depending on whether the high parenteral (1.6×10^6 IU/kg) or the low parenteral (1.6×10^4 IU/kg) dosage was used.¹⁷⁹

It can be given orally for a longer period as no antibodies develop. It has also been used in this manner to treat FIV and FeLV infections. With oral use, antiviral effects are unlikely but immunomodulatory activity occurs. The rationale behind the use of low doses (versus high doses) orally is to mimic natural defense processes. In studies comparing low-doses oral IFN- α with higher concentrations, increasing the dose did not improve the effect.²⁴

Human IFN- α is active against FIV in vitro.¹⁴⁸ It is frequently used in the field for treating FIV-infected cats. However, no placebo-controlled studies that evaluate the effect of either low-dose oral or high-dose parenteral use of human IFN- α in FIV-infected cats have been conducted. However, use of oral human IFN- α should be considered critically because of the expected immunomodulatory activities but lack of antiviral activity after oral use. As in HIV infection, nonspecific stimulation of the immune system in FIV infection can lead to increased viral replication and activation of latently infected lymphocytes and macrophages and potential progression of disease. In cell culture, stimulation of FIV-infected cells is consistently associated with enhanced production of FIV.

Several studies have been conducted on the use of human IFN- α in FeLV-infected cats. In vitro, FeLV replication is inhibited by human IFN- α .⁶⁷ Another study¹⁸⁰ compared the therapeutic efficacy of either

high-dose human IFN- α (1.6×10^4 IU/kg to 1.6×10^6 IU/kg SC) or AZT, or IFN- α plus AZT in experimentally FeLV-infected presymptomatic cats with high levels of persistent antigenemia. Treatment with IFN- α , either alone or in combination with AZT, resulted in significant decreases in circulating FeLV p27 antigen beginning 2 weeks after the initiation of therapy. However, because of anti-IFN- α antibody development, cats became refractory to therapy 3 or 7 weeks after the beginning of treatment. In naturally FeLV-infected cats using a similar high dose treatment regimen, however, treatment with human IFN- α (1×10^5 IU/kg SC every 24 hours for 6 weeks) with or without AZT did not lead to a statistically significant improvement of clinical, laboratory, immunologic, or virologic parameters.⁵⁸ Low-dose oral IFN- α was used in a placebo-controlled study in experimentally induced FeLV infection; 0.5 IU/cat (eight cats) or 5 IU/cat (five cats) was given orally (following experimental challenge) on 7 consecutive days on alternate weeks for a period of 1 month.²⁵ No difference was found in the development of viremia between groups; however, treated cats had significantly fewer clinical signs and longer survival times when compared with the placebo group (with a better response in the cats given 0.5 IU/cat). Several uncontrolled studies reported a beneficial response in cats when treated with low-dose oral IFN,^{139,153, 169} but they only include a limited number of cats and are difficult to interpret without control groups. In a larger study, outcome of 69 FeLV-infected cats with clinical signs that were treated with low-dose oral IFN (30 IU/kg for 7 consecutive days on a 1-week-on

Infectious Diseases of the Dog and Cat, 3rd Edition

–1-week-off schedule) was compared with historical controls, and significant longer survival times were reported in the treated cats.¹⁶⁹ In a placebo-controlled study, treatment of ill client-owned FeLV-infected cats with low-dose oral IFN- α (30 IU/cat for 7 consecutive days on a 1-week-on–1-week-off schedule) either alone or in combination with SPA did not result in any statistically significant difference in FeLV status, survival time, clinical or hematologic parameters, or subjective improvement in the owners' impression when compared to a placebo group.¹⁰²

In vitro, FHV-1 replication can be inhibited when cells are treated with human IFN- α .³⁸ Weiss¹⁶⁴ demonstrated a synergistic effect of IFN- α when combined with AZV against FHV-1 in cell culture. In one experimental in vivo study, 12 kittens infected with FHV-1 received either 10⁸ IU/kg human IFN- α SC every 12 hours for 2 consecutive days starting 1 day before the challenge or placebo. IFN- α was effective in reducing the clinical signs in the cats over a 14-day period.¹⁸ In practice, IFN- α is commonly used topically in FHV-1–induced keratoconjunctivitis. Topical use is preferred over systemic use because an antiviral effect can develop directly at the application site; however, frequent application is important. Combination with a nucleoside analogue (e.g., AZV) is recommended owing to the synergistic effects. However, no controlled studies have been conducted using this combination in naturally infected animals.

FCV replication can also be reduced in vitro when cell cultures are treated with human IFN- α .³⁸ In vivo studies are lacking.

Antiviral activity of human IFN- α against an FIP-causing FCoV strain was demonstrated in vitro. Combination of IFN- α with RTCA in vitro resulted in antiviral effects significantly greater than the sum of the observed effects from either RTCA or IFN- α alone.¹⁷⁰ In one study, 74 cats (52 treated, 22 controls) with experimentally induced FIP received IFN- α , *P. acnes*, a combination, or placebo. Prophylactic and therapeutic administration of high-dose (10⁴ or 10⁶ IU/kg) IFN- α did not significantly reduce mortality in treated versus untreated cats; only the mean survival time in cats treated with 10⁶ IU/kg IFN- α and *P. acnes* was significantly prolonged for a few days.¹⁶⁸

In dogs, knowledge about efficacy of human IFN- α is limited. It has been used in dogs with viral papillomatosis, but controlled studies are lacking. In people with papillomatosis, IFN- α is used at 10⁶ IU/person parenterally until regression occurs; a similar treatment regimen, or oral low-dose treatment, might be effective in dogs as well.¹⁵ Intralesional injection, however, might be more beneficial.

In cats with ocular manifestation of FHV-1 infection, topical use of human IFN- α every 4 to 6 hours for a duration of 1 week beyond clinical resolution has been recommended. Combination with topical nucleoside analogues (e.g., AZV) is recommended to exacerbate synergistic effects.⁹⁶ For further information on this and other available human IFNs such as IFN- β and IFN- γ , see the Drug Formulary, [Appendix 8](#).

2.2.2.2

Feline IFN- ω

IFNs are species-specific and the feline IFN is less antigenic and has greater antiviral activity in feline cells than the human recombinant IFNs. IFNs of dogs and cats are closely related, and feline IFN- ω is almost as effective in canine cells as it is in feline cells. Besides antiviral activity, it has antitumor effects against canine neoplastic cells, including antiproliferation and anti-colony-forming activities. It might be useful for treatment of some feline and canine neoplastic conditions,^{122,150} but in vivo studies are lacking.

Infectious Diseases of the Dog and Cat, 3rd Edition

In one placebo-controlled, multi-center study, 62 cats naturally infected with FIV were treated with IFN- ω at 10^6 IU/kg SC every 24 hours on 5 consecutive days. No significant changes in survival rate were reported; however, some clinical improvement was noted.¹⁰⁰ The treatment regimen used, however, was probably too short to treat a chronic FIV infection.

Feline IFN- ω inhibits FeLV replication in vitro.¹²⁸ In a placebo-controlled field study involving 48 cats with FeLV infection, treatment was IFN- ω at 10^6 IU/kg SC every 24 hours on 5 consecutive days. A statistically significant prolongation of the survival time was found in treated versus untreated cats in a 2-month follow-up period.¹⁰⁰ Virologic parameters were not measured throughout the study to support the hypothesis that the IFN actually had an anti-FeLV effect rather than inhibited secondary infections.

Feline IFN- ω has an antiviral effect on FHV-1 in vitro.^{38,155} No in vivo data have been conducted to support its efficacy in FHV-1 infected cats. Because human IFN- α seems to have a beneficial effect when it is applied topically in the eye of cats with FHV-1-induced ocular change, similar effects of feline IFN- ω might be considered.

Feline IFN- ω also inhibits FCV replication in vitro,^{38,110,155} although the antiviral effect was less prominent than against other feline viruses when tested in the same cell culture system.¹⁵⁵ In a noncontrolled field study, cats with clinical signs (e.g., stomatitis) that were suspected to have acute FCV infection were treated with 2.5×10^6 IU/kg IFN- ω IV every 48 hours (three times) and showed improvement of clinical signs.¹⁵⁷ Controlled studies, however, are not available.

Data on the efficacy of feline IFN- ω in cats with FIP are limited. FCoV replication is inhibited by feline IFN- ω in vitro.^{110,155} In one uncontrolled study, involving 12 cats suspected of having FIP, IFN- ω (10^6 IU/kg) was given SC every 48 hours in combination with glucocorticoids and supportive care. Dexamethasone (1 mg/kg intrathoracic or IP) or prednisolone (2 mg/kg PO every 24 hours) was continued until clinical improvement was demonstrated, and then the prednisolone was gradually tapered to 0.5 mg/kg every 48 hours. Although most cats died, four cats survived over a period of 2 years; all of them had initially presented with effusions.⁶⁵ Although no control group was in this study and FIP was not confirmed in the four surviving cats, these results suggest either another disease or therapeutic success. Cats with chronic effusions from FIP or other causes usually do not survive for 2 years without proper treatment.

Feline panleukopenia virus (FPV) replication can be inhibited by feline IFN- ω in vitro.^{110,155} No data are found in cats with panleukopenia; however, a large number of studies have been done that prove the efficacy of feline IFN- ω in dogs with canine parvovirus (CPV) infection, and thus beneficial effect would also be expected in cats with panleukopenia. Feline IFN- ω has the best efficacy in feline cells compared with cells of dogs or other species.

Feline IFN- ω also inhibits CPV replication in vitro.¹⁵⁵ The effect of feline IFN- ω on the outcome of experimental parvovirus infection was examined in 29 beagle puppies of 3 to 4 months of age in a placebo-controlled study. Although the number of dogs that developed clinical signs did not differ significantly between the treated dogs and the placebo group, clinical signs were less severe in dogs treated with IFN- ω .⁶⁶ In a placebo-controlled, double-blind challenge, 10 beagle puppies of 8 to 9 weeks of age, inoculated with CPV, developed clinical illness. One half was treated with saline placebo, and the other received IFN- ω 2.5×10^6 IU/kg IV every 24 hours for 3 consecutive days starting 4 days after challenge. All

Infectious Diseases of the Dog and Cat, 3rd Edition

five dogs in the placebo-group died within 10 days postinoculation. In the treated group, one animal died on day 2 after the treatment was started, whereas the other four dogs survived the challenge and recovered gradually.⁹⁷ Efficacy of feline IFN- ω was also evaluated under field conditions for treating dogs with CPV infection in a multi-center, placebo-controlled, double-blind trial. Ninety-two dogs from 1 to 28 months of age were randomly assigned to two groups (43 IFN- ω , 49 placebo) and were treated IV with either feline IFN- ω (2.5×10^6 IU/kg, every 24 hours for 3 consecutive days) or placebo. Clinical signs of the treated animals improved significantly, and mortality was lower, in comparison with control animals. In the IFN- ω group, three dogs died compared with 14 in the placebo group.²⁹ In a similar field study including 93 dogs with CPV infection in Japan, mortality was also significantly reduced in the dogs treated with IFN- ω (14/72) when compared to the control group (13/21).¹⁰⁷ These data suggest that the feline IFN- ω can be beneficial in treating dogs with parvovirus infections by improving clinical signs and reducing mortality. See the Drug Formulary, [Appendix 8](#), for dosages.

2.2.3 Growth Factors and Cytokines

Besides IFNs, other cytokines have been used in some viral infections. They do not have a direct antiviral effect but may alter bone marrow function and interfere with viral infections that disrupt hematopoiesis. Hematopoietic growth factors are glycoproteins that affect growth and differentiation of blood cells, including erythrocytes, platelets, monocytes, granulocytes, and lymphocytes. Several feline and canine hematopoietic growth factors have been cloned but are not commercially available. Human factors must be used instead; however, cats and dogs develop antibodies against them, limiting the length of treatment.

2.2.3.1 Filgrastim

Filgrastim, granulocyte colony-stimulation factor (G-CSF), is on the market as recombinant human product (rHuG-CSF). Potential uses in viral infections are neutropenias associated with FIV, FeLV, or parvovirus infections or concurrent with antiviral chemotherapy to avoid neutropenic side effects. See the Drug Formulary, [Appendix 8](#) or further information.

Filgrastim has been used in FIV-infected cats. In one study, a small number of naturally FIV-infected cats were treated, but no significant changes were seen when compared with untreated cats.⁷⁷

Data on the use of filgrastim in FeLV infection are limited. In one study involving treatment of a few naturally FeLV-infected cats, no significant changes in neutrophil counts were found.⁷⁷ Filgrastim was also used in cats with severe neutropenia caused by FPV infection. Differences in numbers of neutrophils were not observed in the cats with panleukopenia when compared with control cats, but the number of cases in this study was limited.⁷⁷ Furthermore, use of filgrastim in parvovirus-infected animals may be contraindicated because the virus replicates in actively dividing cells.

In dogs, filgrastim has been used to treat gray collies with cyclic hematopoiesis (see [Chapter 95](#)). In other instances, it has been recommended to treat CPV infection (see [Chapter 8](#)). Use of filgrastim in this disease, however, is questionable. In one uncontrolled study including profoundly neutropenic dogs, an improvement of neutrophil count was observed 24 hours after treatment.³⁷ In a randomized, placebo-controlled, clinical trial including 23 puppies with confirmed parvoviral infection and neutropenia (less than 1000 neutrophils/ μ l); however, treatment did not cause significant differences between the treatment and placebo group regarding duration of hospitalization, lowest neutrophil count, or time until neutrophil count increased.¹²⁵ Similar results

Infectious Diseases of the Dog and Cat, 3rd Edition

were found in another clinical double-blind study including 43 dogs.¹⁰⁸ These disappointing results might be explained by the fact that endogenous G-CSF is already increased in dogs with CPV infection. G-CSF was not detectable in plasma of experimentally infected dogs before the onset of neutropenia, but became detectable just after it, and reached very high concentrations throughout the remaining infection,²⁰ making the necessity of filgrastim treatment questionable. As in cats with FPV infection, use of filgrastim in CPV-infected dogs may exacerbate the disease because the virus replicates in actively dividing cells. Increasing the proportion of cycling neutrophil precursors may actually prolong the neutropenic period, owing to viral infection and destruction of these cells.⁸⁶ Extended use of this drug in dogs and cats may result in antibody formation to the drug and resultant neutropenia. See the Drug Formulary, [Appendix 8](#) for further information on this drug.

2.2.3.2

Sargramostim

Also known as granulocyte-macrophage colony-stimulating factor (GM-CSF), sargramostim controls the differentiation and proliferation of bone marrow precursors of granulocyte and monocyte lineages. GM-CSF also induces the proliferation of myeloid and erythroid progenitors. Cats may show increases in neutrophils, eosinophils, lymphocytes, and monocytes in varying combinations. Sargramostim (5 mg/kg every 12 hours for 14 days) was used in treating clinically healthy cats (control group) and those that were chronically infected with FIV.³ Side effects of treatment in some cats were irritation of the injection site and low-grade fever. All cats developed neutrophilia; however, only FIV-infected cats developed a significant increase in viral load of FIV in peripheral blood mononuclear cells during treatment. Enhancement of the viremia may relate to increased replication in or enhanced expression of the virus by infected lymphocytes. Therefore use of sargramostim in FIV-infected cats is contraindicated. High-dose treatment (150 µg/kg) of dogs with rHuGM-CSF induces neutralizing antibodies to the drug beginning 10 days after treatment and presumably resulted in a subsequent decline in the observed leukocytosis during treatment.⁹⁹ Cats treated with rHuGM-CSF had a similar inducement of antibodies; however, their leukocytosis was maintained suggesting another mechanism for the transient response in the dog.

2.2.3.3

Erythropoietin

Erythropoietin (EPO) is on the market as recombinant human erythropoietin (rHuEPO) and is effectively used in cats and dogs with nonregenerative anemia caused by endogenous EPO deficiency in chronic renal failure. EPO treatment increases not only erythrocyte counts, but also platelet and megakaryocyte numbers in animals and humans with clinical disease.¹¹⁵ Human EPO also increases leukocyte counts in cats.³

22

23

In one study, FIV-infected cats were treated with human EPO (100 IU/kg SC three times a week for 2 weeks). All treated cats had a gradual increase in erythrocytes and either neutrophils or lymphocytes, or both. In contrast to treatment with filgrastim, no increased viral loads were observed, and thus human EPO can be used safely in FIV-infected cats with cytopenias.³

2.2.3.4

Interleukin-2 and interleukin-8

This lymphokine is produced by activated helper T cells and is responsible for stimulating specific cell-B-mediated cytotoxicity. It has been synthesized in large quantities through recombinant DNA technology; however, it may cause toxicity. Potential applications include treatment of neoplastic and viral diseases. IL-2 in low doses has been shown to increase the immune response to concurrent vaccination when it was given to

Infectious Diseases of the Dog and Cat, 3rd Edition

immunodeficient people.¹⁰⁵ IL-8, a cytokine produced by monocytes and a variety of other tissue cells, has a role in activating neutrophils and has been given to dogs to potentiate neutrophil chemotaxis.¹⁸¹

2.2.3.5

Insulinlike growth factor-1

Insulinlike growth factor-1 (IGF-1) is on the market as recombinant human product (rHuIGF-1) and it acts as an immunostimulant of thymic tissue and T lymphocytes. In HIV infection, thymus inhibition and limited T-cell maturation result in depletion the peripheral lymphoid pool. Therapeutic modulation to protect or enhance thymus function may ameliorate peripheral lymphopenia and retard disease progression in lentivirus infections.

In experimental FIV-infected cats, treatment with rHuIGF-1 resulted in a significant increase in thymus size and weight and evidence of thymic cortical regeneration and a reduction in B cells.^{45,174} Although T-cell stimulation was observed, viral load was not increased during treatment, and no data have yet been found for naturally FIV-infected cats. The drug is administered by continuous infusion (see the Drug Formulary, [Appendix 8](#)).

2.2.4

Interferon and Other Cytokine Inducers

Nonspecific immunostimulants, which induce synthesis of IFNs and other cytokines, are widely used medications in virus-infected cats and dogs. Several macromolecules and certain microorganisms (viruses) are known to produce antiviral and other antimicrobial activities in the host. Most of the substances known to have this effect have a structure similar to double-stranded nucleic acid that can be of microbial origin or new synthetic nucleic acid polymers.

Therapy and prophylaxis with IFN inducers have become more attractive in treating infections in veterinary practice because they provide a more natural means of restoring compromised immune function, thereby allowing the patient to control the viral burden and recover from the disease. Their effect is generally transient, lasting for approximately 1 week; thus they must be given repeatedly to be clinically helpful. However, administration at an interval shorter than every 2 weeks can cause pronounced interference with IFN induction. Effects of these compounds on nonspecific defense functions are difficult to test, and in vitro test results cannot simply be transferred to in vivo situations. Most reports are difficult to interpret because of unclear diagnostic criteria, lack of clinical staging or follow-up, the natural variability of the course of disease, the lack of placebo-control groups, the small number of animals used, and concurrent supportive treatments given. Although reports of uncontrolled studies frequently suggest clinical improvement or increased survival times, these effects have not always been supported by subsequent controlled studies. In some cases, nonspecific stimulation of the immune system in already infected animals might be detrimental. In people, and perhaps cats with retroviral infection, these drugs can lead to an increased viral replication caused by activation of latently infected lymphocytes and macrophages and can therefore cause progression of disease. In cell culture, stimulation of FIV-infected cells is consistently associated with enhanced production of FIV. These compounds should also be avoided in cats with FIP because clinical signs develop as a result of an immune-mediated response to the mutated FCoV.

2.2.4.1

Polyriboinosinic-polyribocytidylic acid

Polyriboinosinic-polyribocytidylic acid (poly-IC) is a chemical IFN inducer that was used to treat cats and dogs. It only induced minimal IFN induction in dogs,¹³⁴ but it was reported to be effective in protecting dogs

Infectious Diseases of the Dog and Cat, 3rd Edition

from infectious canine hepatitis (ICH).⁴² In a controlled experimental study, however, mortality in dogs with ICH was not decreased, and survival time was prolonged only for a few days.¹⁷⁵ In one report, poly-IC was helpful in preventing CHV infections in newborn puppies.⁴²

The recommended dose of poly-IC is 0.2 mg/kg SC once. The concentration of IFNs generally peaks 8 hours after administering poly-IC but declines gradually by 24 hours. Inhibition of IFN production is pronounced if poly-IC is readministered at a frequency greater than every 2 weeks. The duration of the effect of IFNs is less than 2 weeks; thus a continuous effect cannot be maintained. Side effects in cats and dogs include lymphopenia, lymphoid necrosis, CNS depression, hemorrhagic gastroenteritis, and coagulation disorders.⁴²

2.2.4.2

Parapoxvirus avis and parapoxvirus ovis

Parapoxvirus avis (PIND-AVI) and parapoxvirus ovis (PIND-ORF) (Baypamun®, Bayer, Mijdrecht, Netherlands) are γ -ray inactivated poxviruses that are so-called “paramunity inducers.” Their proposed mode of action is through induction of IFNs and colony-stimulating factors, and activation of natural killer cells. They are available in some European countries and have been used to treat a variety of viral infections in animals, both prophylactically and therapeutically. However, most reports on their efficacy are anecdotal or lack control animals. In all placebo-controlled, double-blind studies published thus far, no beneficial effect have been documented. Paramunity inducers may be contraindicated in already immunosuppressed cats with FIV infection because nonspecific immunostimulation may lead to progression of infection.

PIND-AVI and PIND-ORF were reported to cure 80% to 100% of FeLV-infected cats⁶³ when they were administered at a dose of 1 ml SC one to three times a week for 4 to 30 weeks. However, two placebo-controlled, double-blind trials in naturally FeLV-infected cats under controlled conditions were not able to repeat these results.^{56,57} In 120 cats treated with either compound or placebo, no significant difference was found in eliminating viremia during the 6-week treatment period (12% in the treated cats, 7% in the control group). In the second study, 30 naturally infected cats were treated in a placebo-controlled, double-blind trial, and 20 immunologic, clinical, laboratory, and virologic parameters were examined (including FeLV p27 antigen concentration, clinical signs, lymphocyte subsets, and survival time), but no statistically significant differences were demonstrated between paramunity inducer and placebo application in any of these parameters.

Similar to other immunomodulators that produce nonspecific stimulation of the immune system, PIND-AVI and PIND-ORF are probably contraindicated in cats with FIP. No controlled studies have been conducted supporting an effect in any other viral infections in cats and dogs.

23

2.2.4.3

Acemannan

24

Acemannan (Carrisyn, Carrington Labs, Irving, Tex.) is a water-soluble, long-chained complex carbohydrate (mannan) polymer derived from the aloe vera plant and licensed for veterinary use. Acemannan may be taken up by macrophages, which stimulate release of cytokines, producing cell-mediated immune responses, including cytotoxicity. Acemannan has been used as an adjuvant in vaccines or intralesional, by itself, to enhance regression of tumors, such as in the management of postvaccinal injection-site sarcomas in cats.^{51,72}

Acemannan has been used in clinically ill FIV-infected cats that received acemannan for 12 weeks, either by IV or SC injection once weekly or by daily oral administration.¹⁷⁸ The reported beneficial effects observed in

Infectious Diseases of the Dog and Cat, 3rd Edition

this study are not clear because cats were concurrently treated with antibiotics and other symptomatic or supportive therapies and the study did not contain a control group. Presently, acemannan should be used with caution in FIV-infected cats because of its immunostimulatory effects, which can stress an already impaired immune system.

In one noncontrolled, open-label trial, 50 cats with natural FeLV infection were treated with acemannan (2 mg/kg IP every 7 days for 6 weeks).¹³³ Use of concurrent supportive care was not described. At 12 weeks, 71% of the cats were alive, and results for FeLV antigen were positive. No significant change in clinical signs or hematologic parameters was found. No control group or clinical and laboratory evaluations were available to document improvement from pretreatment evaluations.

In dogs, data on the effect of acemannan in viral infections are limited. Intralesional injection of acemannan have been recommended as treatment for dogs with papillomatosis.¹⁵ For specific information on its use, see the Drug Formulary, [Appendix 8](#).

2.2.5 Other Drugs with Immunomodulatory Activity

A significant number of drugs used for different other reasons in animals also have immunomodulatory activity. Some of these drugs have been used to treat virus infections in dogs and cats.

2.2.5.1 Levamisole

This broad-spectrum anthelmintic, used for example for heartworm treatment in cats and dogs,^{30,123} nonspecifically stimulates cell-mediated immunity in a variety of species. Levamisole was detected as immunomodulatory substance when treatment applied against nematode infection not only killed the parasites, but also improved clinical signs of other infections. Levamisole influences phosphodiesterase activity, leading to increased cyclic guanosin-3',5'-monophosphate and decreased cyclic adenosine monophosphate. Increased cyclic guanosin-3',5'-monophosphate in lymphocytes stimulates proliferative and secretory responses. It also potentiates mononuclear cells in phagocytosis, chemotaxis, and intracellular destruction of bacteria. Levamisole has been used in cats with mammary tumors but has had no significant effect.⁹⁰

Levamisole has been given to FIV- and in FeLV-infected cats,²² but its effect has never been substantiated by controlled studies; it remains investigational.

Toxicity of levamisole is relatively high; hypersalivation, vomiting, diarrhea, and CNS signs have been observed similar to signs observed in nicotine poisoning.⁶⁴ Morphologic lesions, characterized by perivascular, nonsuppurative, or granulomatous meningoencephalitis, were described in the CNS of treated dogs.^{144,160} Potential facilitation of the cell-mediated immune system may produce the lesions in the CNS by causing the body to react against latent agents (e.g., canine distemper virus).⁴²

2.2.5.2 Cimetidine

The H₂-receptor antagonist cimetidine has been shown to be effective in potentiating CMI in people with common immunodeficiencies. It appears to block receptors on suppressor T cells. Controlled studies in dogs or cats are not available.

Infectious Diseases of the Dog and Cat, 3rd Edition

2.2.5.3

Diethylcarbamazine

Diethylcarbamazine (N,N-diethyl-4-methyl-1-piperazine carboxamide [DEC]) is an antiparasitic agent widely used, especially in tropical regions, to prevent and treat filariasis in humans and that has been used as heartworm preventative in cats and dogs. The antifilarial effect of this drug has been attributed to immunomodulation.

Some evidence indicates that DEC might mitigate the course of FeLV infection in cats. Uncontrolled studies have suggested that continuous oral DEC treatment given shortly after evidence of FeLV infection prevents or delays FeLV-associated lymphopenia and prolongs survival.^{73,74} In one controlled study, its therapeutic effect against FeLV infection was investigated in 24 SPF kittens experimentally infected with a lymphoma-causing strain of FeLV. The kittens were divided into four groups and were orally administered a high dose of DEC (12 mg/kg, every 24 hours), a low dose of DEC (3 mg/kg, every 24 hours), AZT (15 mg/kg every 12 hours), or a placebo for 10 weeks. Although AZT was effective in preventing persistent viremia, DEC in either dose was not effective; however, both doses of DEC, as well as AZT, prevented lymphoma development.¹¹⁴ DEC has potentially severe side effects, including hepatic injury.¹⁴

2.2.5.4

Lactoferrin

Lactoferrin is a protein of bovine origin that binds iron, reducing its availability for bacteria. It has been used for its local immunomodulatory effect in the oral cavity, and it has been shown to increase phagocytic activity of neutrophils.¹³¹ A protective effect of lactoferrin during lethal bacteremia has been reported in mice. In a study in healthy humans, orally administered lactoferrin increased the phagocytic activity of peripheral mononuclear cells in some but not all individuals.¹⁷⁷ In vitro studies suggest activity against canine herpesvirus (see [Chapter 5](#)).

Lactoferrin has been used in cats with FIV infection and stomatitis. It was applied topically (40 mg/kg every 24 hours for 14 days) to the oral mucosa of the cats with intractable stomatitis (FIV-infected cats and FIV-negative control cats) and improved clinical signs of disease (pain-related response, salivation, appetite, and oral inflammation) in all cats independent of their FIV status.¹³¹

Recently, a cat with stomatitis and FCV infection was treated with lactoferrin powder (200 mg) applied directly to the lesions. Clinical signs began to resolve after 11 months, and resolution of clinical signs coincided with the cessation of FCV shedding.² However, the cat also received other medications, and further studies are necessary to investigate beneficial effects of lactoferrin. The studies suggest, however, that lactoferrin might be beneficial for local treatment of stomatitis in cats because many of these inflammatory reactions are probably caused or triggered by viral infections. For further information, see the Drug Formulary, [Appendix 8](#).

2.2.5.5

Liposomes

These synthetic microscopic structures are composed of multiple concentric lipid bilayers surrounding an equal number of aqueous layers. The lipid layers are relatively impermeable to aqueous substances trapped within. Immunologic mediators, antigenic substances, and drugs have been placed within the aqueous compartment of liposomes to facilitate delivery of these substances to selected tissues in the body. Liposomes

24

Infectious Diseases of the Dog and Cat, 3rd Edition

25

themselves are relatively nonantigenic, nontoxic, and biodegradable because they are prepared from lipids normally found in cell membranes. As with microspheres, alterations in their physical properties can be used to modify antigen release. Liposomes may have potential to act as carriers of immunogens for purposes of vaccination. Adding adjuvants within the liposomal membrane can increase immunogenicity. Liposomal antigens, which normally stimulate only humoral immunity, can stimulate CMI if bacterial wall substances such as lipid A or muramyl dipeptide are added in the membrane. Liposomes also have been employed for selective in vivo delivery of drugs to cells of the mononuclear phagocyte system, which preferentially removes these compounds from the circulation. Intracellular parasites (e.g., systemic fungi, mycobacteria, *Babesia canis*, *Ehrlichia canis*, *Trypanosoma cruzi*, *Leishmania donovani*) that reside in these cells may be more susceptible to chemotherapeutic agents delivered in liposomes (see also Lipid-Based Amphotericin B in [Chapter 57](#) and the Drug Formulary, [Appendix 8](#)).

2.2.5.6

Nosodes

Nosodes are homeopathic preparations of tissues from animals with the disease for which they are intended to prevent. Recommendations are that nosodes be given immediately after exposure to an infectious agent. These alternative medical therapeutic preparations have been claimed to protect animals as specific immunomodulators against a variety of infectious diseases, including viral infections. Preparations consist of serial dilutions with intervening agitation (succession, potentiation, vortexing) of tissues, discharges, or excretions from animals with corresponding diseases; they are administered orally. Clinical trials involving nosodes to prevent infectious diseases have usually not been controlled, and information about their usefulness or toxicity is limited. In one controlled CPV challenge of puppies, nosodes were not protective.¹⁷⁶

3 CHAPTER 3 Canine Distemper

Craig E. Greene

Max J. Appel

3.1 ETIOLOGY

Canine distemper virus (CDV) is a member of the genus *Morbillivirus* of the family Paramyxoviridae and is closely related to other viruses (Table 3-1). CDV has a relatively large, variable diameter (150-250 nm) with single negative-stranded RNA enclosed in a nucleocapsid of helical symmetry. It is surrounded by a lipoprotein envelope derived from virus glycoproteins incorporated into the cell membrane (Fig. 3-1 and Table 3-2). Viruses such as CDV that code for proteins capable of integrating in the cell membrane make infected cells susceptible to damage by immune-mediated cytolysis. CDV also may induce cellular fusion as a means of direct intercellular spread. Genetic analysis of a 388-bp P gene fragment and of the H-protein encoding region has been used to separate the genotypes of wild and vaccine types.⁷⁵

CDV is susceptible to ultraviolet light, although protein or antioxidants help protect it from inactivation. Extremely susceptible to heat and drying, CDV is destroyed by temperatures greater than 50° C to 60°C for 30 minutes. In excised tissues or secretions, it survives for at least an hour at 37°C and for 3 hours at 20°C (room temperature). In warm climates, CDV does not persist in kennels after infected dogs have been removed. Storage and survival times of CDV are longer at colder temperatures. At near-freezing (0° C to 4°C), it survives in the environment for weeks. Below freezing the virus is stable, surviving at –65°C for at least 7 years. Lyophilization reduces the lability of the virus and is an excellent means of preserving it for commercial vaccine and laboratory use. CDV remains viable between pH 4.5 and 9.0. As an enveloped virus, it is susceptible to ether and chloroform, dilute (<0.5%) formalin solution, phenol (0.75%), and quaternary ammonium disinfectant (0.3%). Routine disinfection procedures are usually effective in destroying CDV in a kennel or hospital.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 3-1 Host Susceptibility to Morbilliviruses

DISEASE (VIRUS ABBREVIATION)	NATURAL HOSTS	EXPERIMENTAL INFECTION
Measles (MV)	Domestic: human	Macaque, marmoset, mouse, hamster, rat
	Wild: nonhuman primate	
Rinderpest (RPV)	Domestic: cattle, pig, goat, sheep	Rabbit, mouse, hamster, dog, ferret, rat, suslik
	Wild: buffalo, eland, giraffe, kudu, warthog, wildebeest, banteng, black buck, gaur, nilgai, sambhar	
Peste des petits ruminants (PPRV)	Domestic: goat, sheep	Goat, cattle, pig, deer
	Wild: gazelle, ibex, gemsbok	
Phocine distemper (PDV)	Seal	Dog, mink, seal
Canine distemper (CDV)	Seal (previously PDV-2)	Dog, mouse, rat, hamster, mink, pig, cat, nonhuman primate, ferret
	Canidae (e.g., dog, fox, wolf, coyote)	
	Mustelidae (e.g., weasel, mink, skunk, badger, ferret)	
	Procyonidae (e.g., kinkajou, coati, red panda, raccoon)	
	Felidae (e.g., cat, lion, leopard, tiger)	
	Suidae (peccary)	
Dolphin morbillivirus (DMV)	Dolphin	Cattle, sheep, goat, dog
Porpoise morbillivirus (PMV)	Porpoise	Cattle, sheep, goat, dog
Equine morbillivirus (EMV; Hendra virus)	Domestic: horse, human	Cat
	Wild: Pteropus bat	
Porcine morbillivirus (Menangle virus)	Domestic: pig, human	No data
	Wild: Pteropus bat

Table 3-3 Order Carnivora Susceptible to Canine Distemper

ORDER	DESCRIPTION
Ailuridae	Lesser panda
Canidae	Coyote, dingo, raccoon dog, wolf, fox
Mustelidae	Ferret, marten, mink, otter, skunk, wolverine, badger
Procyonidae	Coati, kinkajou, raccoon
Ursidae	Bear, giant panda
Viverridae	Binturong, fossa, linsang, civet
Herpestidae	Mongoose, meerkat
Felidae	Cheetah, lion, jaguar, margay, ocelot

From Appel MJG, Summers BA. 1995. Pathogenicity of morbilliviruses for terrestrial carnivores. *Vet Microbiol* 44:187–191.

The disease and natural host ranges of CDV include certain species of terrestrial carnivores (see [Tables 3-1](#) and [3-3](#)), and other species can be infected experimentally with varying degrees of susceptibility.¹³ Central nervous system (CNS) signs have been produced in mice and hamsters by intracerebral inoculation. Rabbits and rats are resistant to parenteral inoculation. Inapparent, self-limiting infections, produced in domestic cats, nonhuman primates, and humans by parenteral inoculation of virulent CDV, resemble those in dogs that have been given modified live virus (MLV) vaccines. In recent years the host range of this disease appears to have widened as interspecies transmissions occurred, leading to epizootics with high mortality.⁷⁵ Despite the wide host range, dogs are the principal reservoir host for CDV, and they likely act as reservoirs of infection for wildlife.^{40,75} Certain wildlife species such as raccoons may serve as a reservoir of infection for susceptible dog populations. CNS infections in captive and wild, large, exotic Felidae have been attributed to infection with CDV^{14,110,135,147,171} (see Feline Paramyxovirus Infections, [Chapter 18](#)). Pigs are subclinically infected, and peccaries (*Tayassu tajacu*) that have been naturally infected develop encephalitis.¹⁴ Encephalitis was documented in a naturally infected monkey.¹⁷⁶ Phocine distemper virus, *Morbillivirus* most closely related to CDV, and some wild strains of CDV have caused severe morbidity in Baikal (*Phoca sibirica*) and Caspian (*Phoca caspica*) seals (see [Tables 3-1](#) and [3-4](#)).^{50,87} It may have spread to the seals from dogs or other susceptible terrestrial carnivores. Genetic analysis of strains causing outbreaks shows that CDV does not become more virulent and spread to new host species in a region, but the same strain circulates among susceptible animals of several host species in a given geographic area.^{28,34,75} Other closely related but distinct morbilliviruses cause illness in other aquatic mammals (dolphins and porpoises), and they are more closely related to ruminant morbilliviruses.

3.2 EPIDEMIOLOGY

Viral shedding occurs by 7 days postinfection. CDV, most abundant in respiratory exudates, is commonly spread by aerosol or droplet exposure; however, it can be isolated from most other body tissues and secretions, including urine. Transplacental infection can occur from viremic dams. Virus can be excreted up to 60 to 90 days after infection, although shorter periods of shedding are more typical. Contact among recently infected (subclinical or diseased) animals maintains the virus in a population, and a constant supply of puppies helps provide a susceptible population for infection. Although immunity to virulent canine distemper is prolonged or lifelong, it is not as absolute after vaccination. Dogs that do not receive periodic immunizations may lose their protection and become infected after stress, immunosuppression, or contact with diseased individuals. The infection rate is higher than the disease rate, which reflects a certain degree of natural and vaccine-induced immunity in the general dog population. Estimates are that 25% to 75% of susceptible dogs become subclinically infected but clear the virus from the body

Infectious Diseases of the Dog and Cat, 3rd Edition

without showing signs of illness. Although most dogs that recover clear the virus completely, some may harbor virus in their CNS.

The prevalence rate of spontaneous distemper in cosmopolitan dogs is greatest between 3 and 6 months of age, correlating with the loss of maternal antibodies in puppies after weaning. In contrast, in susceptible, isolated populations of dogs, the disease is severe and widespread, affecting all ages. Increased susceptibility among breeds has been suspected but not proved. Brachiocephalic dogs have been reported to have a lower prevalence of disease, mortality, and sequelae compared with dolichocephalic breeds.

Despite minor genetic variation, CDV isolates are serologically homogeneous. However, different strains differ in their pathogenicity, which may affect the severity and extent or type of clinical disease. Certain isolates, such as Snyder Hill, A75/17, and R252 strain, are highly virulent and neurotropic. The first causes polioencephalomyelitis, whereas the other two cause demyelination. Others vary in their ability to cause CNS lesions. Properties of the N and M-genes contain the determinants of viral persistence.¹⁵⁰

27

28

Table 3-4 Aquatic Morbillivirus Infections

VIRUS	DATE	SPECIES	LOCATION
Dolphin morbillivirus (DMV)	1990s	Striped dolphin	Mediterranean
Porpoise morbillivirus (PMV)	Late 1980s	Harbour porpoise	Northwestern Europe
Phocine distemper virus (PDV)	Late 1980s	Harbour seal, grey seal	Northwestern Europe
Canine distemper virus (CDV)	Late 1980s	Baikal seal	Siberia

3.3 PATHOGENESIS

3.3.1 Systemic Infection

During natural exposure, CDV spreads by aerosol droplets and contacts epithelium of the upper respiratory tract (Fig. 3-2). Within 24 hours, it multiplies in tissue macrophages and spreads in these cells via local lymphatics to tonsils and bronchial lymph nodes. By 2 to 4 days postinfection, virus numbers increase in tonsils and retropharyngeal and bronchial lymph nodes, but low numbers of CDV-infected mononuclear cells are found in other lymphoid organs.⁹ By days 4 to 6 postinfection, virus multiplication occurs within lymphoid follicles in the spleen, the lamina propria of the stomach and small intestines, the mesenteric lymph nodes, and the Kupffer's cells in the liver. Widespread virus proliferation in lymphoid organs corresponds to an initial rise in body temperature and leukopenia between days 3 to 6 postinfection. The leukopenia is primarily a lymphopenia caused by viral damage to lymphoid cells, affecting both T and B cells.

Further spread of CDV to epithelial and CNS tissues on days 8 to 9 postinfection probably occurs hematogenously as a cell-associated and plasma-phase viremia and depends on the dog's humoral and cell-mediated immune status. Shedding of virus begins at the time of epithelial colonization and occurs from all body excretions, even in dogs with subclinical infections. By day 14, animals with adequate CDV antibody titers and cell-mediated cytotoxicity clear the virus from most tissues and show no clinical signs of illness. Specific IgG-CDV antibody is effective in neutralizing extracellular CDV and inhibiting its intercellular spread.

Dogs with intermediate levels of cell-mediated immunoresponsiveness with delayed antibody titers by days 9 to 14 postinfection have virus spread to their epithelial tissues. Clinical signs that develop may eventually resolve as antibody titer increases. Virus is cleared from most body tissues as antibody titers increase but may persist for

Infectious Diseases of the Dog and Cat, 3rd Edition

extended periods as complete virus in uveal tissues and neurons and in integument such as footpads. Recovery from CDV infection is associated with long-term immunity and cessation of viral shedding. Protection may be compromised if the dog is exposed to a highly virulent or large quantity of virus or if it becomes immunocompromised or stressed.

Dogs with poor immune status by days 9 to 14 postinfection undergo virus spread to many tissues, including skin, exocrine and endocrine glands, and epithelium of the gastrointestinal (GI), respiratory, and genitourinary tracts. Clinical signs of disease in these dogs are usually dramatic and severe, and virus usually persists in their tissues until death. The sequence of pathogenic events depends on the virus strain and may be delayed by 1 to 2 weeks.¹⁵² Secondary bacterial infections increase the severity of clinical illness.

Studies on serologic response to CDV in gnotobiotic dogs confirm that serum antibody titers vary inversely with the severity of the disease. Antibody response in dogs has been separated into envelope and core determinants of the virus. Only dogs producing anti-envelope antibodies appear to be able to prevent persistent viral infection of the CNS. The outcome of CNS infection seems to depend on the appearance of circulating IgG antibodies to the H glycoprotein.¹³⁴ Mortality in gnotobiotic dogs approaches that of naturally infected animals, deemphasizing the role of secondary bacterial infection in influencing the severity of CNS disease. However, bacteria are probably important in complicating the signs of disease in the respiratory and GI tracts.

Studies have documented the occurrence of cell-mediated immunosuppression after CDV infection. Lymphocyte transformation testing of experimentally infected neonates has shown profound depression of lymphocyte response to phyto mitogens at a time corresponding to acute viremia and lymphopenia. This depressed response persisted for more than 10 weeks in convalescing puppies and never returned to baseline values in those that died of acute causes.^{92a} Prenatal and neonatal distemper infections are causes of immunodeficiency in surviving puppies and may make concurrent infections with other viruses such as parvovirus more severe.

3.3.2

Central Nervous System Infection

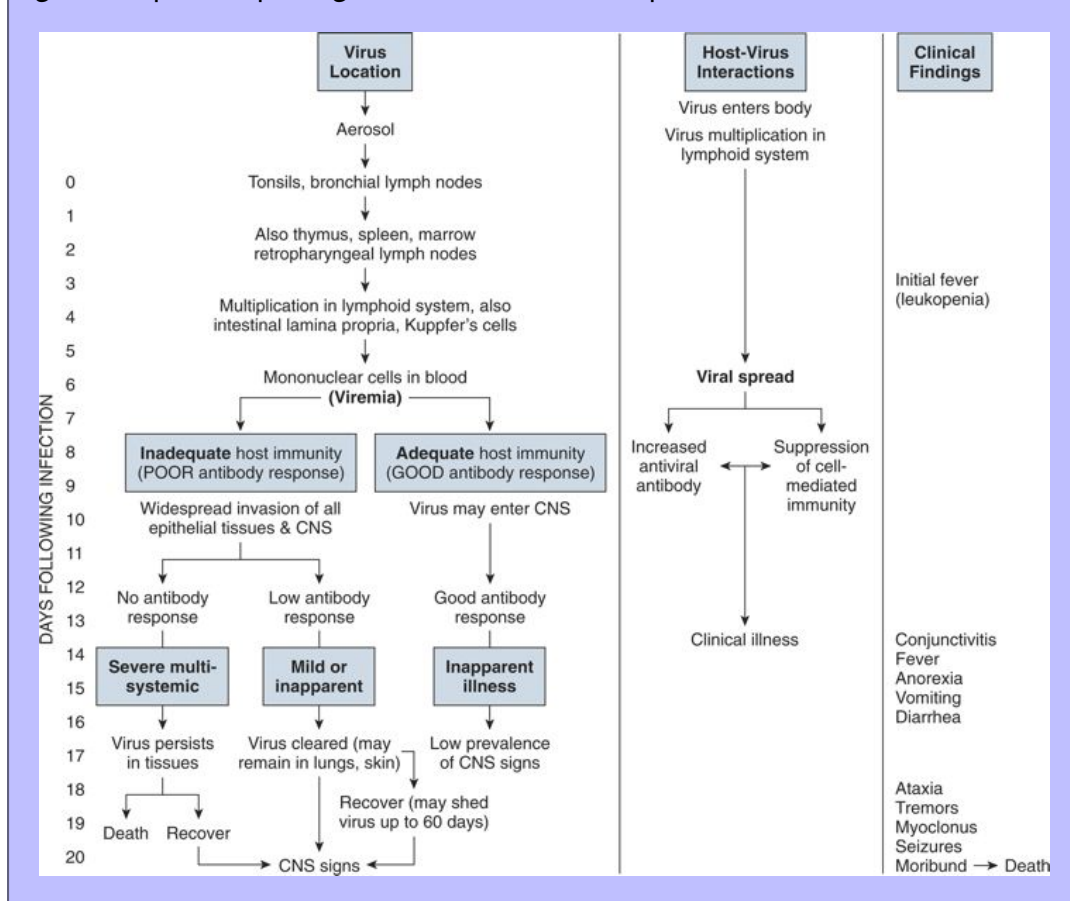

As previously discussed, the spread of virus to the CNS depends on the degree of systemic immune responses mounted by the host. Virus probably enters the nervous system of many viremic CDV-infected dogs whether neurologic signs are observed or not. Antiviral antibody and resultant immune complex deposition may facilitate the spread of virus to the CNS. Virus (free, platelet- or mononuclear cell-associated) may enter the perivascular spaces in the meninges, the choroid plexus epithelial cells of the fourth ventricle, and the ependymal cells lining the ventricular system. Viral antigen is first detected in CNS perivascular astrocytic foot processes and then neurons. The infection of choroid plexus epithelium is productive throughout the course of infection because virus is continually being produced. Primary spread of CDV to the CNS is hematogenous. From the choroid plexus, free or lymphocyte-associated virus may enter the cerebrospinal fluid (CSF), where it spreads to periventricular and subpial structures. Spread of virus through CSF pathways might explain the early distribution of lesions in subependymal areas, such as the cerebral cortex (primarily archicortex and paleocortex), optic tracts and nerves, rostral medullary velum, cerebral peduncles, and spinal cord.

28

29

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 3-2 Sequential pathogenesis of canine distemper.

The type of lesion produced and the course of infection within the CNS depend on numerous factors, including the age and immunocompetence of the host at the time of exposure, the neurotropic and immunosuppressive properties of the virus, and the time at which lesions are examined. Either acute or chronic encephalitis can occur independently, or acute-phase lesions may progress to the chronic form in animals that survive.²²

Acute CDV encephalitis, which occurs early in the course of infection in young or immunosuppressed animals, is characterized by direct viral replication and injury. CDV antigen and messenger RNA (mRNA) are detected in lesions, whereas inflammatory cells and class II major histocompatibility complex (MHC) antigen expression are minimal or absent. These animals have lymphoid depletion, and CDV is found concurrently in lymphoid cells and macrophages throughout the body.¹⁷³ Virus causes multifocal lesions in the gray and white matter. Gray matter lesions are the result of neuronal infection and necrosis and may lead to predominant polioencephalomalacia. However, neuronal infection can also occur with minimal evidence of cytolysis. Early in the clinical illness, inflammatory changes are minimal, and theories for the lack of inflammation have included immunodeficiency resulting from the physiologic immaturity of the immune system and virus-induced immunosuppression.

Infectious Diseases of the Dog and Cat, 3rd Edition

Light and electron microscopy (EM) reveal noninflammatory demyelination in acute lesions to be associated with viral infection of microglial and astroglial cells rather than oligodendroglial cells, the myelin-producing cells.^{33,56,113} Despite the lack of viral replication in oligodendroglial cells, their function has been impaired when observed in primary canine brain cell cultures, where CDV causes a slow-spreading, noncytolytic infection. CDV viral proteins and nucleocapsids are difficult to detect in oligodendroglia by immunocytochemical or ultrastructural methods. However, the use of in situ hybridization shows that the complete viral genome is present.¹⁸² The restricted infection likely leads to metabolic dysfunction and morphologic degeneration of oligodendroglial cells⁶² and results in demyelination via a down-regulation of myelin gene expression.¹⁷⁹

In the normal brain, expression of class II MHC antigen is low. As effector cells, microglia express class II MHC when activated, presumably through increases in interferon (IFN), a T-cell cytokine. Elevated levels of IFN- γ are seen in the CNS during viral infection and in human multiple sclerosis (MS). Class II MHC is up-regulated in demyelinating diseases such as experimental allergic encephalomyelitis and MS. In a study of acute CDV encephalitis in dogs, virus was present in a diffuse or multifocal distribution, and class II MHC was up-regulated throughout the white matter and in CDV-infected foci.⁷ Despite the visible absence of an inflammatory response in the CNS and an apparent lack of systemic immune response, entry of CD3+ lymphocytes occurs in the CNS in response to the presence of CDV nucleocapsid protein and increased interleukin (IL)-8 activity.¹⁵⁶ CD8+ lymphocytes dominated the infiltrates during all states of distemper encephalitis.¹⁷² In the CNS, up-regulation of proinflammatory cytokines such as IL-6 and tumor necrosis factor is balanced by increased IL-10 and transforming growth factor, which help temper the immune response.⁵²

In contrast to acute CDV encephalitis, subacute to chronic CDV encephalitis is characterized by reduced expression of CDV antigen and mRNA and a strong up-regulation of class II MHC expression. This results in perivascular mononuclear cell infiltrations and a virus-independent immunopathologic process. These animals have no evidence of lymphoid depletion throughout the body, and they have a significant increase in T- and B-lymphocyte populations compared with dogs with acute CDV encephalitis. Virus is found predominantly in follicular dendritic cells of the lymphoid system, suggesting a change in cell tropism for viral persistence.¹⁷³ Perivascular infiltrates in subacute and chronic distemper encephalitis consists of CD4+ and B cells. These cells result in a strong humoral immune response, and increased intrathecal virus-neutralizing antibodies are present.^{109,172} Antimyelin antibodies are thought to be a secondary reaction to the inflammatory process. Antibodies to CDV appear to interact with infected macrophages in CNS lesions, causing their activation with the release of reactive oxygen radicals. This activity can lead to destruction of oligodendroglial cells and myelin through an “innocent bystander” mechanism.^{29,33} The reaction of the immune system, not viral interference, is the pathogenic mechanism for demyelination in this phase.

In surviving animals, CDV is cleared from the inflammatory lesions but can persist in brain tissue in unaffected sites.¹¹² If the spread through the CNS has been extensive by the time the host responds to the virus, widespread damage occurs. Some unaffected areas of virally infected brain tissue are spared the inflammatory process and immune recognition, presumably because of noncytolytic infections.^{164,177,181} Reduced expression of CDV proteins on the surface of inflammatory cells has also been implicated as a means of immune avoidance.^{5,6,112}

Old dog encephalitis (ODE) is a rare, chronic, active progressive inflammatory disease of the gray matter of the cerebral hemispheres and brainstem of the CNS, which may result from neural persistence of virus after acute CDV infection. This form of infection occurs in infected animals that are immunocompetent and have virus

Infectious Diseases of the Dog and Cat, 3rd Edition

persisting in their nervous tissue. ODE is a unique variant of CDV-CNS infection in which persistent virus exists strictly in neurons in a replication-defective form.¹⁵ Transmission of infection using brain homogenates of dogs with ODE was unsuccessful; however, reisolation of infectious virus required prolonged cocultivation of brain explant cells with susceptible Vero cells.¹⁵ Similar observations have been made with persistent measles virus in humans with subacute sclerosing panencephalitis.

Inclusion body polioencephalitis is a variant form of encephalitis with lesions and pathogenesis similar to ODE. It can occur after vaccination¹¹⁶ or in dogs with a sudden onset of only neurologic manifestations of distemper.¹¹⁷ Multifocal gray matter necrosis, perivascular lymphocytic inflammation, and cytoplasmic and intranuclear inclusions are observed. The immune response is dominated by T-cell infiltration and class II MHC up-regulation. Abundant expression of all viral protein mRNAs and reduced or lacking protein expression, especially of matrix and fusion proteins, are evident. Low viral protein antigen levels may be a means by which CDV persists by evading immune recognition.

3.4 CLINICAL FINDINGS

3.4.1 Systemic Signs

Clinical signs of canine distemper vary depending on virulence of the virus strain, environmental conditions, and host age and immune status. More than 50% of CDV infections are probably subclinical. Mild forms of clinical illness are also common, and signs include listlessness, decreased appetite, fever, and upper respiratory tract infection. Bilateral serous oculonasal discharge can become mucopurulent with coughing and dyspnea. Many mildly infected dogs develop clinical signs that are indistinguishable from those of other causes of “kennel cough” (see [Chapter 6](#)). Keratoconjunctivitis sicca may develop after systemic or subclinical infections in dogs. Persistent anosmia was reported as a sequela in dogs that had recovered from canine distemper.⁶⁶

Severe generalized distemper is the commonly recognized form of the disease. It can occur in dogs of any age, but it most commonly affects unvaccinated, exposed puppies 12 to 16 weeks of age that have lost their maternal immunity or younger puppies that have received inadequate concentrations of maternal antibody. The initial febrile response in natural infections is probably unnoticed. The first sign of infection is a mild, serous-to-mucopurulent conjunctivitis, which is followed within a few days by a dry cough that rapidly becomes moist and productive. Increased lower respiratory sounds from the thorax can be heard on auscultation. Depression and anorexia are followed by vomiting, which is commonly unrelated to eating. Diarrhea subsequently develops, varying in consistency from fluid to frank blood and mucus. Tenesmus can be present, and intussusceptions may occur. Severe dehydration and emaciation can result from adipsia and fluid loss. Animals can die suddenly from systemic illness, but adequate therapy can decrease the risk in many cases.

3.4.2 Skin Lesions

Vesicular and pustular dermatitis in puppies is rarely associated with CNS disease ([Fig. 3-3](#)), whereas dogs developing nasal and digital hyperkeratosis usually have various neurologic complications ([Figs. 3-4 and 3-5](#)).
Viral invasion of these tissues has been demonstrated.⁹⁷ Lesions consist of hyperkeratosis and parakeratosis with vesicles and pustule formation.¹²³ Virus has entered the footpad keratinocytes as it causes the observed hyperkeratosis; however, neither the virus nor its nucleic acid appear to persist indefinitely.^{68,70}

Fig 3-3 Pustular dermatitis in a puppy with canine distemper. Rarely associated with neurologic complications, this is usually a favorable prognostic sign. (Courtesy University of Georgia, Athens, Ga.)

3.4.3 Neurologic Signs

Neurologic manifestations usually begin 1 to 3 weeks after recovery from systemic illness; however, no way is known to predict which dogs will develop neurologic disorders. Neurologic signs can also coincide with multisystemic illness or less commonly, they can occur weeks to months later. Neurologic signs frequently develop in the presence of nonexistent or very mild extraneural signs.¹⁵⁸ Empirically, certain features of systemic disease can be predictive of the incidence of neurologic sequelae. Mature or partially immune dogs that have been previously vaccinated and have no history of systemic disease can suddenly develop neurologic signs.¹²⁹ Neurologic signs, whether acute or chronic, are typically progressive. Chronic relapsing neurologic deterioration with an intermittent recovery and a later, superimposed acute episode of neurologic dysfunction can occur. ODE is characterized by this type of progressive history.

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 3-4 Nasal hyperkeratosis in a dog with systemic distemper. (Courtesy University of Georgia, Athens, Ga.)

Fig 3-5 Digital hyperkeratosis (“hard pads”) in a dog dying of distemper encephalomyelitis. (Courtesy University of Georgia, Athens, Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Neurologic complications of canine distemper are the most significant factors affecting prognosis and recovery from infection. Neurologic signs vary according to the area of the CNS involved. Hyperesthesia and cervical or paraspinal rigidity can be found in some dogs as a result of meningeal inflammation, although parenchymal rather than meningeal signs usually predominate. Seizures, cerebellar and vestibular signs, paraparesis or tetraparesis with sensory ataxia, and myoclonus are common. Seizures can be of any type, depending on the region of the forebrain that is damaged by the virus. The “chewing-gum” type of seizures, classically associated with CDV infection, often occurs in dogs developing polioencephalomalacia of the temporal lobes. However, lesions in these lobes from other causes can produce similar seizures.

Myoclonus, the involuntary twitching of muscles in a forceful simultaneous contraction, can be present without other neurologic signs. With more extensive spinal cord damage, the dog may have upper motor neuron paresis of the affected limb associated with myoclonus. The rhythmic contractions can be present while the dog is awake, although they more commonly occur while it is sleeping. The neural mechanisms for myoclonus originate with local irritation of the lower motor neurons of the spinal cord or cranial nerve nuclei. Although considered specific for CDV infection, myoclonus can also be seen in other paramyxovirus infections of dogs and cats (see [Chapters 7](#) and [18](#)) and less commonly, in other inflammatory conditions of the CNS.¹⁵⁵

3.4.4 Transplacental Infection

Young puppies infected transplacentally may develop neurologic signs during the first 4 to 6 weeks of life.⁹² Mild or inapparent infections are seen in the bitch. Depending on the stage of gestation at which infection occurred, abortions, stillbirths, or the births of weak puppies may occur. Puppies infected in utero that survive such infections may suffer from permanent immunodeficiencies because of damage to primordial lymphoid elements.

3.4.5 Neonatal Infections

Young puppies infected with CDV before the eruption of permanent dentition may have severe damage to the enamel, dentin, or roots of their teeth.²³ The puppies may have enamel or dentin with an irregular appearance ([Fig. 3-6](#)), in addition to partial eruption, oligodontia, or impaction of teeth. Enamel hypoplasia with or without neurologic signs may be an incidental finding in an older dog and is relatively pathognomonic for prior infection with CDV.

Neonatal (<7 days old) gnotobiotic puppies have developed virus-induced cardiomyopathy after experimental infection with CDV. Clinical signs including dyspnea, depression, anorexia, collapse, and prostration develop from 14 to 18 days postinfection. Lesions are characterized by multifocal myocardial degeneration, necrosis, and mineralization, with minimal inflammatory cell infiltration. The clinical significance of this process after natural infection is uncertain, and whether it has a relationship with onset of adult cardiomyopathy in dogs remains to be determined. Other viruses such as CPV-1 and CPV-2 can produce similar lesions (see Canine Enteric Viral Infections, [Chapter 8](#)).

37

Fig 3-6 Enamel hypoplasia characterized by irregularities in the dental surface in an older dog that survived neonatal distemper. (Courtesy University of Georgia, Athens, Ga.)

3.4.6 Bone Lesions

Young, growing dogs with experimentally and naturally induced CDV infection develop metaphyseal osteosclerosis of the long bones.^{2,19,51,96,104} Large-breed dogs between 3 and 6 months of age are most commonly affected. Studies have not shown animals with systemic distemper to develop overt clinical signs related to these long bone lesions. However, CDV RNA transcripts have been seen in the bone cells of young dogs with hypertrophic osteodystrophy (HOD), a metaphyseal bone disease which can be similar to and confused with metaphyseal osteomyelitis (see Musculoskeletal Infections, [Chapter 86](#)).^{106,108} Juvenile cellulitis, HOD, or both have developed in some puppies in association with MLV distemper vaccination (see [Chapter 100](#) and Modified-Live Virus Vaccines in this chapter).¹⁰⁰ Morbilliviral RNA transcripts have also been detected in the bony lesions of people with Paget's disease (see Public Health Considerations in this chapter).

3.4.7 Rheumatoid Arthritis

Dogs with rheumatoid arthritis had high levels of antibodies to CDV in sera and synovial fluid compared with dogs with inflammatory and degenerative arthritis.²¹ CDV antigens were found in immune complexes from synovial fluid of dogs with rheumatoid arthritis but were not found in synovial fluid from dogs with inflammatory or degenerative arthropathies.

3.4.8 Ocular Signs

Dogs with CDV encephalomyelitis often have a mild anterior uveitis that is clinically asymptomatic. More obvious ophthalmologic lesions in canine distemper have been attributed to an effect of the virus on the optic nerve and the retina (see Canine Distemper, [Chapter 93](#)). Optic neuritis can be characterized by a sudden onset of blindness, with dilated unresponsive pupils. Degeneration and necrosis of the retina produce gray-to-pink

Infectious Diseases of the Dog and Cat, 3rd Edition

irregular densities on the tapetal or nontapetal fundus or both. Bullous or complete retinal detachment can occur where exudates dissect between the retina and choroid. Chronic, inactive fundic lesions are associated with retinal atrophy and scarring. These circumscribed, hyperreflective areas are called *gold medallion lesions* and are considered characteristic of previous canine distemper infection.

3.4.9

Combined Infections

Immunosuppression caused by or responsible for systemic CDV infection can be associated with combined opportunistic infections. Salmonellosis has been a common complication, causing protracted or fatal hemorrhagic diarrhea or sepsis in affected dogs. Combined infections with *Toxoplasma gondii* or *Neospora caninum* have produced lower motor neuron dysfunction from myositis and radiculoneuritis (see [Chapter 80](#)). *Pneumocystis carinii* pneumonia has also been associated with CDV infection (see [Chapter 68](#)).¹⁵¹

3.5

DIAGNOSIS

Practical diagnosis of canine distemper is primarily based on clinical suspicion. A characteristic history of a 3- to 6-month-old unvaccinated puppy with a compatible illness supports the diagnosis. Most dogs with severe disease have clinical signs distinctive enough to make a presumptive diagnosis, but upper respiratory infections in older dogs are often incorrectly diagnosed as infectious tracheobronchitis (see [Chapter 6](#)). Specific laboratory tests are not always available to confirm the suspicion of CDV infections, so the practicing veterinarian must rely on nonspecific findings of routine laboratory procedures.

Infectious Diseases of the Dog and Cat, 3rd Edition

3.5.1 Clinical Laboratory Findings

Abnormal hematologic findings include an absolute lymphopenia caused by lymphoid depletion. This frequently persists in very young dogs with rapidly progressive systemic or neurologic signs. Thrombocytopenia (as low as 30,000 cells/ μ l) and regenerative anemia have been found in experimentally infected neonates (<3 weeks) but have not been consistently recognized in older or spontaneously infected dogs. Distemper inclusions can be detected in the early phase of disease by examination of stained peripheral blood films, in low numbers in circulating lymphocytes, and with even less frequency in monocytes, neutrophils, and erythrocytes.

Wright-Leishman-stained inclusions in lymphocytes are large (up to 3 μ m), single, oval, gray structures, whereas erythrocytic inclusions (which are most numerous in polychromatophilic cells) are round and eccentrically placed and appear light blue (Fig. 3-7). The sizes of erythrocytic inclusions are between those of metarubricyte nuclei and Howell-Jolly bodies. Buffy coat and bone marrow examination and use of phloxinophilic stains can improve the chances of detecting inclusions. EM has confirmed that these inclusions consist of paramyxovirus-like nucleocapsids.

32

33

The magnitude and type of serum biochemistry changes in acute systemic infections are nonspecific. Total protein analysis includes decreased albumin and increased α - and γ -globulin concentrations in nonneonates. Some puppies infected prenatally or neonatally with CDV have marked hypoglobulinemia from persistent immunosuppression caused by the virus.

3.5.2 Radiology

Thoracic radiography demonstrates an interstitial lung pattern in early cases of distemper. An alveolar pattern is seen with secondary bacterial infection and more severe bronchopneumonia (Fig. 3-8).

3.5.3 Cerebrospinal Fluid Analysis

Abnormalities are detectable in dogs with neurologic signs of distemper; however, false-negative results can be anticipated. Dogs with acute noninflammatory demyelinating encephalomyelitis may have normal CSF analysis results. Increases in protein (>25 mg/dl) and cell count (>10 cells/ μ l with a predominance of lymphocytes) are characteristic of subacute to more chronic, inflammatory forms of CDV encephalomyelitis. Intracytoplasmic inclusions may be found in CSF cells.¹ When increased protein is present in CSF, it is primarily IgG with specific anti-CDV activity. IFN levels are also increased in the CSF of dogs with acute and chronic distemper encephalitis.¹⁶⁰ Differences in the humoral immune response in CSF and sera to the H and F envelope proteins (see Table 3-2) have been noted between some dogs with chronic progressive encephalitis and those with other forms of distemper encephalitis.¹³⁴

Increased anti-CDV antibody in CSF offers definitive evidence of distemper encephalitis because antibody is locally produced; these increases have not been found in vaccinated dogs or those with systemic distemper without CNS disease. CSF antibody may be increased from traumatic collection procedures causing contamination by whole blood. An antibody ratio can help identify the effect of nonspecific leakage of distemper-specific IgG into the CSF from serum. Divide the concentration of distemper-specific IgG in CSF by that of IgG in serum. Compare the result with a corresponding CSF-serum antibody ratio for another infectious agent for which serum antibody titers are expected, such as canine adenovirus (CAV) or canine parvovirus (CPV). If the ratio for CDV is higher than that for CAV or CPV, then de novo local production of CSF antibody caused by CNS infection with distemper is expected. Ideally the titer determination for both diseases should use

Infectious Diseases of the Dog and Cat, 3rd Edition

the same methodology (e.g., neutralization, enzyme-linked immunosorbent assay [ELISA], indirect fluorescent antibody [FA]). Alternatives are to compare the CDV-specific CSF-serum ratio with the ratio of IgG or albumin in CSF and serum,¹⁵⁷ but this approach is less accurate because of the differences in methodology used in their determinations. The CSF IgG antibody concentration is more likely to be increased in dogs with inflammatory demyelinating encephalitis than in younger or immunosuppressed dogs with acute polioencephalitis and noninflammatory virus-induced cellular injury.^{145,158} Although the test for CSF antibodies is sensitive and specific for CDV, it can be performed only by properly equipped diagnostic or research laboratory personnel (see [Appendix 5](#)). In acute CNS infections, some mononuclear cells may contain large (15 to 10 μm), oval homogenous eosinophilic intracytoplasmic inclusions.⁸

3.5.4

Immunocytology

Immunofluorescent techniques can facilitate a specific diagnosis of canine distemper; however, these tests also require special equipment and are usually handled by regional diagnostic laboratories. In clinically affected dogs, immunofluorescence is usually performed on cytologic smears prepared from conjunctival, tonsillar, genital, and respiratory epithelium. The technique also can be performed on cells in CSF, blood (buffy coat), urine sediment, and bone marrow ([Fig. 3-9](#)). Smears should be made on precleaned slides, air-dried thoroughly, and preferably fixed in acetone for 5 minutes before transport to the laboratory. At the laboratory, they are stained directly or indirectly with fluorescein-conjugated CDV antibody and examined by fluorescent microscopy.

Infectious Diseases of the Dog and Cat, 3rd Edition

Antigen, first detected in buffy coat smears from 2 to 5 days postinfection decreases as antibody titer increases by 8 to 9 days postinfection. Clinical signs become apparent shortly after this time (day 14), and positive results are not recognized except in dogs that do not mount a sufficient immune response and succumb to infection. Positive fluorescence in conjunctival and genital epithelium is usually detected only within the first 3 weeks postinfection, when systemic illness is apparent. Virus also disappears in these tissues after the first 1 to 2 weeks of clinical illness (21 to 28 days postinfection) as antibody titers rise in association with clinical recovery. Beginning with the recovery stage, antibody may bind and mask antigen in infected cells, resulting in false-negative results. Virus may be detected for longer periods in epithelial cells and macrophages from the lower respiratory tract, and transtracheal washings can be obtained for diagnosis. Virus also persists for at least 60 days in the skin, uveal tissue, footpad, and CNS. Direct FA examination of cells in conjunctival scrapings, CSF, or blood films is helpful in acute phases of illness. In chronic cases, it is usually unrewarding because antibody coating or elimination of viral antigen yields negative results with diagnostic immunofluorescence. ELISA has been used to detect viral antigen in serum and CSF of naturally and experimentally infected dogs.^{60,82,144} A test based on this methodology would be extremely valuable to the practitioner. In one study, MLV vaccination produced a false-positive result in testing for serum antigen.¹⁴⁴ Viral antigen detected by FA or ELISA is difficult to find in body fluid specimens from dogs with neurologic distemper that lack or have recovered from systemic signs. More sensitive tests such as the polymerase chain reaction (PCR) might be more valuable in such instances.

Fig 3-9 Immunofluorescence confirming CDV in a buffy coat smear of a dog with acute distemper.

Infectious Diseases of the Dog and Cat, 3rd Edition

3.5.5 Immunohistochemistry

CDV antigen detected in the nasal mucosa, footpad epithelium, and haired skin of the dorsal neck has been used consistently for the antemortem diagnosis of infection.⁷² FA techniques can also be performed on frozen sections of biopsy or necropsy specimens. Tissues collected from dogs that died from distemper should include spleen, tonsils, lymph nodes, stomach, lung, duodenum, bladder, and brain. Animals dying of generalized infection frequently have abundant quantities of virus in these tissues. FA techniques can also be adapted to paraffin-embedded sections if special cold (4°C) ethanol (95%) fixation is used. Footpad biopsy has been recommended as an antemortem diagnostic technique (Fig. 3-10).

Other immunochemical techniques have been developed for histologic detection of distemper antigen in formalin-fixed and paraffin-embedded tissues and cell culture.^{20,59} Immunohistochemical demonstration of CDV antigen is superior to reliance on inclusion bodies in brain tissue to confirm distemper encephalitis (Fig. 3-11).¹²⁴ Results are more likely to be positive in acute than chronic infections in which viral antigens may not be expressed. Monoclonal antibodies are available to detect CDV by immunohistochemical methods (VMRD Inc., Pullman, Wash.).

Fig 3-10 Immunofluorescence confirming CDV in a footpad biopsy of an infected dog.

3.5.6 Nucleic Acid Detection

Reverse transcription has been used to detect CDV RNA in buffy coat cells from dogs with acute CDV infection¹⁶⁷ and the serum, whole blood, and CSF from dogs with systemic or neurologic distemper.⁵³ Regardless of the duration and form of distemper, a positive result was highly specific for diagnosis. This test is very valuable for premortem diagnosis; however, it is not widely available. As with FA methods, viral mRNA

Infectious Diseases of the Dog and Cat, 3rd Edition

was detected in footpad specimens from infected dogs.^{68,70} Similarly, PCR and nucleic acid hybridization studies using single-stranded RNA probes have been performed to detect virulent virus in tissue culture and histologic sections.¹⁷⁸ Seminested PCR was also efficient in detecting CDV in paraffin-embedded nervous tissue.¹⁴⁸ In general, a positive PCR result is indicative of infection, whereas a negative one can result from many factors including improper sample handling. During an outbreak of distemper in Alaska, PCR was used to detect the infection and trace the origin of the responsible strain to Siberia.⁹⁹

3.5.7

Serum Antibody Testing

The neutralization test is still considered the gold standard for measuring protection against infection, and serum titers correlate well with the level of protection.¹² Neutralizing antibodies are directed against the membrane proteins (H and F) of the virus, appear beginning 10 to 20 days postinfection, and may persist for the life of a recovered animal. A microneutralization method has further simplified neutralizing antibody testing in diagnostic

34

35

laboratories. A plaque-staining method has been shown to be more sensitive than the neutralization assay.¹⁴³ Indirect FA testing has also been used to measure postvaccination titers and gives results comparable to those of neutralization.¹⁶¹ Although sometimes less specific, whole-virus ELISA has been used to detect serum IgG and IgM antibodies to CDV. Increased specificity has been achieved using recombinant N protein-based ELISA in dogs.^{16,167} Antibody to N and P proteins may appear 6 to 8 days postinoculation when measured by ELISA. Increased titers of serum IgM-neutralizing antibody can be measured in dogs that survive the acute phase of infection and usually disappear by 3 months. High serum IgM titers have been more accurate in detecting acute clinical distemper cases (81%) compared with chronic progressive inflammatory encephalitis (60%). Transient IgM increases can also be seen for up to 3 weeks after first immunization with CDV vaccine. Unlike increases in serum IgM titers, high IgG titers are ambiguous and can indicate either past or present infection with CDV or past vaccination for CDV. Analyzing CSF-specific IgG levels and determining a CSF-serum ratio may be more reliable uses of antibody measurements in detecting chronic CDV infections of the nervous system (see Cerebrospinal Fluid Analysis in this chapter).

Fig 3-11 Immunocytochemical demonstration of CDV antigen within the cell body and processes of neurons.

3.5.8 Viral Isolation

Virulent CDV can be readily cultured in macrophages or activated lymphocytes, but it grows only with adaptation in epithelial or fibroblast cell lines. As a result, isolation of virulent CDV has been difficult in routine cell cultures. The most successful viral replication occurs during direct cultivation of target tissues from the infected host. Buffy coat specimens taken during the early course of illness provide the best opportunity. Alveolar macrophage cultures detect the virus in 24 to 48 hours. Giant cell (syncytia) formation, a characteristic cytopathic effect of CDV in many tissue cultures, is detected within 2 to 5 days, at which time the virus can be isolated by overlays made on other cells. Macrophage cultures have been replaced by dog lymphocyte cultures for isolation of CDV.¹⁰ Buffy coat cells or tissues from infected animals can be cultivated with mitogen-stimulated canine blood lymphocytes, and cultures are examined 72 to 144 hours later by immunofluorescence.¹⁰ A marmoset lymphoid cell line (B95a) has also been used.⁸⁶

Infectious Diseases of the Dog and Cat, 3rd Edition

Growth in pulmonary macrophages or lymphocytes was once considered an essential feature of virulent CDV isolates, although virulent CDV has occasionally been isolated in Vero cells or primary dog kidney and bladder epithelial cell cultures without the need for adaptation or loss of virulence of the virus. However, the success rate is low. In general, titers of vaccine viruses are high in macrophage, lymphocyte, kidney cell, and epithelial cell lines, whereas virulent field strains grow better in macrophages⁴⁸ and lymphocytes.¹⁰ Cultures can be examined with FA for virus when cytopathic effects are not observed. Because of defective viral replication, specimens from dogs with chronic or vaccine-induced encephalitis do not yield successful cultures.

3.6 PATHOLOGIC FINDINGS

Young dogs prenatally or neonatally infected with CDV have thymic atrophy. Pneumonia and catarrhal enteritis are present in infected puppies with systemic disease. Upper respiratory tract lesions include conjunctivitis, rhinitis, and inflammation of the tracheobronchial tree. Hyperkeratosis of the nose and footpads may be seen in dogs with neurologic disease. Gross lesions in the CNS are not often found except for occasional meningeal congestion, ventricular dilation, and increased CSF pressure resulting from brain edema in acute encephalitis. Necrosis and cavitation may develop in the white matter in chronic inflammatory lesions.

Lymphoid depletion is a typical histologic finding in a dog with systemic illness. Diffuse interstitial pneumonia is characterized by thickened alveolar septa and proliferation of alveolar epithelium. Alveoli contain desquamated epithelial cells and macrophages; transitional epithelium of the urinary system may contain cytoplasmic inclusions. Puppies developing distemper may have defects in dental enamel, and necrosis and cystic degeneration of ameloblastic epithelium are usually present. (See [Chapter 93](#) for a description of ophthalmic lesions.) Mild interstitial epididymitis and orchitis are commonly seen in dogs with canine distemper, an observation that may help explain the transient decrease in spermatogenesis, prostate fluid, and testosterone that occurs in recovering animals.

With acute fatal encephalitis of neonates, neuronal and myelin degeneration or primary demyelination can occur without significant perivascular inflammation ([Fig. 3-12](#)). In surviving animals, patchy areas of necrosis are replaced by hypertrophic astrocytes that form a network for macrophages ingesting myelin. The most severe white matter changes in the CNS can be found in the predilection sites of lateral cerebellar peduncles, the dorsolateral medulla adjacent to the fourth ventricle, and the deep cerebellar white matter. Lesions are also present in the midbrain, basal nuclei, and pyriform lobes of the cerebral cortex. Superficial areas such as the optic tracts, crus cerebri, central components of cranial nerve pathways, and infundibulum also can be affected. Noninflammatory polioencephalomyelitis in some dogs can predominantly affect the cerebrum and thalamus.¹⁵⁴ Acute noninflammatory lesions include demyelination with spongy vacuolation of white matter and reactive gliosis. Intracytoplasmic or intranuclear inclusions can be found predominantly in astrocytes and neurons.

Older or more immunocompetent dogs tend to develop leukoencephalomyelitis with a predominance of lesions in the caudal brainstem and spinal cord. These lesions are usually associated with signs of ataxia and vestibular involvement. Lesions are characterized by widespread perivascular lymphoplasmacytic infiltration with areas of demyelination and neuronal degeneration ([Fig. 3-13](#)). They can be more widespread and severe than lesions in dogs with acute encephalitis. In more chronic cases the lesion may develop into sclerosing panencephalitis characterized by infiltration and replacement of nervous tissue by a dense astrocytic network.

35

36

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 3-14 Postvaccinal form of CDV with numerous inclusion bodies in brainstem neurons.

In contrast, lesions of vaccine-induced distemper are typically those of a necrotizing polioencephalitis of the caudal brainstem with preference for the ventral pontine nuclei (see previous section Neurologic Signs in this chapter and Postvaccinal Complications in [Chapter 100](#)).^{163,169} Inclusions can be found in the nucleus or cytoplasm of astrocytes and neurons ([Fig. 3-14](#)).

Histologic examination reveals that CDV inclusions are most commonly cytoplasmic and acidophilic staining. They are 1 to 5 μm in diameter and can be found in epithelial cells of the mucous membranes, reticulum cells, leukocytes, glia, and neurons. Inclusions can be found up to 5 to 6 weeks postinfection in the lymphoid system and urinary tract. Intranuclear inclusions are most common in lining or glandular epithelium and ganglion cells.

The morphologic significance of distemper inclusions is not completely understood. Histochemically, they are composed of aggregates of viral nucleocapsids and cellular debris as a result of viral infection. Intranuclear inclusions contain viral nucleocapsid and heat shock protein.¹¹⁹ Caution must be used when absolutely confirming a diagnosis of canine distemper based solely on the presence of inclusions. Cytoplasmic inclusions typical for CDV infection have been identified in the urinary bladder of normal dogs. Unfortunately, inclusion bodies are not only nonspecific but also may appear too late in the disease to be routinely useful. In contrast, using only the presence of inclusion bodies to detect CDV infection can lead to a false-negative diagnosis in dogs, whereas immunocytochemical and in situ hybridization methods are more sensitive for CDV detection in tissues (see previous sections Immunohistochemistry and Nucleic Acid Detection).

Infectious Diseases of the Dog and Cat, 3rd Edition

Formation of giant cells primarily in CNS white matter and anterior uvea of the eye and secondarily in lymph nodes, lung, and leptomeninges is specific to paramyxoviruses such as CDV. This finding can be used to substantiate CDV infection.

3.7 THERAPY

Despite vast advances in research on canine distemper, only minor changes have been made in therapeutic recommendations. Although supportive and nonspecific, aims in treatment are frequently beneficial because they reduce mortality. The only reason for refusing to initiate treatment at an owner's insistence is the presence of neurologic signs that are incompatible with life. Even in the absence of neurologic signs, owners should always be warned that such sequelae may develop at a later time. The spontaneous improvement seen in many dogs with symptomatic management of nonneurologic systemic distemper can be inappropriately credited to the success of certain treatment regimens. However, unlike the systemic signs, neurologic signs themselves are not usually reversible unless they are caused by vaccine strains and frequently are progressive.

Dogs with upper respiratory infections should be kept in environments that are clean, warm, and free of drafts. Oculonasal discharges should be cleaned from the face. Pneumonia is frequently complicated by secondary bacterial infection, usually with *Bordetella bronchiseptica*, which requires broad-spectrum antibiotic therapy and expectorants or nebulization and coughage. Good initial antibiotic choices for bronchopneumonia include ampicillin, tetracycline, and chloramphenicol (Table 3-5). However, because of dental staining, tetracycline use must be avoided in puppies, and chloramphenicol is less desirable because of its public health risks. Newer parenteral florfenicol should be considered (see Drug Formulary, Appendix 8). Parenteral therapy is essential when GI signs are present. Antimicrobial therapy should be altered when indicated by susceptibility testing based on transtracheal washing or by lack of response to the initial antibiotics.

Food and water and oral medications or fluids should be discontinued if vomiting and diarrhea are present. Parenteral antiemetics may be required. Supplementation with polyionic isotonic fluids such as lactated Ringer's solution should be given intravenously (IV) or subcutaneously (SC), depending on the hydration status of the patient. B vitamins should be administered as nonspecific therapy to replace vitamins lost from anorexia and diuresis and to stimulate the appetite. Historically, IV administration of ascorbic acid has been beneficial; however, this treatment is controversial, and its effectiveness remains unproven. Controlled studies have documented a decrease in morbidity and mortality in children with measles who received two 200,000-IU (60-mg) doses of vitamin A within 5 days of the onset of systemic illness.⁷⁹ Although its effectiveness in treating distemper is unproven, a similar regimen could be tried for puppies with acute systemic infection.

36

37

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 3-5 Drug Therapy for Canine Distemper

DRUG ^a	DOSE ^b (mg/kg)	ROUTE	INTERVAL (HOURS)	DURATION (DAYS)
Antimicrobial				
Ampicillin, amoxicillin	20	PO, IV, SC	8	7
Doxycycline ^c	5–10	PO, IV	12	7
Chloramphenicol	15–25	PO, SC	8	7
Florfenicol	25–50	SC, IM	8	3–5
Cephapirin	10–30	IM, IV, SC	6–8	3–5
Anticonvulsive				
Phenobarbital	2	PO, IV, IM	12	prn
Antiinflammatory				
<i>Dexamethasone</i>				
CNS edema	1–2	IV	24	1
Optic neuritis ^d	0.1	PO, IV, SC	24	3–5

PO, By mouth; IV, intravenous; SC, subcutaneous; IM, intramuscular; prn, as needed; CNS, central nervous system.

- a See [Appendix 8](#), Drug Formulary, for more detailed information on these drugs.
- b Dose per administration at specified interval.
- c In dogs younger than 6 months of age, dental staining is less of a problem with doxycycline than with tetracycline.
- d Equivalent glucocorticoid dosage of prednisolone in mg/kg is 5 times this dose.

Therapy for neurologic disturbances in canine distemper is less rewarding. Progressive multifocal encephalitis usually leads to tetraplegia, semicoma, and incapacitation so great that euthanasia should be recommended. Despite ineffective therapy, dogs should not be euthanized unless the neurologic disturbances are progressive or incompatible with life. Variable or temporary success in halting neurologic signs in some dogs may result from a single anti-CNS edema dose (2.2 mg/kg IV) of dexamethasone. Subsequent maintenance therapy with antiinflammatory doses may be needed, and this treatment can be tapered with time.

Seizures, myoclonus, or optic neuritis are three neurologic manifestations in dogs that can be tolerated by many owners. Myoclonus is usually untreatable and irreversible; many forms of therapy have been attempted without success. Recommendations have been made to administer anticonvulsants after the onset of systemic disease but before the development of seizures. No evidence shows that anticonvulsants prevent entry of the virus into the CNS; however, they may suppress irritable foci from causing seizures, which may prevent seizure circuits from becoming established. Seizures are best treated with parenteral diazepam (5- to 10-mg dose rectally or slow IV) for status epilepticus and phenobarbital for maintenance prevention. Primidone or potassium bromide are alternative choices, and combinations or higher doses may be needed in refractory cases. Glucocorticoid therapy in antiinflammatory to anti-CNS edema dosages may have variable success in controlling the blindness or papillary dilation from optic neuritis or the other neurologic signs associated with vaccine-induced or chronic inflammatory forms of encephalitis.

3.8 PREVENTION

The following discussion describes features that are unique to CDV protection; see [Chapter 100](#) and [Appendix 1](#) for overall recommendations on vaccination for canine distemper. Immunity to natural CDV infection is considered long term, and lasting immunity and immunologic homogeneity of the virus have made disease prevention possible

Infectious Diseases of the Dog and Cat, 3rd Edition

through vaccination. Maternal antibody, received in utero and in colostrum from the dam, blocks adequate immunization in puppies for a period after birth and a period after weaning. Maternal antibody to CDV decreases with a half-life of 8.4 days. Three percent of antibody transfer for CDV occurs in utero, and 97% occurs in the colostrum, resulting in an initial titer in nursing newborn puppies that is usually equal to 77% of that in the bitch. A puppy that has not had colostrum is probably protected for at least 1 to 4 weeks. In nursing puppies, nomograms based on the bitch's titer can be used to determine when immunization should be done, although this is not routinely practical. Maternal antibodies are usually absent by 12 to 14 weeks of age. Vaccines for CDV are generally given every 3 to 4 weeks between 6 and 16 weeks of age in puppies that have received colostrum.

After recovery from natural infection or booster vaccination, immunity can persist for years. This protection may be adequate unless the dog is exposed to a highly virulent strain of virus or large quantities of virus or becomes stressed or immunocompromised. After a single distemper vaccination, naive puppies do not generally develop immunity that lasts at least 1 year. Therefore despite the lack of maternal antibody interference, at least two distemper vaccines should be given at 2- to 4-week intervals when first vaccinating colostrum-deprived neonates and in dogs older than 16 weeks. Similarly, and because older vaccinated dogs can still develop distemper, periodic boosters are recommended for this disease, despite the relatively long-lived immunity afforded by vaccination.

37

Humoral immune mechanisms do not totally explain resistance to CDV. Vaccination with attenuated virus appears to protect previously unvaccinated dogs when it is given IV at least 2 days before exposure to virulent distemper virus, as compared with at least 5 days with SC vaccination.³⁹ Because of allergic reactions that may develop, CAV-1 and leptospiral antigens should be avoided with IV vaccination. IV or intramuscular (IM) administration should be reserved to protect exposed, unvaccinated dogs. This rapid protection against distemper may be related to immune interference, IFN, or cell-mediated immune mechanisms. Despite a decrease in antibody titer, immunity to distemper after booster or anamnestic vaccination is known to last as long as 7 years, as demonstrated in somewhat isolated, virus-challenged dogs. The duration of protection is much greater than that predicted from antibody titer alone and demonstrates that challenge with virulent organisms is more meaningful than neutralizing antibody titer for predicting the duration of immunity. However, the neutralizing antibody titer is the best indicator of protection against infection.

38

3.8.1

Nonliving Antigen Vaccines

Inactivated canine distemper whole-virus vaccines do not produce sufficient immunity to prevent infection after challenge exposure (sterile immunity), but vaccinated dogs show an anamnestic immune response and less severe disease than unvaccinated controls. Inactivated vaccines are not available in the United States. They were discontinued when MLV vaccines became available. Inactivated or recombinant products produce shorter immunity that is often bolstered by natural exposure. With improved adjuvants, some animals such as exotic species may be given some protection without any associated risk. Inactivated or recombinant CDV vaccines are recommended in vaccine virus-susceptible wild or exotic species such as ferrets or red pandas. Whereas inactivated whole-virus vaccines have provided inconsistent protection, purified surface glycoproteins (F) of CDV (see [Table 3-2](#)) have been used to protect dogs against subsequent experimental challenge with virulent virus.^{118,149} Similarly, an inactivated subunit vaccine containing membrane F antigen and H glycoprotein modified into immune-stimulating complexes has been effective in protecting dogs from challenge by virulent virus.⁴⁴ Vaccination of puppies born to immune dams with a CAV-2 vector vaccine expressing the F antigen and H glycoprotein was effective against virulent CDV challenge.⁴⁹ A vaccine produced by expressing measles virus H protein in Vaccinia virus has been effective in producing neutralizing antibody and protecting dogs against challenge with virulent CDV.¹⁵³ Experimental vaccines of recombinant pox or canarypox viruses expressing genes for H proteins of measles or CDV have been tested in mice and dogs.^{39,168} A commercial recombinant

Infectious Diseases of the Dog and Cat, 3rd Edition

canarypox-based CDV vaccine is available for dogs (see [Chapter 100](#)).¹²⁵ A DNA plasmid vaccine containing genes for H and F proteins induced persistent humoral immune responses in mice and protected them against intracerebral challenge.¹⁴² Recombinant vaccines may fail when the interval of booster vaccinations extends beyond 1 year or the vaccines are being used to protect naive pups entering an endemic environment. Protection does not occur until 2 to 3 weeks after the second immunization.

3.8.2

Modified Live-Virus Vaccines

Vaccination with MLV vaccines offers superior protection against CDV infection. Vaccine-induced immunity is never as long lasting as the immune response that occurs after natural or experimental infection with virulent virus. However, despite changes in the H protein of wild-type CDV strains, it is unlikely that virulent CDV strains can break through solid MLV vaccine-induced immunity. Not all MLV distemper vaccines produce the same level of protection.¹³³ Often, increased potency of protection means higher vaccine virulence. Unfortunately the most potent vaccines have been associated with induced illness, especially in certain wild or immunocompromised domestic carnivores.

Use of MLV vaccines for distemper has led to questions concerning vaccine stability and safety. Efficacy and safety of MLV distemper vaccination in dogs with compromised immune systems are important considerations. Unlike virulent virus, MLV itself does not appear to suppress measurable cell-mediated immunity. However, when CDV has been combined with CAV-1 or CAV-2 antigens, significant suppression in lymphocyte transformation testing response occurred.^{67,127} The clinical significance of this suppression is self-limiting and mild.

MLV viruses have not reverted to virulence under natural conditions and do not spread to other dogs. However, reversion to virulence has been experimentally demonstrated in attenuated vaccine virus passed serially in dogs and ferrets or in pulmonary macrophages in tissue culture. Two major types of MLV distemper vaccines exist. The Onderstepoort strain was adapted to chicken embryos and chicken cells. This vaccine strain may produce lower measured levels of humoral immunity¹²¹ but no postvaccinal disease. The canine-cell-adapted Rockborn strain, grown in canine kidney cells, induces high titers of neutralizing antibody and longer term protection. The Snyder Hill strain is indistinguishable from the Rockborn strain. Unfortunately the Rockborn strain occasionally produces a postvaccinal encephalitis in dogs and more commonly in exotic carnivores. Red pandas (*Ailurus fulgens*), black footed ferrets (*Mustela nigripes*), European mink (*Mustela lutreola*), gray foxes (*Urocyon cinereoargenteus*), and African wild dogs (*Lyacon pictus*) are highly susceptible to vaccine-induced illness with MLV vaccines. However, vaccination with an MLV strain provided no untoward effects and good protection in African wild dogs, whereas inactivated vaccine failed to provide adequate immunity.¹⁶⁵ Postvaccinal distemper can be prevented in ferrets by using inactivated virus or recombinant vector vaccines rather than canine-cell-propagated vaccines. Domestic ferrets and lions are less susceptible to vaccine-induced illness and have been successfully vaccinated with MLV Onderstepoort strain vaccines.^{89,170}

Encephalitis has been reported in dogs after vaccination with MLV distemper vaccines^{41,98,116} (see Postvaccinal Encephalomyelitis, [Chapter 100](#)). The Rockborn strains have been the most common cause, although they generally provide very strong protection against the disease. Onderstepoort strain vaccines, which have been adapted to chick embryo or avian cell cultures vaccines, appear safer. The recombinant poxvirus-vectored vaccine is the safest.

Infectious Diseases of the Dog and Cat, 3rd Edition

MLV vaccination of dams in whelp or during the first few days postpartum has resulted in systemic infection, encephalitis, or both in their puppies.^{30,101} CDV vaccine-induced encephalomyelitis has been documented in 3-week-old puppies simultaneously infected with virulent canine parvovirus; however, similar findings were not reported in 11- to 15-week-old puppies.⁶⁶ CDV vaccine-induced disease is usually encephalitis, although immunosuppression or neonatal or prenatal infections can result in systemic manifestations. The neurologic signs typically begin 3 to 20 days^{41,42,169} after receiving an MLV canine distemper vaccine. The clinical signs vary but often consist of an acute onset of “chewing-gum” or generalized motor seizures, paraparesis, tetraparesis, and vestibular or sensory ataxia. The seizure form is often progressive and difficult to control with anticonvulsants. The ataxic form can be progressive but may improve in some dogs. Unlike naturally acquired infections from virulent virus, the neurologic signs of vaccine-induced illness may stabilize, improve, or disappear with time or antiinflammatory or supportive therapy. Lesions in the CNS may be multifocal and typically involve the gray matter or white matter but are usually most severe in the pontomedullary gray matter (see Pathologic Findings in this chapter). CSF findings are indistinguishable from those of virulent CDV infections. If it could be isolated, vaccine virus could be distinguished by the ease with which it propagates in tissue culture (see Viral Isolation in this chapter) or by genetic analysis of very minor differences of the N gene (see [Table 3-2](#)) that have been detected.^{98,178} Vaccine virus replication is incomplete in that viral protein mRNAs are expressed, but protein translation is reduced or absent.¹¹⁶ This makes culture of virus or demonstration by routine histochemistry difficult.

38

39

HOD and juvenile cellulitis has also been associated with distemper vaccination in young, growing dogs (see Vaccine-Associated Hypertrophic Osteodystrophy and Juvenile Cellulitis, [Chapter 100](#)).^{2,76,96,104} Signs usually develop within 10 days of MLV vaccination, but the range has been from 4 days to 3 weeks. All MLV vaccine strains have been associated with this phenomenon. Lesions typical of HOD are detected in the metaphyseal regions of many long bones and sometimes the pharynges ([Fig. 3-15](#)). These lesions must be differentiated from metaphyseal osteomyelitis caused by systemic bacteremia in young puppies (see Hematogenous Osteomyelitis, [Chapter 86](#)). Weimaraners are the most frequently affected breed, probably because of an immunodeficiency (see Immunodeficiency in Weimaraners, [Chapter 95](#)), and some dogs have an associated hypoglobulinemia.² Additional laboratory abnormalities include increased activity of serum alkaline phosphatase and neutrophilic leukocytosis. Many dogs have systemic signs including an increased rectal temperature, anorexia, a reluctance to walk, and limb hyperesthesia, especially on palpation of the long bones. In some dogs, especially Weimaraners, multisystemic signs of GI, respiratory, or neurologic disease have been reported.² Treatment with restricted activity and nonsteroidal analgesics generally offers temporary or no improvement, and antiinflammatory to immunosuppressive doses of glucocorticoids are often needed for up to 1 week. Dogs that are not treated early may have an extended course of recovery or develop relapses after treatment is discontinued; treatment must be extended for 4 to 6 weeks in these animals. Use of recombinant distemper vaccine in young Weimaraners is suggested, especially if a familial tendency for this syndrome exists. Subsequent vaccination with MLV vaccines after growth is complete does not cause problems in previously affected dogs.

Fig 3-15 Forelimb radiographs from a dog with vaccine-associated HOD. Periosteal reaction can be noted at arrows. (Courtesy University of Georgia, Athens, Ga.)

3.8.3 Measles Vaccines

CDV and human measles virus are antigenically related, and experimental infection of dogs with measles virus protected the dogs from subsequent infection with CDV. Distemper virus antibody titers are minimally elevated after measles vaccination despite the adequate protection provided. Cell-mediated immunity and other factors are thought to be the primary elements involved in the protective response. Measles vaccine virus produces a self-limiting, noncontagious infection in the lymphoid system of dogs, an infection similar to that of MLV-CDV vaccines. Danger of reversion to virulence is likely minimal, as is the danger to humans, when proper

Infectious Diseases of the Dog and Cat, 3rd Edition

vaccination procedures are followed. Only measles vaccines licensed for use in dogs (not human products) should be administered by veterinarians. Higher antigen mass in canine products is required because of the heterologous nature of the product.

Theoretically, measles vaccination protects young puppies that have high concentrations of maternal antibodies to distemper. It should only be used as a replacement for the first vaccination in 6- to 12-week-old puppies. Dogs younger than 6 weeks with very high maternal antibody concentrations (serum-neutralizing antibody titer > 1:300) do not respond well to either distemper or measles vaccination. If female puppies are vaccinated with measles vaccine after 12 weeks of age, they will passively transfer measles antibody to their offspring, especially if they are bred during the first heat cycle.

Immunity to distemper acquired from measles vaccination is not only transient but also weaker than that derived from successful vaccination with MLV distemper vaccine. Sterile immunity is not produced after challenge with virulent CDV. SC inoculation of measles vaccine is not as effective as the initially recommended IM route. However, puppies older than 6 weeks immunized with measles virus vaccine are protected within 72 hours of challenge with CDV, despite the lack of increase in distemper virus antibody titer.³⁸ During an initial vaccination series, measles vaccination alone or in combination with distemper vaccination should be followed by at least two distemper vaccinations to produce adequate long-term immunity of at least 12 months.

3.8.4

Vaccine Failures

Viability of MLV canine distemper vaccines is an important factor in vaccination failures. Lyophilized tissue culture vaccines are stable for 16 months under refrigeration (0°C to 4°C), 7 weeks at 20°C, and 7 days when exposed to sunlight at 47°C. When reconstituted, tissue culture virus remains stable for 3 days at 4°C and 24 hours at 20°C. Vaccine should be used immediately once it is reconstituted for injection, or it should be refrigerated if the delay until usage will be longer than 1 hour.

39

40

Adverse environmental influences can affect the response to distemper vaccination in dogs. High humidity (85% to 90%) and high temperatures that cause dogs to have rectal temperatures averaging 39.8°C (103.6°F) reduce the immune response after distemper vaccination.⁶⁶

Dogs that received anesthesia (barbiturate induction with halothane maintenance) and underwent surgery were studied for their response to distemper vaccination.⁶⁶ The humoral antibody response to vaccination had no demonstrable impairment, although challenge studies were not performed. Some depression of the peripheral blood lymphocyte response to phytohemagglutinin did occur.

Glucocorticoid therapy given at immunosuppressive doses for 3 weeks did not suppress the normal humoral response to distemper vaccine, although treated dogs developed depressed responses to phytohemagglutinin stimulation of lymphocytes.⁶⁶ These dogs also survived subsequent challenge with virulent CDV.

Concurrent parvoviral infection has been suspected of reducing the antibody response of dogs vaccinated against canine distemper. Simultaneous vaccination against parvoviral infection was suspected of inhibiting dogs' response to vaccination against CDV infection, although adequate control data were lacking; this finding has not been substantiated in older dogs.⁶⁶ (See [Chapters 8](#) and [100](#) for an additional discussion of canine parvovirus-induced immunologic interference with CDV vaccination.)

Antigenic drift of wild-type CDV strains might cause distemper outbreaks in domestic dog and wild animal populations. Serologic studies of H protein antigens have confirmed recognizable differences in epitopes, as

Infectious Diseases of the Dog and Cat, 3rd Edition

expected from genetic analyses.⁷⁵ Because heterotypic vaccination with measles and rinderpest virus offers at least partial protection, it is unlikely that currently available CDV vaccines are ineffective. Unfortunately the current vaccination programs, low vaccination rates, use of less virulent or nonliving vaccines, lapses in booster frequency, and presence of largely unvaccinated, highly susceptible feral or wild canids or other carnivores may contribute to the outbreaks that have been reported. Outbreaks in Europe have been related to reduced population immunity caused by lapses in booster vaccination with concurrent use of chick-embryo–adapted CDV vaccine that produced less immunity than vaccines adapted to canine cell cultures.⁴⁷ Outbreaks have occurred in animal shelters where dogs were not vaccinated with an MLV vaccine immediately on entry before being exposed to an endemically infected population of animals.

The broad host range of potential reservoirs makes eradication of this disease difficult. Several measures can be instituted to help control the disease in carnivores. First, every attempt should be made to achieve the highest vaccination rate possible in domestic dogs, especially in areas where they cohabitate or live near feral or wild animal populations. The most potent vaccines that can be tolerated without producing vaccine-induced illness should be used. Use of recombinant products must be considered for exotic carnivores with a high susceptibility to vaccine strains. Unfortunately the shorter duration of immunity of these products necessitates more consistent booster administration and likely chemical restraint. Perhaps after being exposed to products of lesser or no virulence, these animals might better tolerate vaccination with some of the more virulent products. Research is needed to substantiate this possibility. Because of the emerging host range of CDV, exposure to a vaccine strain may be preferred to an epidemic from virulent wild virus. Vaccination of captive and free-ranging wild carnivores should be seriously considered.

3.8.5

Serum Antibody Monitoring and Duration of Immunity

Immunity to MLV canine distemper vaccines is longer than 1 year, despite vaccine label recommendations that annual vaccination of dogs be performed. The American Veterinary Medical Association and American Animal Hospital Association recommendations are for 3-year intervals after the initial series and a 1-year later booster. The clinician decides whether to provide more frequent vaccination based on the animal and environmental considerations. Serum-neutralizing antibody titers are most accurate for withstanding infection, and a serum-neutralizing antibody titer of 1:100 or greater is considered protective when the dog has received maternal antibodies. A serum-neutralizing antibody titer of 1:20 is considered protective when measuring a vaccination response. ELISA-based test kits for use in the clinic are available to determine this response (see [Appendix 6](#)). In a study of dogs brought to a veterinary hospital for vaccination, titers decreased with older age and number of years since boosters had been given (see Immunoprophylaxis in [Chapter 100](#)).¹⁰² Overall, 25% of all dogs examined required a booster based on marginal titer values; 17% that had received a booster in fewer than 400 days, 24% of those that had received one in 461 to 476 days, and 44% of those receiving one in 787 to 1665 days required boosters.¹⁰² Dogs with prior mean vaccination intervals of 5 years show lower antibody titers.¹²⁰

3.8.6

Environmental Control

CDV is extremely susceptible to common disinfectants. Infected animals are the primary source of the virus, so they should be segregated from other healthy dogs. Dogs usually shed the virus in secretions for 1 to 2 weeks after the acute systemic illness. Those recovering from systemic illness or that are developing later neurologic signs (without systemic disease) may still be shedding some virus.

Infectious Diseases of the Dog and Cat, 3rd Edition

3.9 PUBLIC HEALTH CONSIDERATIONS

Multiple sclerosis (MS) is a neurologic affliction of humans that is similar to subacute sclerosing panencephalitis (SSPE), an encephalitis of humans thought to be caused by a chronic infection with defective or latent measles virus, and chronic progressive distemper encephalitis in dogs. SSPE and chronic progressive distemper encephalitis have similar pathologic findings, with demyelination, glial proliferation, and other findings characteristics of a chronic, persistent nonsuppurative encephalitis. The cause of MS is still uncertain, but no substantial evidence for human measles virus or CDV involvement exists.⁷⁷ The evidence for the role of CDV is indirect, and examination of the case control data for reported associations reveals that the existing evidence is weak.⁷⁷ Human measles and paramyxovirus are still likely candidates for MS involvement, and herpesviruses have also been implicated.¹³⁷ Furthermore, the incidence of MS has not decreased since before 1960, despite the widespread reduction of measles and distemper through effective vaccines.

Some have suggested that Paget's disease, an inflammatory bone disorder in humans, might be related to CDV acquired from exposure to dogs. Paget's disease is a chronic disease that leads to progressive destruction, remodeling, and deformity of bone. Evidence shows that the disease may be caused by chronic paramyxovirus infection of osteoclasts. Nuclei and cytosol of pagetic osteoclasts contain viral-like inclusions. Erythroid and osteoclast cells from patients with Paget's disease express paramyxoviral mRNA.¹³⁰ Using in situ hybridization, CDV genetic sequences have been found in the bone of 63.5% of untreated humans with Paget's disease.^{37,63,64,65} 40
In a study using in situ hybridization, CDV RNA was detected in 100% of lesions from pagetic patients but in none of the control specimens, including uninvolved sites of pagetic patients, normal bone, and active remodeling bone.¹⁰⁵ 41
Owning a dog was found to be highly correlated with Paget's disease, but this indirect relationship should not be overstated because a similar correlation was found between Paget's disease and ownership of cats and birds. Other studies have implicated other paramyxoviruses such as measles virus variants.^{131,132,136,141} Until such viruses are isolated and completely sequenced, CDV's role if any in such infections is questionable.

4 CHAPTER 4 Infectious Canine Hepatitis and Canine Acidophil Cell Hepatitis

Craig E. Greene

4.1 INFECTIOUS CANINE HEPATITIS

4.1.1 Etiology

Infectious canine hepatitis (ICH), caused by canine adenovirus (CAV)-1, has worldwide serologic homogeneity, as well as immunologic similarities to human adenoviruses. It is antigenically and genetically distinct from CAV-2, which produces respiratory disease in the dog (see Etiology and Pathogenesis, [Chapter 6](#)). Genetic variants of CAV-2 have been isolated from the intestine of a puppy with hemorrhagic diarrhea and from kennel dogs with diarrhea. Human adenoviruses have been used as vectors for recombinant vaccine testing in dogs.¹⁶

As with other adenoviruses, CAV-1 is resistant to environmental inactivation, surviving disinfection with various chemicals such as chloroform, ether, acid, and formalin and is stable when exposed to certain frequencies of ultraviolet radiation. CAV-1 survives for days at room temperature on soiled fomites and remains viable for months at temperatures below 4° C. CAV-1 is inactivated after 5 minutes at 50° to 60° C, which makes steam cleaning a plausible means of disinfection. Chemical disinfection has also been successful when iodine, phenol, and sodium hydroxide are used.

CAV-1 causes clinical disease in dogs, coyotes, foxes, and other Canidae and in Ursidae (bears). The high incidence of naturally occurring neutralizing antibodies in the unvaccinated feral and wildlife dog population suggests that subclinical infection is widespread.^{5,7} CAV-1 has been isolated from all body tissues and secretions of dogs during the acute stages of the disease. By 10 to 14 days postinfection (PI), the virus can be found only in the kidneys and is excreted in the urine for at least 6 to 9 months. Aerosol transmission of the virus via the urine is unlikely insofar as susceptible dogs housed 6 inches apart from virus shedders do not become infected. Viral spread can occur by contact with fomites, including feeding utensils and hands. Ectoparasites can harbor CAV-1 and may be involved in the natural transmission of the disease.

4.1.2 Pathogenesis

After natural oronasal exposure, the virus initially localizes in the tonsils ([Fig. 4-1](#)) where it spreads to regional lymph nodes and lymphatics before reaching the blood through the thoracic duct. Viremia, which lasts 4 to 8 days PI, results in rapid dissemination of the virus to other tissues and body secretions, including saliva, urine, and feces. Hepatic parenchymal cells and vascular endothelial cells of many tissues are prime targets of viral localization and injury.

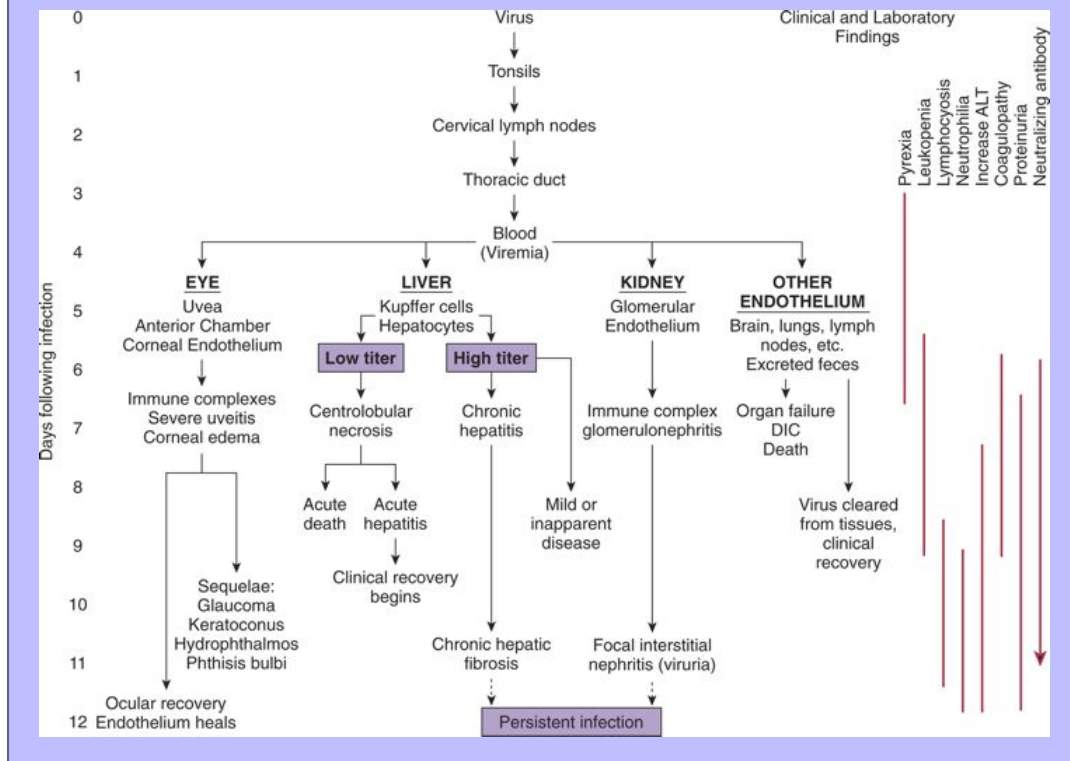

Initial cellular injury of the liver, kidney, and eye is associated with cytotoxic effects of the virus. A sufficient antibody response by day 7 PI clears the virus from the blood and liver and restricts the extent of hepatic damage. Widespread centrilobular to panlobular hepatic necrosis is often fatal in experimentally infected dogs, with a persistently low (less than 1:4) antibody titer. Acute hepatic necrosis can be self-limiting and centrilobularly restricted such that hepatic regeneration occurs in dogs that survive this phase of the disease. Dogs demonstrating a partial neutralizing antibody titer (greater than 1:16, less than 1:500) by day 4 or 5 PI develop chronic active hepatitis and hepatic fibrosis. Persistent hepatic inflammation continues, probably as a

42

Infectious Diseases of the Dog and Cat, 3rd Edition

result of chronic latent hepatic infection with virus. Dogs with sufficient antibody titers (1:500 or greater) on the day of infection usually show little clinical evidence of disease. Dogs immune to parenteral challenge with CAV-1 are still susceptible to respiratory disease via aerosolized viral particles.

Fig 4-1 Sequential pathogenesis of ICH. Solid vertical bars on the right correspond to the chronologic occurrence and duration of the respective clinical or laboratory findings associated with ICH.

Both virulent and modified live strains of CAV-1 produce renal lesions. Virus detected by positive immunofluorescence and ultrastructural evaluation initially localizes in the glomerular endothelium in the viremic phase of disease and produces initial glomerular injury. An increase in neutralizing antibody at approximately 7 days PI is associated with the glomerular deposition of circulating immune complexes (CICs) and transient proteinuria. CAV-1 is not detected in the glomerulus after 14 days PI; however, it persists in renal tubular epithelium. Tubular localization of the virus is primarily associated with viruria, and only a transient proteinuria is noted. A mild focal interstitial nephritis is found in recovered dogs; however, unlike the liver disease, evidence that chronic progressive renal disease results from ICH cannot be found.

Clinical complications of ocular localization of virulent CAV-1 occur in approximately 20% of naturally infected dogs and in less than 1% of dogs after subcutaneous-modified live virus (SC-MLV) CAV-1 vaccination. The development of ocular lesions begins during viremia, which develops 4 to 6 days PI; the virus enters the aqueous humor from the blood and replicates in corneal endothelial cells.

Severe anterior uveitis and corneal edema develop 7 days PI, a period corresponding to an increase in neutralizing antibody titer. CIC deposition with complement fixation (CF) results in chemotaxis of inflammatory

Infectious Diseases of the Dog and Cat, 3rd Edition

cells into the anterior chamber and extensive corneal endothelial damage. Disruption of the intact corneal endothelium causes accumulation of edematous fluid within the corneal stroma.

Uveitis and edema are usually self-limiting unless additional complications or massive endothelial destruction occurs. Clearing of corneal edema coincides with endothelial regeneration and restoration of the hydrostatic gradient between the corneal stroma and aqueous humor. Normal recovery of the eye is usually apparent by 21 days PI. If the inflammatory changes are severe enough to block the filtration angle, increased intraocular pressure may result in glaucoma and hydrophthalmos.

Complications are often associated with the pathogenesis of ICH. Dogs are more prone to develop pyelonephritis as a result of renal damage after ICH infection. Disseminated intravascular coagulation (DIC), a frequent complication of ICH, begins in the early viremic phase of the disease and may be triggered by endothelial cell damage, with widespread activation of the clotting mechanism, or by the inability of the diseased liver to remove activated clotting factors. Decreased hepatic synthesis of clotting factors in the face of excessive consumption compounds the bleeding defect.

42

43

Although the cause of death in ICH is uncertain, the liver is a primary site of viral injury. Hepatic insufficiency and hepatoencephalopathy may result in a semicomatose state and death. Some dogs die so suddenly that liver damage with resulting hepatic failure does not have time to occur. Death in these dogs may result from damage to the brain, lungs, and other vital parenchymal organs or from the development of DIC.

4.1.3

Clinical Findings

ICH is most frequently seen in dogs younger than 1 year, although unvaccinated dogs of all ages can be affected. Severely affected dogs become moribund and die within a few hours after the onset of clinical signs. Owners frequently believe that their dog was poisoned. Clinical signs in dogs that survive the acute viremic period include vomiting, abdominal pain, and diarrhea with or without evidence of hemorrhage.

Abnormal physical findings in the early phase of infection include increased rectal temperature (39.4°C to 41.1°C [103°F to 106°F]) and accelerated pulse and respiratory rates. Fever may be transient or biphasic early in the course of the disease. Tonsillar enlargement, usually associated with pharyngitis and laryngitis, is common. Coughing and auscultated harsh lower respiratory sounds are manifestations of pneumonia. Cervical lymphadenomegaly is frequently found with SC edema of the head, neck, and dependent portions of the trunk. Abdominal tenderness and hepatomegaly are usually apparent in the acutely ill dog. A hemorrhagic diathesis that is demonstrated by widespread petechial and ecchymotic hemorrhages, epistaxis, and bleeding from venipuncture sites may occur. Icterus is uncommon in acute ICH, but it is found in some dogs that survive the acute fulminant phase of the disease. Abdominal distention is caused by accumulation of serosanguineous fluid or hemorrhage. Central nervous system (CNS) signs, including depression, disorientation, seizures, or terminal coma, may develop at any time after infection.

Clinical signs of uncomplicated ICH frequently last 5 to 7 days before improvement. Persistent signs may be found in dogs with a concurrent viral infection such as canine distemper or in dogs that develop chronic active hepatitis.

Corneal edema and anterior uveitis usually occur when clinical recovery begins and may be the only clinical abnormalities seen in dogs with inapparent infection (also see ICH in [Chapter 93](#)). Dogs with corneal edema show blepharospasm, photophobia, and serous ocular discharge. Clouding of the cornea usually begins at the limbus and spreads centrally ([Fig. 4-2](#)) (see [Fig. 93-12](#)). Ocular pain, present during the early stages of infection, usually subsides when the cornea becomes completely clouded. However, pain may return with the development

Infectious Diseases of the Dog and Cat, 3rd Edition

of glaucoma or corneal ulceration and perforation. In uncomplicated cases, clearing of the cornea begins at the limbus and spreads centrally.

4.1.4

Diagnosis

Early hematologic findings in ICH include leukopenia with lymphopenia and neutropenia. Neutrophilia and lymphocytosis occur later in dogs with uncomplicated clinical recovery. An increased number of dark staining (activated) lymphocytes and nucleated erythrocytes may be found. Serum protein alterations, detectable only on serum electrophoresis, are a transient increase in α^2 -globulin by 7 days PI and by a delayed increase in γ -globulin, which peaks 21 days PI.

The degree of increased activities of alanine aminotransferase (ALT), aspartate aminotransferase, and serum alkaline phosphatase (ALP) depends on the time of sampling and the magnitude of hepatic necrosis. These enzyme increases continue until day 14 PI, after which they decline, although persistent or recurrent elevations may be found in dogs that develop chronic active hepatitis. Moderate to marked bilirubinuria is frequently found owing to the low renal threshold for conjugated bilirubin in the dog; hyperbilirubinemia is uncommon. Bromsulphalein retention at 30 minutes may be increased during the acute course of ICH or later in dogs that develop chronic hepatic fibrosis. Hypoglycemia may be found in dogs in the terminal phases of the disease.

Fig 4-2 Blue eye characteristic of ICH being caused by viral and subsequent immunologic damage to the corneal endothelium. (Courtesy University of Georgia, Athens, Ga.)

Coagulation abnormalities characteristic of DIC are most pronounced during the viremic stages of the disease. Thrombocytopenia with or without altered platelet function is usually apparent. One-stage prothrombin time (PT), activated partial prothrombin time (aPTT), and thrombin time (TT) are variably prolonged. Early

Infectious Diseases of the Dog and Cat, 3rd Edition

prolongation of the aPTT probably results from factor VIII consumption. Factor VIII activity is decreased, and fibrin or fibrinogen degradation products (FDPs) are increased. Platelet dysfunction and later prolongation of the aPTT probably result from increased FDPs. Prolongation of the PT is usually less noticeable.

Proteinuria (primarily albuminuria) is a reflection of the renal damage caused by the virus and can usually be detected on random urinalysis because the concentration is greater than 50 mg/dl. The increase in glomerular permeability can result from localization of the virus in initial stages of infection. Alternatively, as the disease progresses, glomeruli become damaged by CICs or as an effect of DIC. Abdominal paracentesis yields a fluid that varies in color from clear yellow to bright red, depending on the amount of blood present. It is usually an exudate with a protein content ranging from 5.29 to 9.3 g/dl (specific gravity from 1.020 to 1.030).

Bone marrow cytology reflects the dramatic change in leukocytes in the peripheral circulation. Megakaryocytes are absent or decreased during the viremic stage of the disease, and those that are present may have altered morphology.

Cerebrospinal fluid (CSF) is normal in dogs with neurologic signs caused by hepatoencephalopathy; it is usually abnormal in dogs that develop nonsuppurative encephalitis from localization of the virus within the brain. Protein concentration (greater than 30 mg/dl) increases with mononuclear pleocytosis (more than 10 cells/mm³). The aqueous humor also has increased concentrations of protein and cells associated with anterior uveitis.

43

44

Results of laboratory procedures previously discussed are suggestive of ICH and are the primary means of making a diagnosis in clinical practice. Antemortem confirmation, although not essential for appropriate therapy, can be obtained by serologic testing, virus isolation, and immuno-fluorescent evaluation. Serologic tests include indirect hemagglutination assay, CF, immunodiffusion, and enzyme-linked immunosorbent assay. These tests usually show higher titers after infection with virulent virus in contrast with MLV vaccines.

CAV-1 can be isolated because it readily replicates in cell cultures of several species, including dogs. Typical adenovirus-induced cytopathology includes clustering of host cells and detachment from the monolayers with the formation of intranuclear inclusions. When viremia begins, on day 5 PI, CAV-1 can be cultured from any body tissue or secretion. The virus is isolated in the anterior chamber during the mild phase of uveitis before antibody infiltration and immune complex formation. Culturing the virus from the liver of dogs is often difficult because hepatic arginase inhibits viral nucleic acid replication. The virus has not been isolated from the liver later than 10 days PI, even in dogs with chronic active hepatitis, perhaps because viral latency develops. The kidney is the most persistent site of virus localization, and CAV-1 can be isolated from the urine for at least 6 to 9 months after the initial infection.

Immunofluorescent techniques are used experimentally to confirm the presence of virus within various tissues. This method has helped locate the sites of viral replication, the spread of the virus within the cells, and the presence of viral antigen in inclusion bodies. Immunoperoxidase procedures, applied to formalin-fixed, paraffin-embedded tissues, have detected virus in liver tissues stored for up to 6 years. Polymerase chain reaction (PCR) techniques have been developed to detect CAV-1 in biologic specimens and to separate the virus from CAV-2 in clinical specimens without resorting to hemagglutination and neutralization tests.^{3,10}

4.1.5

Pathologic Findings

Findings on necropsy or biopsy examination of tissues from dogs can usually confirm a diagnosis of ICH. Dogs that die during the acute phase of the disease are often in good flesh, with edema and hemorrhage of superficial lymph nodes and cervical SC tissue. Icterus is not usually apparent. The abdominal cavity may contain fluid that varies from clear to bright red in color. Petechial and ecchymotic hemorrhages are present on all serosal surfaces.

Infectious Diseases of the Dog and Cat, 3rd Edition

The liver is enlarged, dark, and mottled in appearance, and a prominent fibrinous exudate is usually present on the liver surface and in the interlobar fissures (Fig. 4-3). The gallbladder is thickened and edematous and has a bluish-white opaque appearance. Fibrin may be deposited on other abdominal serosal surfaces, giving them a ground glasslike appearance. Intraluminal gastrointestinal (GI) hemorrhage is a frequent finding. The spleen is enlarged and bulges on the cut surface.

Variable gross lesions in other organs include multifocal hemorrhagic renal cortical infarcts. The lungs have multiple, patchy, gray-to-red areas of consolidation. Hemorrhagic and edematous bronchial lymph nodes are found. Scattered hemorrhagic areas, present on coronal section of the brain, are primarily located in the midbrain and caudal brain stem. Ocular lesions, when present, are characterized by corneal opacification and aqueous humor clouding.

Dogs surviving the acute phase of the disease may have lesions that can be found on subsequent necropsy examination. The liver of those with chronic hepatic fibrosis may be small, firm, and nodular. The kidneys of many dogs that recover are studded with multiple white foci (0.5 cm diameter) extending from the renal pelvis to the outer cortex. Ocular sequelae from the acute disease can include either glaucoma or phthisis bulbi.

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 4-4 Histologic appearance of massive centrolobular necrosis in a fatal case of ICH, which shows a few remaining viable hepatocytes (*H*) around a portal vein (*P*) in the peripheral lobular area (H and E stain, $\times 250$). (Courtesy University of Georgia, Athens, Ga.)

Histologic changes in the liver of dogs that die of acute hepatitis include widespread centrilobular to panlobular necroses. In dogs with mild hepatocellular necrosis, the margin between necrotic and viable hepatocytes is sharply defined within the liver lobule (Fig. 4-4). The preservation of the underlying support stroma allows for eventual hepatic regeneration. Only in severe cases does coagulation necrosis of entire hepatic lobules prevent regeneration of the liver. Neutrophilic and mononuclear cell infiltrates are associated with the removal of underlying necrotic tissue. Bile pigment rarely accumulates in most cases because of the transient nature of hepatocellular necrosis and the frequent lack of peripheral lobular involvement of portal radicles. Intranuclear inclusions are initially found in Kupffer's cells and later in viable hepatic parenchymal cells. Subacute to chronic hepatic disease is marked by sporadic foci of necrosis with neutrophilic, mononuclear, and plasma cell infiltration and is found in dogs with partial immunity that survive initial stages of infection.

44

45

Historically, CAV-1 has been observed with direct fluorescent antibody in hepatocytes of recovered dogs with chronic hepatic inflammation. PCR and histochemical staining of tissues was used to examine for CAV-1 in the livers of dogs with naturally occurring ICH, chronic active hepatitis, and hepatic fibrosis.³ Although the ICH cases had positive test results, viral DNA or antigens were not detected in specimens from the other animals.

Widespread histologic alterations occur in other organs as a result of endothelial injury caused by the virus. The gallbladder has marked subserosal edema, but the epithelium remains intact. Viral inclusions are first found in the renal glomeruli but are later found in renal tubular vascular endothelium. Focal interstitial accumulations of

Infectious Diseases of the Dog and Cat, 3rd Edition

neutrophils and mononuclear cells are found in the renal cortex and medulla. These mild changes often progress to focal interstitial fibrosis. Lymphoid organs, including the lymph nodes, tonsils, and spleen, are congested with neutrophilic and mononuclear cell infiltrates. Lymphoid follicles are dispersed with central areas of necrotic foci. Intranuclear inclusions are present in vascular endothelial cells and histiocytes. The lungs have thickened alveoli with septal cell and peribronchial lymphoid accumulations. Alveoli in consolidated areas are filled with an exudate consisting of erythrocytes, fibrin, and fluid. Mucosal and submucosal edema with focal subserosal hemorrhage is found in the intestinal tract. Widespread vascular degeneration and tissue hemorrhage and necrosis are associated with the presence of intravascular fibrin thrombi.

Swollen, desquamated endothelial cells in meningeal vessels contain intranuclear inclusions. Mononuclear cuffing is present around small vessels throughout the parenchyma of the CNS. Mild endothelial proliferation and mononuclear perivascular infiltration persist for at least 3 weeks after clinical recovery.

Ocular changes are characterized by granulomatous iridocyclitis with corneal endothelial disruption and corneal edema. Iridial and ciliary vessels are congested with inflammatory cells that are also present in the iris and filtration angle.

The **inclusion bodies** seen in ICH have been classified as Cowdry type A and are present in both ectodermal and mesodermal tissues. That they are abundant in the liver makes this the most logical tissue for impression smears obtained by biopsy or at necropsy (Fig. 4-5). Initial hypertrophy of the cell nucleus is followed by peripheral margination of the chromatin network and nucleolus, which forms a central, dark-staining nuclear remnant surrounded by a halo of chromatin. The initial inclusions are acidophilic but become basophilic as the chromatin marginates. Care must be taken to distinguish inclusions from faintly staining hepatocyte nucleoli.

4.1.6 Therapy

Clinical management of dogs that develop ICH is primarily symptomatic and supportive. Fulminant hepatic failure from hepatocellular necrosis is a common cause of death in dogs that do not survive the acute stages of the disease. In the absence of complicating factors, clinical recovery and hepatocellular regeneration can occur with centrilobular necrosis. Therapy is supportive until adequate time is available for hepatocellular repair. Because the dogs are frequently semicomatose, predicting whether the neurologic signs are related to hepatoencephalopathy or viral encephalitis is impossible. However, this issue can be partially resolved by evaluating blood glucose or ammonia concentrations when therapy is instituted.

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 4-5 Cytologic appearance of intranuclear inclusions in hepatocytes (*arrows*) from an impression smear of liver tissue at necropsy (Wright stain, $\times 400$) from a pup that died of ICH. Compare to hepatocyte nucleolus (*N*). (Courtesy University of Georgia, Athens, Ga.)

Immediate placement of an indwelling intravenous (IV) catheter is a necessity in severely affected dogs; however, because of incoagulability, care must be taken to avoid excessive hemorrhage. Fluid therapy with a polyionic isotonic fluid such as Ringer's solution will correct losses from vomiting and diarrhea and assist in lowering the body temperature. Animals that are too depressed to drink or that continue to vomit must be given daily maintenance fluid requirements (45 ml/kg) by parenteral route.

Treatment of DIC depends on the stage of the clotting deficit. Removal of the inciting stimulus is the initial aim of therapy, but this is not possible in viral diseases. Because of insufficient hepatic synthesis, replacement of clotting factors and platelets by fresh plasma or whole blood may be necessary in conjunction with anticoagulant therapy when marked incoagulability is present.

Because the possibility exists that hypoglycemia is responsible for the comatose state, an IV bolus of 50% glucose (0.5 ml/kg) should be given over a 5-minute period. Hypoglycemia is likely to recur if continuous infusion of hypertonic glucose is not maintained. Hypertonic glucose infusion should be continued at a rate not greater than 0.5 to 0.9 g/kg/hr for efficient utilization. Therapy to decrease the blood ammonia concentration is

Infectious Diseases of the Dog and Cat, 3rd Edition

directed at reducing protein catabolism by colonic bacteria and ammonia resorption in the renal tubules. Ammonia production from protein degradation in the bowel can be reduced by decreasing the quantity of protein intake and by stopping GI hemorrhage. The colon can be evacuated by cleansing and acidifying enemas that relieve bowel stasis and retard ammonia absorption. Nonabsorbable oral antibiotics such as neomycin have been advocated to reduce ammonia-producing bacteria in the intestine, but their effectiveness is questionable. Acidification of the colonic contents can also be achieved by feeding oral lactulose to nonvomiting animals. Renal resorption of ammonia can be reduced by administration of parenteral or oral potassium and correction of the metabolic alkalosis. Urinary acidification with a nontoxic acidifier such as ascorbic acid may greatly reduce ammonia reabsorption by the kidney.

45

46

Polyinosinic-polycytidylic acid, an interferon inducer, has been used experimentally to reduce the mortality of dogs experimentally infected with ICH virus, but its clinical application is impractical (see Interferon Inducers, [Chapter 100](#)).

4.1.7 Prevention

4.1.7.1 Maternal Immunity

The duration of passively acquired immunity in the pup is dependent on the antibody concentration of the bitch. The half-life of ICH antibodies is 8.6 days compared with 8.4 days for antibodies to distemper virus, and these values correlate well with the half-life for canine globulin (see Maternal Immunity, [Chapter 100](#)). Immunization for ICH is usually successful when maternal antibody titers decrease below 100, which may occur beginning at 5 to 7 weeks of age. The level of ICH maternal antibodies in the newborn pup declines to negligible concentrations by 14 to 16 weeks.

4.1.7.2 Vaccination

Canine hepatitis caused by CAV-1 has been effectively controlled and practically eliminated from the domestic dog population because of vaccination. Sporadic cases are still seen in which dogs do not get adequate vaccination during puppyhood. Because the virus is environmentally resistant and has a reservoir in wild carnivore, vaccination must be continued as a core antigen for all dogs. Inactivated CAV-1 vaccines do not produce any lesions in vaccinated dogs, but they must be given frequently to equal the protection afforded by MLV vaccines. MLV vaccines can be given every 3 to 5 years because they provide long-term protection, and infections are never reported in adult animals that received an adequate puppyhood series. Adjuvants must be added to inactivated products to make them more immunogenic; however, this also makes them potentially more allergenic than MLV vaccines. Annual revaccination against ICH with an inactivated CAV-1 vaccine provides continuous protection against infection. These products are not available in the United States.

An inactivated CAV-2 vaccine was tested for use in dogs against challenge infection with CAV-2 infection. Dogs received two doses of vaccine at a 14-day interval and were challenged 14 days after the second dose. All dogs became seropositive after vaccination but had mild clinical signs of infection compared with challenged unvaccinated dogs. The clinical usefulness of this vaccine remains to be determined, and long-term protection studies are needed.

In contrast to inactivated vaccines, modified live CAV-1 vaccines can produce lifelong immunity with a single dose. A potential disadvantage of MLV vaccines, however, has been that vaccine virus localizes in the kidney and causes mild subclinical interstitial nephritis and persistent shedding of vaccine virus. Increased passage of the virus in cell culture can reduce the incidence of urinary shedding. Ocular localization with

Infectious Diseases of the Dog and Cat, 3rd Edition

associated anterior uveitis occurs in approximately 0.4% of dogs after IV and SC injection. IV CAV-1 vaccination produces a transient systemic illness characterized by pyrexia and tonsillar enlargement and a 20% incidence of anterior uveitis. A summary of the pathogenicity of modified live CAV-1 vaccine and a comparison with that for CAV-2 vaccine are listed in [Table 4-1](#).

Table 4-1 Comparison of Pathogenicity of Modified Live Canine Adenovirus Vaccines

ROUTE ADMINISTERED	CLINICAL SIGNS OBSERVED	
	CAV-1 ^a	CAV-2 ^b
Intravenous	Fever Uveitis (20%) Urinary shedding	Fever Mild respiratory disease Tonsillitis
Intranasal	None	Mild respiratory disease
Intraocular (anterior chamber)	Uveitis (100%)	Uveitis (100%)
Intramuscular or subcutaneous	Uveitis rare (0.4%), urinary shedding (some strains)	None
<p>a Canine adenovirus 1.</p> <p>b Canine adenovirus 2.</p>		

Some CAV-1 and CAV-2 strains are known to be oncogenic in hamsters, but those in commercial vaccines do not appear to produce this side effect. Oncogenic reactions in dogs have not been reported in more than 20 years of field use of these products.

CAV-2 vaccines have been developed as an alternative in the prevention of ICH. Modified live CAV-2 vaccine rarely, if ever, produces ocular or renal disease when given intramuscularly or SC, although the vaccine virus may localize in and be shed from the upper respiratory tract. The vaccine produces ocular lesions only when experimentally injected into the anterior chamber. Given IV and intranasally (IN), modified live CAV-2 vaccine may produce a mild respiratory disease with associated coughing and tonsillar enlargement, although such an infection has been shown to be subclinical and self-limiting. More severe respiratory signs might develop with CAV-2 vaccine with secondary bacterial infections. Care should be taken to avoid aerosolizing the vaccine when it is given by the IM or SC routes. Dogs are adequately protected by the heterotypic antibody titer against CAV-1 infection if CAV-2 vaccine is used; however, the homotypic antibody response is usually greater. CAV-2 vaccine was experimentally given to 3- to 4-week-old pups in an attempt to break through the heterotypic maternal antibodies to ICH virus. Although parenteral vaccination at this age was ineffective, IN vaccination produced a delayed antibody response to CAV-2 and a weak response to CAV-1, 4 to 8 weeks later. Modified live CAV-2 probably localized in the respiratory tract until maternal antibody declined and then spread systemically, stimulating an immune response.

The recommended schedule with any vaccine for ICH involves at least two vaccinations 3 to 4 weeks apart at 8 to 10 and 12 to 14 weeks of age. This is most commonly accomplished through the combination of this antigen with the canine distemper virus vaccination protocol (see Immunoprophylaxis, [Chapter 100](#), and [Appendix 1](#)). Earlier and more frequent vaccination may be advised in areas of high prevalence. Sporadic ICH infection will be noted in puppies when their vaccinations are delayed. Annual vaccination is often

46

47

Infectious Diseases of the Dog and Cat, 3rd Edition

recommended but is probably not essential because of the long-standing immunity produced by MLV vaccines.

4.2 Canine Acidophil Cell Hepatitis

A hepatitis distinct from ICH and characterized by acute, persistent, or chronic forms was described in Great Britain.¹¹ Evidence implying that this syndrome has an infectious nature came from the high prevalence of hepatocellular carcinoma in dogs. The agent, suspected to be a virus, has not been identified, although the disease can be reproduced by inoculating bacteriologically sterile liver homogenates not containing CAV-1 and CAV-2 from spontaneously affected animals into experimental dogs. Presumably, acute infections with this agent lead to acute to chronic hepatitis; cirrhosis with multilobular hyperplasia; and, in some cases, hepatocellular carcinoma.¹²

Clinical findings in the early phase of the illness can be vague and include variable fever, inappetence, vomiting, and abdominal pain, but fever is usually lacking. Terminal clinical signs include abdominal distention with ascites, episodes of seizures, mental status abnormalities, and semicoma.

The only consistent laboratory abnormalities include episodic increased ALT and ALP activities. Diagnosis involves gross and microscopic examination of liver tissue. Gross biopsy or necropsy findings include hepatomegaly with rounded lobe edges and enlarged tonsils, regional lymph nodes, and Peyer's patches. Chronically affected dogs may have reduced hepatic size with exaggerated delineation of the portal radicles or nodular proliferation. Increased fibrous tissue is apparent histologically, both centrally and peripherally. Acidophil cells are scattered throughout hepatic lesions and are characterized by angular cytoplasm with acidophil cytoplasm and hyperchromatic nucleus.

Therapy for this condition is uncertain, and it appears to progress with time. Prevention would not seem plausible until the nature of the suspected infectious agent is determined. Although reported only in Great Britain, the disease may be more widespread. It should be suspected when a high frequency of chronic active hepatitis or hepatic fibrous, hepatocellular carcinoma is reported.

5 CHAPTER 5 Canine Herpesvirus Infection

Craig E. Greene

Leland E. Carmichael

5.1 ETIOLOGY

Canine herpesvirus (CHV) has a worldwide distribution, with biologic and pathogenic properties similar to α -herpesviruses affecting other species. α -Herpesviruses are cytocidal, causing tissue necrosis and localized mucosal or generalized systemic infection in young or immunosuppressed animals. Recovery is associated with a lifelong latent infection, usually localized to nerve ganglia. CHV has a relatively narrow host specificity compared with other members of the α -herpesviruses. CHV only infects dogs or canine tissue cells. Specific receptors on the cell surface have been identified that contribute to this specificity.¹⁴ Although an antigenic relationship to human herpes simplex virus has not been confirmed, CHV shares approximately 51% genetic homology with feline herpesvirus type 1 (FHV-1).²⁵ An antigenic relationship between the canine and feline herpesviruses has also been confirmed in immunoblots with polyvalent or monoclonal antibodies (MAB).^{8,32} One differentiating feature between these viruses is their glycoprotein D hemagglutinins, which offer selective adherence to cells from their like species and may partially explain the species specificity of these viruses.¹¹ Less defined immunologic relationships exist between CHV and herpesviruses isolated from harbor seals (*Phoca vitulina*).⁷ Analysis of CHV isolates by restriction endonuclease cleavage of viral DNA revealed differences in the viruses isolated from unrelated individuals, but cleavage patterns of isolates derived from members of the same litter were indistinguishable.³³

CHV, as an enveloped virus, is readily inactivated by exposure to most disinfectants, to lipid solvents (e.g., ether, chloroform), and to heat above 40°C (56°C for 5 to 10 minutes, 37°C for 22 hours, and longer at 34°C to 35°C). Like other herpesviruses, CHV is readily inactivated at -20°C unless stabilizing solutions are added, when it is stable at -70°C. It is stable at a pH between 6.5 and 7.6 but is rapidly destroyed below pH 5.0 or above pH 8.0.

CHV has a restricted host range and appears to infect only domestic and wild Canidae or canine cell cultures, especially primary or secondary kidney or testicular cells. The virus causes a rapidly spreading, highly destructive cytopathic clear plaque effects in cell cultures with formation of type A intranuclear inclusions; some isolates induce syncytial cell formation (see Viral Isolation in this chapter). Although CHV has not been reported in cats, it is unclear whether an FHV-1 isolate from a pup with a distemper-like syndrome and pancreatic atrophy causes canine infections. Young pups given large ($>10^6$) doses of this FHV-1 virus by multiple routes failed to develop clinical illness or histopathologic changes.⁸ Cross-species infections with herpesviruses may be established in unnatural hosts through artificial means. A nonpathogenic strain of human herpes simplex virus 1 was injected into the brain of normal dogs, establishing a latent infection with no pathologic changes.²⁸

The replication of CHV is similar to that of other α -herpesviruses. Synthesis of viral DNA and nucleocapsids occurs within the host cell nucleus, with the viral envelope being acquired at the nuclear membrane. Virus is transported through the endoplasmic reticulum and Golgi apparatus to the cell surface and released, although most of the virus remains intracellular.

48

Infectious Diseases of the Dog and Cat, 3rd Edition

Equine herpesvirus 9 (EHV-9) is a neurotropic virus that infects horses. Dogs challenged intranasally with EHV-9 developed a fulminant nonsuppurative encephalitis.³⁶ The forebrain was predominantly affected, and virus was detected in neurons. Dogs also had bronchopneumonia and clinical signs of weight loss, fever, anorexia, and neurologic symptoms. The clinical significance of natural infections is unknown.

5.2 EPIDEMIOLOGY

CHV is not stable in the environment, but it is maintained in nature by persistence in its canine host. CHV is a temperature-sensitive virus, with optimal replication at temperatures less than 37°C. It persists in the ganglionic and lymphoid tissues of the oronasal and genital mucosae. As with other herpesviruses, lifelong latent infections are typical. When infections reactivate, CHV replicates in the cooler temperatures of the mucous membranes, and shedding occurs. Virus reshedding occurs sporadically, usually when animals are stressed, such as those in high population densities, those being transported, those that are pregnant, or those that are receiving immunosuppressive therapy. Transmission occurs through direct contact with mucosal secretions from the respiratory or genital tract of infected animals. Serologic surveys in dogs have ranged from 30% to as high as 100% in some kennels.^{21,5} Despite these high rates of exposure, clinical disease may not be evident. Pups that are born in these environments are exposed at birth but have no symptoms. Factors that predispose neonatal pups to generalized infection are hypothermia and poorly developed immune systems.

5.3 PATHOGENESIS

Newborn puppies can acquire CHV infection in utero, from passage through the birth canal, from contact with infected littermates, from oronasal secretions of the dam, or from fomites (although this is rare). A systemic cell-associated viremia is possible in immunoincompetent or immunosuppressed hosts. Neonatal puppies experimentally infected when they are younger than 1 week are particularly susceptible to fatal generalized infections; dogs older than 2 weeks at the time of infection are relatively resistant and generally develop mild or inapparent clinical illness. Virus replication in older dogs is restricted to the nasopharynx, genital tract, tonsils, retropharyngeal lymph nodes, bronchial lymph nodes, and occasionally lungs. Virus may be harbored in the tonsils and parotid salivary gland.³ The breed of dog may play an important role in immunity. Adult European red foxes (*Vulpes vulpes*) developed systemic and respiratory illness after experimental intravenous (IV) challenge that produced mild signs in adult domestic dogs.²² Mucosal immune mechanisms are likely important in natural infection because adult foxes given the same challenge by mouth (per os) had no clinical disease but seroconverted.²² In experimental studies, route of inoculation has also been shown to be important in the spread and tissue localization of virus. Dogs given CHV intranasally (IN) or both IN and IV had virus isolated from nasal secretions.¹² Dogs given an intravaginal inoculation had virus isolated in both nasal and vaginal secretions. Two to 4 months after inoculation, necropsies were performed on the animals, and CHV could not be cultured from any tissues. However, using the polymerase chain reaction (PCR), the CHV genome was found in trigeminal ganglia and retropharyngeal lymph nodes, regardless of the inoculation route. Convalescent dogs also had the viral genome in the lumbosacral ganglia, tonsils, and mediastinal and hypogastric lymph nodes.¹² However, the CHV genome could not be detected in peripheral blood mononuclear cells. Within the trigeminal and lumbosacral ganglia and associated lymph nodes, virus is localized in the neurons or intranuclear in lymphocytes during this quiescent period. These are likely sites for latency, and recrudescence results in virus replicating and shedding from the respiratory and genital mucosae.

Infectious Diseases of the Dog and Cat, 3rd Edition

5.3.1 In Utero Infection

Although neonatal infection usually is acquired at or soon after birth, transplacental transmission may also occur. The effects of transplacental infection with CHV depend on the stage of gestation at which infection occurs (Fig. 5-1). Infertility and abortion of stillborn or weak pups with no clinical signs in the dam have been reported. Although some puppies may survive such in utero infections and appear normal after delivery by cesarean section, others harbor the virus inapparently in their tissues. However, most pups develop systemic herpesvirus infection within 9 days of birth.

48

49

Fig 5-1 Pups delivered by cesarean section from pregnant bitch 31 days after experimental IV infection with CHV. Two fetuses are partially mummified. (From Hashimoto A, Hirai K, Suzuki Y, et al. 1983. Experimental transplacental transmission of canine herpesvirus in pregnant bitches during the second trimester of gestation. *Am J Vet Res* 44:610-614.)

Infectious Diseases of the Dog and Cat, 3rd Edition

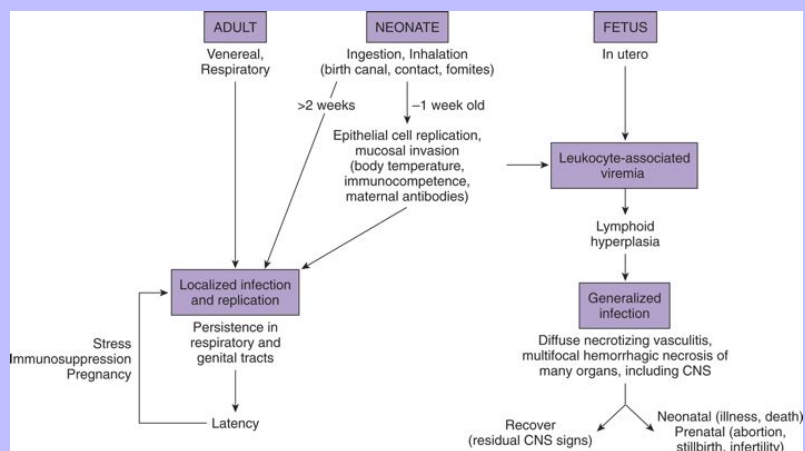

5.3.2 Systemic Neonatal Infection

After oronasal exposure, CHV is first detected in the nasal epithelium and pharyngeal tonsils (Fig. 5-2). Primary replication occurs in epithelial cells and mucosa within 24 hours postinoculation. The virus then enters the blood stream by way of macrophages. Intracellular viremia results in viral spread throughout the body within 3 to 4 days after inoculation. Localization in the mononuclear phagocytic cells of the lymph nodes and spleen results in cell-to-cell spread and lymphoid hyperplasia and necrosis. Progressive multifocal hemorrhagic necrosis occurs in several organs; the highest concentrations of virus are found in the adrenal glands, kidneys, lungs, spleen, and liver. Multifocal hemorrhage associated with necrotic lesions may be related to the vasculitis and marked thrombocytopenia that occurs during infection. Thrombocytopenia may result from disseminated intravascular coagulation associated with widespread vascular endothelial damage and tissue necrosis.

Ganglioneuritis of the trigeminal nerve is a frequent lesion in puppies infected by oronasal exposure. CHV may travel up the nerve axons to the central nervous system (CNS), as does herpes simplex virus in humans. Meningoencephalitis commonly occurs in oronasally infected neonatal puppies, but CNS signs are not always apparent. Under normal circumstances, puppies usually die from systemic illness before neurologic signs are manifest.

Several factors, including temperature regulation and immune status, are involved in the abrupt development of resistance to infection that occurs between 1 and 2 weeks of age. Optimal growth of CHV in cell cultures has been shown to occur between 35°C and 36°C. The normal rectal temperature of adult dogs, 38.4° C to 39.5°C (101°F to 103°F), is above the critical range. Temperature regulation of the newborn pup is not developed until 2 to 3 weeks of age, and rectal temperature is usually 1° C to 1.5°C (2°F to 3°F) lower than that of the adult dog. In addition to having a reduced capacity for temperature regulation, neonatal pups are incapable of adequate fever production. Cell-mediated immune functions are also suppressed at temperatures lower than 39°C, rendering hypothermic pups more susceptible not only to CHV but also to vaccinal distemper and canine adenovirus infection. Puppies 4 to 8 weeks of age are normally clinically asymptomatic after infection, but they develop systemic CHV infection if their body temperatures are artificially reduced. Conversely, elevation of the environmental temperature and consequently the body temperature of CHV-infected puppies younger than 1 week results in reduction of the severity of infection; it does not eliminate the infection.

Fig 5-2 Pathogenesis of CHV infection.

Infectious Diseases of the Dog and Cat, 3rd Edition

Immunity acquired from the dam also appears to be important in the survival of infected puppies. Pups nursing seronegative bitches develop a fatal multisystemic illness when they are infected with CHV. In contrast, puppies suckling seropositive bitches become infected but remain asymptomatic, and the virus is recovered primarily from their oropharyngeal region. Maternal antibody or immune lymphocytes acquired through the milk may explain why naturally infected bitches that give birth to diseased puppies, with rare exception subsequently give birth to healthy litters. Serum antibody titers in previously infected pregnant bitches may also suppress viremia and spread of infection to the fetus.

5.3.3 Adult Genital Infection

Occasionally herpesviruses have been isolated from papulovesicular lesions of the canine genital tract; such lesions may be recurrent episodes in previously infected bitches. With CHV, localized genital or respiratory infections and viral shedding can occur in the presence of circulating antibodies. Infection of the genital tract generally appears to be asymptomatic or limited to vaginal hyperemia with hyperplastic lymphoid follicles.

49

50

Genital localization of the virus in adult dogs may be a means of venereal transmission of the virus, but it is most important as a source of infection for pups at birth. Spread of CHV from seropositive males to susceptible females at the time of breeding does not appear to be a significant mode of transmission, although such a mechanism is believed to occur. PCR has shown persistence of the virus in the lumbosacral ganglion, with presumed recrudescence and mucosal replication with subsequent shedding.^{3,12}

5.3.4 Adult Respiratory Infection

Field evidence suggests that CHV might be a cause of respiratory disease, but studies have failed to incriminate CHV as a primary cause of respiratory illness. Although of uncertain significance, CHV has been recovered from the lungs of dogs with distemper and from dogs with acute conjunctivitis. Neonates that recover from CHV infections or older dogs that have subclinical infections have periodic episodes of viral recrudescence in their oronasal secretions. Viral latency has been demonstrated in intranasally infected dogs for as long as 6 months after infection, with recrudescence occurring within 1 week after treatment with glucocorticoids or antilymphocyte serum. Recrudescence of latent virus also has been demonstrated in seropositive adults after being exposed to seronegative juveniles, suggesting a stress mechanism for CHV transmission that is similar to that of FHV infection. Reactivation of latent infections with asymptomatic shedding of virus from nasal, oral, ocular, and vaginal secretions occurred in most bitches given repeated high immunosuppressive doses of glucocorticoids.¹⁸ Recrudescence is a plausible explanation for subclinical persistence and the rare recurrences of abortions, fetal infections, or neonatal illnesses. It also serves as a mode of viral transmission to susceptible dams, especially when they are in a kennel for breeding.

5.4 CLINICAL FINDINGS

5.4.1 Neonatal Puppies

No premonitory signs of illness or history of neonatal mortality is seen in bitches with litters of puppies that die of CHV. Transplacental infections may occur at mid to late gestation and can result in abortion of mummified or dead fetuses, premature or stillborn pups, or weak or runt newborn puppies. Death of neonatal puppies younger than 1 week appears to be less common and probably indicates in utero infection. Among puppies born alive within a litter, some may not be affected, and the gestational age when illness occurs may vary among those that are affected.

Infectious Diseases of the Dog and Cat, 3rd Edition

CHV infection in postnatally infected puppies is associated with an acute and fatal illness, primarily occurring between 1 and 3 weeks of age. If affected when older than 3 weeks, pups have disseminated CHV infection that is believed to be exacerbated by concurrent infection or immunosuppression. Infected puppies appear dull and depressed, lose interest in nursing, lose body weight, and pass soft, yellow-green feces. They cry persistently and show discomfort during abdominal palpation. Despite the continued muscular activity associated with crying, restlessness, and shivering, the pups have no elevation in body temperature. Rhinitis is frequently manifest by serous to mucopurulent or, although rare, hemorrhagic nasal discharges. Petechial hemorrhages are widespread on the mucous membranes. An erythematous rash consisting of papules or vesicles and subcutaneous edema of the ventral abdominal and inguinal region are occasionally noted. Vesicles are occasionally present in the vulva and vagina of the female puppies, prepuce of the males, and the buccal cavity. Puppies lose consciousness and may have opisthotonos and seizures just before death. Rectal temperatures become subnormal before death, which usually occurs within 24 to 48 hours after the onset of clinical illness.

Fig 5-3 CHV vaginitis. *Arrow points to vesicular lesion.* (Courtesy Akira Hashimoto, Hokkaido University, Sapporo, Japan.)

Some puppies develop mild clinical disease with subsequent recovery. Animals that survive the systemic infection are likely to have persistent neurologic signs. Ataxia, blindness, and cerebellar vestibular deficits are most common.

5.4.2

Older Puppies and Adult Dogs

Dogs older than 3 to 5 weeks develop a mild or inapparent upper respiratory infection as a result of CHV. Signs of systemic infection are rare in older pups; however, vomiting, anorexia, depression, serous ocular discharge, hepatomegaly, and sudden death have been reported in naturally infected 8- to 10-week-old coyote pups (see [Chapter 93](#) for a discussion of ocular lesions).

Infectious Diseases of the Dog and Cat, 3rd Edition

Primary genital infections in older female dogs are characterized by lymphofollicular lesions, variable degrees of vaginal hyperemia, and occasionally petechial or ecchymotic submucosal hemorrhage (Fig. 5-3). No discomfort or vaginal discharge is noted in affected pregnant dogs, even in those who had abortions or stillbirths. Vesicular lesions have been noted during the onset of proestrus and regress during anestrus. Male dogs with similar lesions over the base of the penis and preputial reflection may have a preputial discharge.

5.5 DIAGNOSIS

5.5.1 Clinical Laboratory Findings

The determination of CHV infection in neonatal pups usually depends on information obtained from the clinical history, physical examination, and characteristic pathologic changes seen in affected puppies. Hematologic and biochemical abnormalities are nonspecific, but marked thrombocytopenia may be observed. A marked increase in the alanine aminotransferase activity can be found in infected neonates.

5.5.2 Viral Isolation

CHV can be isolated from several parenchymal organs of puppies dying of acute systemic infection but are most commonly obtained from the adrenal glands, kidneys, lungs, spleen, lymph nodes, and liver. In animals that have recovered or are older, growth of CHV is usually restricted to the oral mucosa, upper respiratory tract, and external genitalia. Viral isolation has not been demonstrated later than 2 to 3 weeks after infection. As noted, viral recrudescence may be provoked by immunosuppressive doses of glucocorticoids and may also be caused by stressful situations, such as the introduction of unfamiliar dogs into a kennel.

50

51

CHV grows only in cultured cells of canine origin, primarily in dog kidney cells at an optimal temperature range of 35° C to 37°C. Infected cells become rounded and detach from the glass surfaces, leaving clear plaques surrounded by necrotic cells. Plaque formation is best observed by overlaying monolayers with semisolid media such as agar or methylcellulose. Plaque morphology has been used as a marker for virus pathogenicity. CHV produces Cowdry type A intranuclear inclusions, which can be difficult to demonstrate and are best revealed in tissues that have been fixed in Bouin's fluid. Multinucleation of infected cells is unusual with CHV, but it has been observed with one isolate from the canine genital tract. Fluorescent antibody techniques, electron microscopy, and PCR can be used to detect CHV in tissues and cell cultures (Fig. 5-4). Although not routine, screening animals for infection is best done by viral detection during recrudescence with respiratory or genital signs. PCR has shown that latent herpesvirus infections are prevalent in asymptomatic dogs.³

5.5.3 Serologic Testing

Serologic testing for CHV antibodies has been based on virus neutralization (VN) tests, which rely on reduction in cytopathogenicity or plaque formation. An enzyme-linked immunosorbent assay and an hemagglutination inhibition assay also have been developed.^{15,23,30,33} Neutralizing antibodies increase after infection and may remain high for only 1 to 2 months; low titers may be detected for at least 2 years. Seropositivity merely indicates exposure, not necessarily active infection, although viral persistence and latent infection might be presumed. Serum neutralization titers increase after treatment of convalescent animals with dexamethasone, presumably because of reactivation of latent infection.¹² Because serologic tests are not standardized, variations in the level and prevalence of positive results can be expected among laboratories.

Fig 5-4 Focus of herpesvirus-infected cells in nasal turbinate epithelium from a 12-week-old pup inoculated with CHV (fluorescent antibody method, $\times 125$). (From Appel MJG, Menegus M, Parsonson IM, et al. 1969. Pathogenesis of canine herpesvirus in specific-pathogen-free dogs: 5- to 12-week-old pups. *Am J Vet Res* 30:2067-2073.)

5.5.4 Organism Detection

Virus can be isolated from tissues of fatally infected pups using primary canine lung or kidney cells. Nucleic acid detection has been evaluated in suspected cases of spontaneous CHV infection and is the most reliable means of detecting latent infection in older animals. Nested PCR and in situ hybridization was used to detect virus in formalin-fixed, paraffin-embedded tissues from naturally infected puppies.²⁶ Viral nucleic acid has been found within nuclei adjacent to and within hemorrhagic lesions in pups. Many epithelial cells, neurons, fibrocytes, cardiac myocytes, and hepatocytes contain virus. Nucleic acid testing for CHV is offered by at least one commercial laboratory (see [Appendix 5](#), HealthGene, Inc., Toronto, Can.).

5.6 PATHOLOGIC FINDINGS

Gross lesions of fatal CHV infection in neonates include diffuse multifocal hemorrhage and gray discoloration in various parenchymal organs, especially the kidney, liver, and lungs ([Figs. 5-5 and 5-6](#)). On cut surface, the kidney lesions consist of wedge-shape hemorrhages radiating outward from the renal pelvis. These wedge-shape renal lesions are caused by CHV-induced fibrinoid necrosis of interlobular arteries.³⁵ Serous to hemorrhagic fluid is usually present in the pleural and peritoneal cavities. The lungs are usually firm and edematous with pronounced hyperemia and focal areas of hemorrhage; the bronchial lymph nodes are markedly enlarged. Splenomegaly and

Infectious Diseases of the Dog and Cat, 3rd Edition

generalized lymphadenomegaly are consistent findings. Petechial hemorrhages are often distributed throughout the serosal surfaces of the intestinal tract. Icterus has been rarely reported.

Histologic findings in disseminated infections of neonates are characterized by foci of perivascular necrosis with mild cellular infiltration in the lung, liver, kidney, spleen, small intestine, and brain. Less severe lesions develop in the stomach, pancreas, adrenal glands, omentum, retina, and myocardium. The lymph nodes and spleen show reactive hyperplasia of mononuclear phagocyte elements. Multifocal necrotizing lesions have been described in the placentas of pregnant bitches and the pups that acquired infection in utero. Cutaneous or mucosal lesions, which may be seen as the primary lesions in older infected animals, consist of various sizes of vesicles produced by

51

profound degeneration of the epithelial cells, resulting in marked acantholysis. Depending on the stage of cellular infection and method of fixation, basophilic or acidophilic inclusions may be noted, but they are less common than those caused by other herpesvirus infections. Inclusions are more readily seen in the nasal epithelium or kidney than in areas of widespread necrosis, such as the lung or liver. Renal dysplasias may be present in surviving animals.

52

Fig 5-5 Gross CHV lesions of a pup that died 11 days after birth. Note prominent necrotic lesions in lung and liver. Typical kidney lesions are not clearly revealed.

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 5-6 Kidney from a puppy inoculated with CHV. Hemorrhagic areas consist of necrotic foci packed with erythrocytes.

Lesions in the CNS of recovered puppies are nonsuppurative ganglioneuritis and meningoencephalitis. The parenchymal lesions are multifocal and granulomatous, characterized by increased pericapillary cellular proliferation, and they occur primarily in the brainstem and cerebellum. Cerebellar and retinal dysplasias are frequent findings.

5.7 THERAPY

Once a diagnosis has been made, treatment of puppies with signs of systemic CHV infection is unrewarding because of the rapid and fatal progression of the disease. In some cases, mortality may be reduced during an

Infectious Diseases of the Dog and Cat, 3rd Edition

epizootic episode by injecting each pup intraperitoneally with 1 to 2 ml of immune sera. Immune sera can be obtained by pooling sera from bitches that had recently given birth to litters of puppies that died of CHV infection. Only one injection is required because of the short susceptibility period. This empirical treatment seems to help reduce losses within an exposed litter, but its success depends on the presence of adequate levels of serum antibodies and administration of the sera *before* the full development of systemic disease. If neurologic signs have already developed, they will likely persist.

Table 5-1 Therapy for Herpesvirus Infection of Puppies^a

DRUG	DOSE ^b	ROUTE	INTERVAL (HOURS)	DURATION
Acyclovir ^c	10 mg total	Oral	6	Until 3.5 weeks old

IM, Intramuscular; *SC*, subcutaneous; *PO*, oral.

- a See Drug Formulary, [Appendix 8](#) for specific information on each drug. Because of the small size of neonates, fluids or plasma therapy may have to be given intraperitoneally, intramedullary, or subcutaneously rather than the preferred intravenous route. Additional warming of the animals is essential.
- b Dose per administration at specified interval.
- c Available as 200-mg capsules. Contents of capsule are added to 10 ml of warm water. The powder does not dissolve; however, each pup receives 0.5 ml (10 mg) of the suspension orally every 6 hours.

Elevating the environmental temperature of already affected puppies is ineffective. Newborn puppies in experimental conditions maintained at 36.6° C to 37.7° C (98°F to 100°F) and 45% to 55% humidity have been able to maintain rectal temperatures of 38.4° C to 39.5° C (101°F to 103°F). Under experimental conditions in which body temperatures were elevated artificially before exposure to virus, puppies had reduced mortality, less severe clinical signs, and minimal pathologic changes. At elevated temperatures, viral growth in tissues was restricted compared with growth in conventionally reared pups. Pretreatment by raising ambient temperature is obviously not possible for puppies with natural CHV infections; however, it could be tried for remaining unaffected puppies in a litter.

Treatment of systemic CHV infection with antiviral drugs such as 5-iodo-2-deoxyuridine has been unsuccessful, and few studies have been performed on newer antiviral agents that are effective in treating localized and CNS infections of herpes simplex virus in humans and laboratory animals. In one such study, two 15-day-old pups died of confirmed CHV. Five littermates were given a course of vidarabine as soon as the cause of the deaths was identified, and they all survived. The surviving pups had high (>1:64) neutralizing antibody titers 2 months later, indicating that they had been infected.⁴ A 10-mg dose of acyclovir was given to one litter of 1- to 1.5-kg pups every 6 hours until they were 3.5 weeks old² ([Table 5-1](#)). Antiviral treatment may spare the pups, but residual damage to the CNS and myocardium may occur. This possibility must be discussed with owners before considering antiviral treatment of an infected litter. Lactoferrin, an iron-binding protein found in milk and other mammalian secretions, inhibits the replication of CHV in cell culture. Lactoferrin has been used topically to treat other mucosal viral infections (see [Chapter 2](#) and Drug Formulary, [Appendix 8](#)). Lactoferrin could be administered orally on an empirical basis to protect exposed, clinically healthy pups when peroral transmission of virus is suspected or anticipated.²⁹

Infectious Diseases of the Dog and Cat, 3rd Edition

5.8 PREVENTION

The low frequency of clinical outbreaks and poor immunogenicity of CHV reduce the incentive to produce a commercial vaccine for this disease. Reports from Europe and the United States have demonstrated a prevalence of anti-CHV antibodies in 6% of the random dog population, whereas it may be as high as 100% in some kennels.

5.8.1 Vaccination and Immunotherapy

Because CHV infects pups in utero or as neonates, active immunization can only be considered in the dam. Passive immunization has been shown to reduce mortality in affected or exposed pups, so the use of vaccines seems logical. Live virus vaccines, although presumably attenuated, could establish a latent infection. Immunization with a commercially inactivated vaccine in Europe has been shown to provoke fourfold increases in VN titers in most vaccinated dogs, but it did not appear to provide long-term protection.⁴ An attenuated, cold-adapted CHV mutant virus vaccine has been used on an experimental basis. Also experimentally, neutralizing antibodies to CHV have been produced in mice by immunization with antiidiotypic antibodies.³² A lyophilized, inactivated, purified CHV-1 strain F205 vaccine prepared with enriched glycoproteins was used to vaccinate bitches 10 days postcoitus and 6 weeks later near the end of gestation.²⁰ The near-term booster was used to enhance the short-live humoral response. As analyzed by PCR, 100% of vaccinated pups challenged oronasally with virulent CHV-1 at 3 days of age were protected against clinical illness and in most instances (93.5% of 31 pups) against viral infection. In contrast a majority of challenged control pups (81% of 31 pups) died of generalized CHV disease between 6 and 14 days after challenge. A vaccine using this inactivated strain is licensed for use in some European countries (EURICANHerpes205, Merial, Lyons, France). The low prevalence of illness and the paucity of clinical signs in adult animals make such a vaccine justifiable primarily in problematic kennels with valuable breeding stock.

CHV has also been evaluated as a vector for genetically engineered vaccines against other infections in dogs. Recombinant vaccines incorporating genes for *Neospora caninum*, pseudorabies virus, and rabies virus have all been produced.^{16,17,31} The low virulence and species specificity of CHV make it an ideal candidate for a recombinant vector to protect dogs against other pathogens.

If a problem exists in a kennel, prevention of disease in exposed puppies may be achieved with the administration of immune serum or globulin during the first few days of life. Other methods have been of little value, although administration of an interferon inducer (avian poxvirus) to bitches before breeding and whelping and to newborn puppies in problem kennels was claimed to induce nonspecific protection against fatal CHV infection.⁴ This treatment needs additional evaluation in controlled studies.

5.8.2 Husbandry

On a practical basis, eradication of CHV from a kennel is impossible. Screening for infected animals also is impractical (see Diagnosis in this chapter), and owners should be advised that subsequent litters from an affected bitch have a very low risk of developing clinical illness. Accordingly, cesarean delivery or artificial insemination (AI) is not justified to reduce spread of infection. AI could be used when a male that is known or suspected to be infected is bred to a primiparous bitch, but the benefit of such a practice has not been studied.

As a preventive practice, care should be taken to ensure that the environmental temperature of newborn puppies is kept warm with heated whelping boxes, heat lamps, or other warming devices that do not cause excessive

Infectious Diseases of the Dog and Cat, 3rd Edition

dehydration. Viral shedding for 1 week generally ensues with introduction of new dogs in a kennel, during concurrent illnesses, or in a dog with drug-induced immunosuppression.

Inapparent infections are common in dogs that have recovered from CHV-infection, with occasional mild rhinitis, vaginitis, or balanoposthitis as the only clinical sign. Such dogs may act as reservoirs of infection for neonates and should be separated from new litters. Clinically affected puppies shed large quantities of virus in their secretions for 2 to 3 weeks after recovery. Virus persists for only short periods in respiratory or vaginal secretions, so its spread is most common through immediate direct contact with infected animals or through fomites.

5.9 PUBLIC HEALTH CONSIDERATIONS

Herpesviruses are generally highly species specific; the dog does not become naturally infected with the human strains, and the canine organisms do not infect people. In one study, human herpesvirus type 1 was inoculated into the brain of normal dogs, and it established a latent infection without causing clinical illness or pathologic changes.²⁸

6 CHAPTER 6 Canine Infectious Tracheobronchitis

Richard B. Ford

6.1 ETIOLOGY

Infectious tracheobronchitis ([ITB] synonyms: “kennel cough,” “canine cough,” “canine croup”) describes an acute, highly contagious respiratory infection of dogs characterized by sudden-onset, paroxysmal cough with variable expectoration and nasooocular discharge. The cough is typically described as “hoarse” or a loud “honking” sound. Clinical signs are attributed to infection by one or a combination of bacterial or viral agents (or both) that colonize the epithelium of the nasal cavity, larynx, and trachea, as well as bronchi, bronchioles, and the pulmonary interstitium ([Table 6-1](#)).⁵⁵ Vaccines are available for most of the organisms known to be associated with canine ITB, and immunoprophylaxis of puppies and adult dogs is recommended for those considered to be at risk of exposure. Although uncommon, *Bordetella bronchiseptica* infections have been reported in people as a zoonosis (see Public Health Considerations in this chapter).

Respiratory signs of ITB in dogs known to have single-agent infections are generally mild and frequently self-limiting. The prognosis for recovery from uncomplicated infections is excellent, although the duration of postinfection immunity may be short-lived (months). In the clinical setting, the high prevalence of multiple-agent infections complicates the clinical presentation. Canine parainfluenza virus (CPiV) and *B. bronchiseptica* are the most common organisms isolated from dogs with signs of ITB. However, several other viruses and bacteria are known to influence the clinical course and outcome of infection. Compared with adults, puppies appear more vulnerable to life-threatening *B. bronchiseptica* pneumonia.

6.1.1 Viruses

For several years, CPiV-2 has been reported as the most common virus isolated from the respiratory tract of dogs with ITB. Distribution is apparently worldwide. CPiV-2 is a single-stranded RNA virus belonging to the family Paramyxoviridae and is closely related to simian virus 5.⁵ Infection generally results in self-limiting, short-lived cough, with minimal systemic effects. Although natural infection may result in detectable serum antibody for periods of up to 3 years, antibody titer to CPiV-2 does not correlate well with protection from clinical disease.⁴³

Canine adenovirus type 2 ([CAV-2]; cause of infectious laryngotracheitis) and, to a lesser extent, CAV type 1 ([CAV-1]; infectious canine hepatitis virus) are reported to cause mild, self-limiting acute upper respiratory disease, characterized by cough, in dogs. These viruses are antigenically related DNA viruses of the family Adenoviridae (see [Chapter 4](#)).⁴

Depending on virus strain, canine distemper virus (CDV) can cause acute to subacute systemic infections associated with a high mortality rate among infected dogs. Infections are known to occur in dogs worldwide. CDV is also known to cause lower respiratory tract disease in dogs independent of other systemic signs. Although CDV does act synergistically with CPiV-2 and *B. bronchiseptica*, it is not regarded as a primary pathogen in the cause of ITB (also see [Chapter 3](#)).

Other viruses, such as canine herpesvirus (CHV; see [Chapter 5](#)) and reovirus-1, -2, and -3, have occasionally been isolated from coughing dogs. However, none of these viruses is regarded as being primarily responsible for the clinical syndrome described as ITB.⁶

Infectious Diseases of the Dog and Cat, 3rd Edition

6.1.2 Bacteria and Mycoplasmas

B. bronchiseptica is a gram-negative bacterium and a principal etiologic agent of ITB in dogs.^{*} Hundreds of isolates of *B. bronchiseptica*, with variable virulence patterns and pathogenicity, have been recovered from dogs. Several other domestic and wild animal species may become infected with *B. bronchiseptica*, and it may play an important role in kittens with acute herpesvirus-1 or calicivirus infection (see [Chapter 16](#)).²⁷ Of the hundreds of isolates, considerable variation exists among individual clones with respect to host distribution and virulence potential.^{30,38,42}

Other bacteria recovered from the respiratory tract of dogs with ITB include *Streptococcus* sp., *Pasteurella* sp., *Pseudomonas*, and various coliforms.⁴⁹ Although these bacteria are regarded as opportunistic invaders, secondary bacterial infections are the cause of serious, life-threatening complications (pneumonia and sepsis) in the patient with ITB. *Streptococcus equi* subsp. *zooepidemicus* has been associated with increased severity of ITB in kennelled dogs with endemic respiratory disease¹⁰; it is also considered a cause of pneumonia in dogs as a primary pathogen (see Streptococcal Infections, [Chapter 35](#)).

Mycoplasmas are fastidious, prokaryotic microbes that are distinguished from bacteria by the fact that they are enclosed in a cytoplasmic membrane but lack a distinct cell wall.^{7,32,41} Nonetheless, unclassified groups of mycoplasmas, acholeplasmas, and ureaplasmas are commonly recovered in specimens collected from the nasopharyngeal and laryngeal mucosa of healthy dogs and cats. The presence of *Mycoplasma* in specimens collected from the lower respiratory tract of dogs (especially *M. cynos*) and cats (*M. felis*) is usually associated with pneumonia (see [Chapters 32](#) and [88](#)).^{7,41,44}

* References 7, 20, 21, 38, 56.

6.2 EPIDEMIOLOGY

Canine ITB is considered to be among the most prevalent infectious respiratory diseases of dogs. Outbreaks of canine ITB are relatively common. Clinical infections can reach epizootic proportions when dogs are housed in high-density population environments such as pet shops, boarding facilities, commercial kennels,^{6,7} and veterinary hospitals.^{15,23} Despite their apparent synergism in producing disease, *B. bronchiseptica* and CPiV-2 the two pathogens appear to spread independently in the dog population.¹⁷ The host range of *B. bronchiseptica* includes wildlife, rodents, and cats; however, most outbreaks are the result of direct dog-to-dog or airborne contact with infectious respiratory secretions. Theories suggest that *B. bronchiseptica* can be transmitted from dogs to cats. *B. bronchiseptica* has been shown to survive in unsupplemented lake water for up to 24 weeks and replicate in natural waters for at least 3 weeks at 37° C.³⁹ Both CPiV-2 and *B. bronchiseptica* are spread from mixing older carrier animals with younger or otherwise naïve dogs, allowing for outbreaks of clinical disease and more rapid spread of infection.

The common viral agents of ITB are transmitted for up to 2 weeks postinfection. For *Mycoplasma* sp. and *B. bronchiseptica*, however, shedding may occur for 3 months or longer.^{5,6} Although infections are transmitted rapidly and efficiently in high-density populations with high morbidity, death associated with complicated respiratory infection is uncommon, particularly in adult dogs.

Infectious Diseases of the Dog and Cat, 3rd Edition

6.3 PATHOGENESIS

6.3.1 Viruses

Because CPiV does not replicate in macrophages, infections with CPiV are typically restricted to the upper respiratory tract in dogs. CPiV infection of the larynx can cause edema of the vocal folds resulting in the high-pitched, honking cough commonly associated with canine ITB. Damage to the tracheal epithelium allows for secondary infection by other pathogens (Figs. 6-1, A, and 6-1, B). Animals 2 weeks of age and older are susceptible.⁶ Transmission occurs predominantly by aerosolized microdroplets. After a 3- to 10-day incubation period, viral shedding can occur for 6 to 8 days postinfection.⁵ In single-agent infections, signs are limited to a dry, hacking cough and serous nasal discharge. After recovery, a CPiV carrier state does not appear to exist. Cats are capable of becoming subclinically infected and shedding the virus. Whether this is a significant source of infection for dogs is unknown.

Table 6-1 Agents Associated with Infectious Tracheobronchitis in Dogs

Viruses	Canine parainfluenza virus Canine adenovirus-2 Canine distemper virus Canine herpesvirus
Bacteria	<i>Mycoplasma</i> <i>Bordetella bronchiseptica</i> <i>Streptococcus</i> spp.

Fig 6-1 **A**, Electron microscopic (EM) scan of normal canine tracheal epithelium. **B**, EM scan shows mucous hypersecretion and the tracheal epithelium completely denuded of cilia only 72 hours after experimental infection with CPiV. (Courtesy Pfizer Laboratories, New York, N.Y.)

Infection with CAV-2 occurs after oronasal contact. The virus replicates in the epithelium of the nasal mucosa, pharynx, tonsillar crypts, trachea, and bronchi and in nonciliated bronchiolar epithelium. Replication peaks by day 3 to 6 after inoculation corresponding to a peak in serum antibody titer.⁴ In immunocompetent dogs,

Infectious Diseases of the Dog and Cat, 3rd Edition

infection is typically short-lived; virus usually cannot be isolated beyond day 9 of infection. Infection of type-2 alveolar cells has been associated with interstitial pneumonia.⁴ Single-agent infections may be associated with tonsillitis or lung consolidation, or both.⁶ In other dogs, overt clinical signs may not be apparent.

6.3.2 Bacteria and Mycoplasmas

B. bronchiseptica has been associated with respiratory infections in dogs and cats (see [Chapter 16](#)).²⁹ *B. bronchiseptica* is a gram-negative, aerobic coccobacillus regarded as one of the principal causative agents of canine ITB. Although either CPiV or CAV-2 may cause mild clinical infections, clinical disease is expected to be more severe in dogs co-infected with *B. bronchiseptica* than with any these agents alone. Transmission most likely occurs after direct contact with infected dogs or contact with aerosolized microdroplets either from infected dogs or through contaminated dishware, human hands, and other fomites.

During an incubation period of approximately 6 days, *B. bronchiseptica* preferentially attaches to, and replicates on, the cilia of respiratory epithelium. *Bordetella* attach to the surface of ciliated respiratory mucosae by means of adhesin molecules ([Fig. 6-2](#)). Once they colonize the respiratory tract, *Bordetella* produce a variety of potent toxins that impair phagocytic function and induce ciliostasis. *B. bronchiseptica* is uniquely capable of facilitating co-colonization of the respiratory tract by other opportunistic organisms. *B. bronchiseptica* possesses several intrinsic mechanisms for evading host defenses.^{4,15,40,60} It is well recognized for its role as a significant complicating factor in dogs with multiple-agent respiratory infections. For example, fimbriae (hairlike appendages extending from the cell membrane of *B. bronchiseptica*) recognize specific receptors within the respiratory tract.⁸ This allows *B. bronchiseptica* to colonize specific tissues where it then releases various exotoxins and endotoxins that impair the function and integrity of the respiratory epithelium and compromise the ability of the infected host to eliminate the infection.^{15,23} Additionally, although *B. bronchiseptica* has been regarded as an extracellular pathogen, it has the unique ability to invade host cells. Once contained within the intracellular environment, bacteria are able to avoid immunologic defense mechanisms and establish a persistent infection or carrier state. The pathogenesis of *B. bronchiseptica* has recently been reviewed.*

Infectious Diseases of the Dog and Cat, 3rd Edition

Despite the fact that infection elicits production of local antibody, the organisms are not completely cleared from the respiratory tract for an average of 3 months. Although by itself *B. bronchiseptica* can cause rhinitis, mucous nasal discharge, and cough, the most naturally occurring illness is associated with viruses or other bacteria. The organism has been isolated primarily from the upper respiratory tract of clinical healthy dogs. In combined infections with CPiV, tracheal mucosal injury is associated with clinically apparent pneumonia.

In addition to *B. bronchiseptica*, several species of *Mycoplasma* and *Ureaplasma* have been associated with pneumonia in dogs.^{7,32,41,44} Although endogenous to the nasopharynx of dogs and cats, mycoplasmas are not typically found in the lower respiratory tract. Unlike *B. bronchiseptica*, mycoplasmas colonize both ciliated and nonciliated epithelia. Both natural and experimental infections are characterized by purulent bronchitis and bronchiolitis. Epithelial and lymphoid hyperplasia and interstitial pneumonia may develop. Systemic infection is rare. Once bacteria colonize the lower respiratory epithelium, chronic bacterial shedding of several months' duration is likely.⁷

* References 4, 20, 21, 38, 56.

6.4 CLINICAL FINDINGS

B. bronchiseptica and CPiV are among the most common agents isolated from dogs affected with ITB. Because multiple agents cause most natural infections of ITB, associating a distinct set of clinical signs with a particular bacterium or virus is difficult.^{7,49}

Acute-onset, paroxysmal coughing episodes, typically associated with retching, in an otherwise healthy, active dog characterizes the clinical presentation. Swollen vocal folds, associated with laryngitis, restrict airflow through the glottis during a cough. This results in a loud, high-pitched cough described as a honking sound. Cough is likely to be productive. However, expelled secretions are not consistently observed because of the small volume and the tendency for dogs to swallow expectorated secretions. Although dogs are affected most commonly during summer and fall, the high density of dogs living in shelters or kennels can be expected to result in infections at any time of year. Dogs that have received prior vaccination against CDV and CAV-2 may still develop signs.^{4,6,43,49} The time between exposure and onset of signs of canine ITB ranges from 3 to 10 days, regardless of the agents involved in the primary infection.^{4-6,38} A history of exposure to other dogs, particularly in kennel or shelter settings, although common, not a prerequisite. Expectoration of mucus, described as retching or hacking, may occur after a coughing episode and is commonly misinterpreted by owners as vomiting. Physical examination is usually unremarkable, although cough may be easily elicited on manipulation of the trachea, particularly at the thoracic inlet. The ability to elicit a cough on manipulation of the trachea is an inconsistent clinical finding that should not be used exclusively to rule canine ITB in or out. Although secondary bacterial pneumonia can develop in affected dogs, most infections are self-limiting and may resolve without treatment.

A second more severe syndrome is described in dogs with no prior natural or vaccine exposure to the various agents that cause ITB or complicating bacterial infection.⁶ Affected dogs are more likely to have a history of recent stays in a pet shop, boarding facility, kennel, or shelter. ITB may be associated with or without rhinitis and accompanying mucoïd to mucopurulent nasal and ocular discharges. Complications associated with bronchopneumonia may become life threatening, particularly in puppies. On physical examination, affected dogs are usually febrile and may be lethargic, anorexic, or dyspneic. Affected dogs are difficult to distinguish from those with CDV infections or other pneumonias. Outbreaks of ITB may affect more than 50% of dogs in a densely populated environment.

Infectious Diseases of the Dog and Cat, 3rd Edition

6.5 DIAGNOSIS

Clinical diagnosis is based on a history of recent exposure to other dogs, signs, and response to empiric therapy. An uncertain vaccination history can be helpful in determining susceptibility. However, a history of recent vaccination (within 6 months) in a dog with characteristic respiratory signs does not exclude a diagnosis of ITB. Routine hematology and biochemistry profiles are not diagnostic but do serve to establish and monitor the health status of affected dogs. A stress leukogram characterized by mature neutrophilia, lymphopenia, and eosinopenia may be evident. An inflammatory leukogram with significant leukocytosis or left shift may be present in dogs with complicating bacterial pneumonia. Fluid obtained from transtracheal aspirates may provide evidence of a neutrophilic exudate. Neutrophils are often degenerate in the presence of numerous extracellular and intracellular bacteria. Bacterial culture of aspirated fluid may be particularly helpful in confirming bacterial pneumonia and prescribing appropriate therapy.²⁶

56

57

Because of indigenous microflora, bacterial isolates obtained from swabs of the nasal and oral cavities, oropharynx, and nasopharynx do not necessarily represent primary or secondary pathogens. However, bacteria cultured from transtracheal aspiration fluid, endotracheal or bronchoalveolar lavage, or sterile swabs of tracheal epithelium are more likely to represent disease-causing organisms. In collecting specimens for *Bordetella* isolation, nasopharyngeal swab collections yield fewer bacteria than does aspiration of lavage fluids because these bacteria adhere to fiber-tipped swabs made of Dacron, alginate, or cotton.²⁵ The best results are improved if a transport medium intended for *Bordetella* is used.

Thoracic radiographic findings are typically unremarkable in animals with uncomplicated ITB. Dogs with complications associated with ITB may have radiographic signs of pulmonary hyperinflation and segmental atelectasis. Dogs with combined *B. bronchiseptica* and CPiV infections may develop lobar consolidation evident on thoracic radiographs.

Although uncommonly performed on clinical patients, viral isolation of CPiV or CAV-2 can be accomplished on swabs taken from the nasal, pharyngeal, or tracheal epithelium. The ability to inhibit virus growth, cytopathic effect, or hemadsorption with a standardized antiserum confirms the diagnosis.⁶ Acute and convalescent serum neutralizing or hemagglutination inhibition antibody titers can be used to establish exposure to any of the viral agents involved in canine ITB. The ability to demonstrate a rising titer, however, has little clinical application because of the relatively short duration of viral infection. Antibody titers to lipopolysaccharide (LPS) antigens of *B. bronchiseptica* had no predictive value in determining which animals will contract respiratory disease, how severe the disease will be, or which dogs have colonization of their lungs.¹¹

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 6-2 Treatment Options for Canine Infectious Tracheobronchitis

DRUG	DOSE ^a (mg/kg)	ROUTE	INTERVAL (HOURS)	DURATION (DAYS)
Antimicrobials				
Amoxicillin-clavulanate	12.5–25.0	PO	12	10–14 (minimum)
Azithromycin	5.0	PO	24	5–7
Trimethoprim-sulfonamide ^b	15	PO	12	10–14 (minimum)
Doxycycline ^c	2.5–5.0	PO	12	10 (minimum)
Enrofloxacin ^d	5.0	PO	24	10
Chloramphenicol ^e	15–25	PO	12	10
Antitussives				
Hydrocodone	0.22	PO	8–12	prn
Butorphanol	0.55	PO, SC	8–12	prn
Glucocorticoids				
Prednisolone	0.25–0.50	PO	12	3–5 days
Bronchodilators				
Aminophylline	10	PO	8–12	prn
Terbutaline	2.5	PO, SC	8–12	prn

PO, By mouth; SC, subcutaneous; prn, as needed.

- a Dose per administration at specified interval. For additional information on antimicrobials, see formulary, [Appendix 8](#).
- b In vitro susceptibility is higher than clinical efficacy since resistance develops rapidly.
- c Dental staining is possible in young (under 16 weeks) animals, although this is less likely than with tetracycline.
- d Adverse effects on cartilage of young growing animals; susceptibility of *Bordetella* isolates (40%–60%) is not as high as with others gram-negative bacteria.
- e High susceptibility of isolates; however causes idiosyncratic aplastic anemia in people and reversible myelosuppression in dogs.

Nested polymerase chain reaction has been shown to be most sensitive in detecting *B. pertussis* in human patients.²⁵

6.6 THERAPY

6.6.1 Antimicrobials

In uncomplicated cases of ITB, the value of antimicrobial therapy appears limited. However, in at least one study,⁵⁰ administration of an oral or a parenteral antibacterial agent reduced the duration of coughing in affected dogs. Drugs found to be particularly effective were trimethoprim-sulfonamide and amoxicillin. Because dogs with clinical signs of ITB may be at increased risk for bacterial bronchopneumonia, administration of empiric antimicrobial therapy is justified even when infections are not complicated by overt bacterial pneumonia.⁵⁴

Systemic antimicrobial therapy is indicated if deeper respiratory or systemic bacterial infection develops, particularly bacterial bronchopneumonia or interstitial pneumonia. Although the antimicrobial prescribed should be ideally based on results of bacterial culture and susceptibility results, in the clinical setting empiric antimicrobial therapy may be most appropriate.^{21,54} [Table 6-2](#) lists appropriate antimicrobials in the empiric

Infectious Diseases of the Dog and Cat, 3rd Edition

treatment of dogs with signs consistent with ITB. With increasing antimicrobial use, more recent isolates of *B. bronchiseptica* from cats in California and Liverpool have been resistant to a large number of antibiotics, including some cephalosporins, fluoroquinolones, and sulfonamides.^{18,45} Isolates from dogs in Liverpool and California were sensitive to doxycycline, amoxicillin-clavulanate, and enrofloxacin.^{3,46}

57

58

6.6.2 Glucocorticoids

Antiinflammatory doses (see Table 6-2) of orally administered glucocorticoids are effective in ameliorating the cough associated with uncomplicated cases of ITB. Orally administered prednisolone can be used as needed to suppress coughing for periods of up to 5 to 7 days. However, glucocorticoids do not significantly shorten the clinical course.⁵⁰ In contrast to previous claims,⁵² no controlled studies substantiating the value of intratracheal administration of glucocorticoids over oral administration have been conducted.

6.6.3 Antitussives

Antitussives, alone and in combination with bronchodilators, have been recommended in the treatment of canine ITB. Objectively, these drugs are intended to interrupt the cough cycle; however, certain limitations to antitussive therapy should be noted. Over-the-counter cough suppressant drugs appear to offer little or no relief from the cough associated with ITB. Narcotic cough suppressants, such as hydrocodone, are generally effective in suppressing cough frequency and intensity. However, excessive or prolonged use of these drugs can lead to compromised ventilation and reduced expectoration, with subsequent retention of respiratory secretions and diminished clearance of bacteria.^{6,49,50} In cases of ITB that are complicated by bacterial pneumonia, administration of narcotic antitussives is not recommended.

6.6.4 Bronchodilators

The methylxanthine bronchodilators, theophylline and aminophylline (theophylline-ethylenediamine), prevent bronchospasm and may therefore be effective cough suppressants in selected conditions, such as occurs in human asthma. However, dogs with signs of ITB are not expected to derive significant benefit from bronchodilator therapy alone.

6.6.5 Aerosol Therapy

Aerosol therapy (or nebulization) refers to the production of a liquid particulate suspension within a carrier gas, usually oxygen. Patients with ITB that derive the most benefit from aerosol therapy are those with excessive accumulations of bronchial and tracheal secretions and those with secondary bronchial or pulmonary infections, particularly with *B. bronchiseptica*. Small, disposable, hand-held jet nebulizers are inexpensive and available through hospital supply retailers. From 6 to 10 ml of sterile saline can be nebulized over 15 to 20 minutes one to four times daily. Oxygen is delivered at flow rates of 3 to 5 L/min to nebulize the solution. Aerosol therapy must be administered in the hospital. Most patients tolerate aerosol therapy well and generally do not require physical restraint after the first treatment.

There is no value in nebulizing mucolytic agents, for example, acetylcysteine, which can be irritating and induce bronchospasm. Furthermore, liquefying tenacious respiratory secretions may not be an effective means of facilitating airway clearance. Nebulization of glucocorticoid solutions, such as methylprednisolone sodium

Infectious Diseases of the Dog and Cat, 3rd Edition

succinate, has not been critically studied in veterinary medicine. However, in acute paroxysms of cough that may lead to or predispose the animal to airway obstruction, such therapy may provide short-term benefits.

Dogs that are unresponsive to oral or parenteral administration of antibiotics may respond to nebulized antibiotics. Aerosolized nonabsorbable antibiotics, such as kanamycin, gentamicin, and polymyxin B, have been shown to be effective in reducing the population of *B. bronchiseptica* in the trachea and bronchi of infected dogs for up to 3 days after discontinuation of treatment.⁷ Although clinical signs are not eliminated, the severity of signs may be significantly reduced.

6.6.6 Supportive Care

Supportive treatment of the individual dog with ITB is directed at maintaining adequate caloric and fluid intake during the acute infection; preventing secondary or opportunistic bacterial infections, especially pneumonia; suppressing the cough; and reducing exposure to other dogs. When practical, this treatment is better accomplished in the owner's home rather than in a kennel or veterinary hospital. This approach can reduce the potential spread of infection by separating affected dogs from susceptible ones.

6.7 TREATMENTS NOT RECOMMENDED

Considering the fact that canine ITB represents a significant percentage of the total cases of infectious upper respiratory disease in dogs, it is not unusual that creative therapeutic modalities have been administered in an attempt to shorten the course of disease and minimize the clinical signs. The treatments listed in this chapter are largely anecdotal, have not been subjected to scientific scrutiny, and at this time are *not* recommended in the treatment of canine ITB.

6.7.1 Antiviral Therapy

Given that at least three agents associated with canine ITB are viruses (CPiV, CAV-2, and CDV), the administration of various antiviral drugs approved for use in humans has been suggested for use in dogs with ITB. However, antiviral therapy is highly specific and is generally targeted at specific viruses. In veterinary medicine, antiviral therapies for use against viruses associated with canine ITB are not available. At this time, no human antiviral therapy is recommended for use in either the dog or the cat.

6.7.2 Intranasal Vaccination

Unpublished and anecdotal reports from veterinarians have suggested that some dogs with ITB may derive therapeutic benefit from administration of a single dose of an intranasal (IN) *B. bronchiseptica* vaccine. Experience with this treatment modality in outbreaks of canine ITB within a shelter environment have not been shown to diminish the intensity of clinical signs or to shorten the course of disease. Also suggested is that dogs experiencing chronic or persistent cough beyond the expected recovery time for acute ITB may benefit from *therapeutic* vaccination. To date, no controlled studies have been done to support this recommendation. Because attenuated *B. bronchiseptica* vaccines in themselves produce mild respiratory signs, vaccination of already ill animals may cause more severe respiratory illness.

Infectious Diseases of the Dog and Cat, 3rd Edition

6.7.3 Expectorants

A variety of over-the-counter expectorants have been used in canine ITB to facilitate the clearance of mucous secretions within the trachea and bronchi. Saline expectorants, guaifenesin, and volatile oils that can be inhaled as a vapor are intended to stimulate secretion of the less viscous bronchial mucus and, thereby, enhance clearance of viscous respiratory secretions. However, the value of expectorant therapy in dogs with ITB has not been established and is not currently recommended. Numerous over-the-counter cough suppressant medications are available and are occasionally administered to coughing dogs. The author's experience with these products suggests that they offer little to no physical benefit in ameliorating the clinical signs associated with ITB.

58

6.8 PREVENTION

59

6.8.1 Maternal Immunity

Maternal immunity to the viruses known to cause canine ITB provides variable degrees of protection. Maternally derived CPiV antibody does not appear to interfere with parenteral vaccination of puppies that are 6 weeks of age and older.⁵ In contrast, maternal antibody interference to parenteral CAV-2 vaccination can persist for as long as 12 to 16 weeks, but it does not protect against infection.⁴

6.8.2 Natural Immunity

The duration of immunity after recovery from CPiV and CAV-2 infection has not been studied, although one unpublished study documented CPiV neutralizing antibody 2 years after infection in dogs that were not reexposed to virus.⁶ However, enzyme-linked immunosorbent assay–based antibody titers to LPS did not correlate to the degree of protection in infected dogs in one outbreak.¹¹ Dogs that have recovered from *B. bronchiseptica* infection are highly resistant to reinfection for at least 6 months.⁷ However, the level of protection derived from infection should be expected to vary, depending on the age and health status of the individual animal, the viruses and bacteria involved, and the opportunity for reexposure.

6.8.3 Vaccination

Both viral and bacterial vaccines are available against most of the agents having a known pathogenic role in canine ITB. Various *B. bronchiseptica*, CAV-2, and CPiV vaccines are licensed for parenteral administration or for IN administration to dogs. Intranasal vaccines are attenuated and those for parenteral use are inactive whole cell or cellular antigenic extracts (Table 6-3). Vaccines must be administered only by the route indicated on the package label (vaccine insert). Currently, no vaccine has been approved for administration by both routes. CDV, CAV-2, and CPiV vaccines are commonly incorporated into routine vaccine protocols recommended for all dogs (see Table 6-3). *B. bronchiseptica* bacterins are in widespread use throughout the United States; no commercial vaccine is currently in use for protecting dogs against *Mycoplasma* sp. For a listing of some currently available vaccines, see Table 6-4 and Appendix 3. For further recommendations on vaccination for ITB, see Chapter 100 and Appendix 1.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 6-3 Types of Licensed Vaccine for Protection of Dogs Against *Bordetella bronchiseptica*, Canine Parainfluenza Virus, and Canine Adenovirus-2

VACCINE	VOLUME/ROUTE ^a	MINIMUM AGE AT FIRST DOSE	INITIAL SERIES
<i>B. bronchiseptica</i> (killed-extracted cellular antigens)	1 ml parenteral (SC only)	8 weeks	2 doses, 2–4 weeks apart
<i>B. bronchiseptica</i> (a virulent live culture) plus MLV CPiV, CAV-2, CDV	1 ml parenteral SC or IM	Not stipulated (8 weeks recommended)	2 doses, 2–4 weeks apart. Dogs vaccinated before the age of 4 months should receive a single dose on reaching 4 months of age.
<i>B. bronchiseptica</i> (avirulent live culture) plus MLV CPiV	0.4 or 1.0 ml, depending on manufacturer IN	2 or 3 weeks, depending on manufacturer	1 dose (NOTE: some manufacturers stipulate a second dose at 6 weeks of age in puppies that receive the first dose between 3 and 6 weeks of age.)
<i>B. bronchiseptica</i> (avirulent live culture) plus MLV CPiV, CAV-2	0.4 or 1.0 ml, depending on manufacturer IN	3 or 8 weeks, depending on manufacturer	1 dose
CPiV, Canine parainfluenza virus, CAV-2, canine adenovirus-2; CDV, canine distemper virus; IM, intramuscular; SC, subcutaneous; IN, intranasal.			

a When the vaccine manufacturer stipulates the route of administration for a particular vaccine, optional routes are not indicated.

Despite the numerous monovalent and combined canine vaccines on the market today, only *B. bronchiseptica* vaccination has been recently evaluated for efficacy against a defined challenge.^{12,15,16} Studies support the fact that *B. bronchiseptica* vaccines, whether administered by the parenteral or IN route, are effective in providing substantial reduction in clinical signs associated with ITB in puppies challenged under laboratory conditions. Vaccinating seronegative puppies by *both* routes sequentially appears to provide a *greater* degree of protection compared with puppies vaccinated by *either* the parenteral or IN route alone (compare Figs. 6-3 and 6-4).¹⁵ When the disease prevalence is high in an environment, current protocols should be modified to use *at least* two parenteral and one intranasal vaccine during the primary vaccination series. For adult dogs, annual vaccination with parenterally administered products can be used in addition to intranasal vaccination before anticipated exposure.

On the other hand, administering *B. bronchiseptica* vaccine sequentially by the parenteral and IN routes to adult, seropositive (previously vaccinated) dogs does not appear to effectively boost systemic antibody titers. In fact, administration of IN vaccines to adult, seropositive dogs may *not* be effective as a booster inoculation.¹⁶ Parenterally administered (subcutaneous) *B. bronchiseptica* vaccine, on the other hand, has been shown to boost antibody levels in previously vaccinated or exposed dogs.¹⁶ These findings are in contrast to previous reports suggesting that vaccine administered by the IN route induce both local and systemic immunity and protect against challenge more rapidly than parenterally administered vaccines.^{7,26,48} Depending on the vaccine, puppies inoculated by the IN route can be immunized as early as 2 to 3 weeks of age.

a See [Appendix 3](#) for further information on these products and manufacturers.

Fig 6-3 Photomicrograph of a section of trachea from a pup that was vaccinated IN with modified-live, and intramuscularly with inactivated *B. bronchiseptica* and was euthanatized 10 days after challenge exposure. The absence of bacterial colonies is noted on the epithelium. Bar, 100 μ m. (From Ellis JA, Haines DM, West KH, et al. 2001. Effect of vaccination on experimental infection *Bordetella bronchiseptica* in dogs, *J Am Vet Med Assoc* 218:367-375, with permission.)

Fig 6-4 Photomicrograph of a section of trachea from an unvaccinated control pup that was euthanatized 10 days after challenge exposure with *B. bronchiseptica*. Numerous brown-stained bacterial colonies are noted on the epithelium. Immunohistochemical stain; Bar, 100 μ m. (From Ellis JA, Haines DM, West LK et al. 2001. Effect of vaccination on experimental infection *Bordetella bronchiseptica* in dogs, *J Am Vet Med Assoc* 218:367-375, with permission.)

Many parallels can be drawn between *B. bronchiseptica* vaccination for kennel cough for dogs and *B. pertussis* vaccination for whooping cough in people. Vaccines for *B. bronchiseptica* were originally developed based on the genetic homogeneity of the bacteriocin. As for *B. pertussis*, antigenic divergence of strains is one reason for outbreaks that have occurred following vaccination.³⁷ Similarly, in a genetic study of more recent *B. bronchiseptica* isolates from dogs, the genotypic polymorphism of encoding for outer membrane proteins were much more heterogeneous than the original licensed vaccine strains.²⁸ Another problem in people is that primary vaccination has been restricted to children, and waning immunity has occurred beginning in adolescence and an increasing exposure.³¹ The problem of immune senescence may be overcome by broadening recommendations to use boosters in adults at risk with newly developed parenteral acellular products that are less reactogenic. In animals, vaccine development shifted to the use of IN-attenuated products. In the future, purified acellular

60

61

Infectious Diseases of the Dog and Cat, 3rd Edition

vaccines may solve the dilemma of being highly immunogenic for extended immunity with little risk of postvaccinal illness.

Annual revaccination is recommended for dogs considered at risk for exposure. Before known or potential exposure to other dogs (e.g., boarding), a single booster vaccination, administered IN, is recommended at least 5 days before exposure in dogs that have not been vaccinated within the preceding 6 months.^{7,16} Vaccination has not been proven to provide any therapeutic effect in dogs with active infection.

The occurrence of adverse reactions after administration of parenteral vaccine for canine ITB is rare and typically is limited to local irritation at the injection site. In contrast, IN vaccines can be associated with development of a cough or nasal discharge (or both) 2 to 5 days after inoculation, sometimes longer. Postvaccinal signs will rarely be sufficiently severe or persistent that administration of an antimicrobial will be indicated. Occurrence of postvaccinal cough in dogs inoculated by the IN route can have significant implications in animal shelters because it may be difficult to distinguish vaccinates from clinically affected dogs. Inadvertent subcutaneous inoculation of an attenuated IN CPiV-2 and *B. bronchiseptica* vaccine resulted in local inflammation and acute nonseptic hepatocellular degeneration and necrosis.⁵¹

An experimental IN vaccine against *B. bronchiseptica* has been developed by selective inactivation of the *aroA* gene a known virulence gene in *Bordetella* that enables colonization of the respiratory tract.⁴⁷ The vaccine induced higher antibody titers and resulted in lower bacterial counts in the respiratory tract of experimentally challenged mice. Clinical signs were avoided in vaccinates in this rationally attenuated vaccine.

6.8.4

Management of Outbreaks

Environments in which transient dogs are housed in adjoining kennels are conducive to efficient and rapid transmission of the agents capable of causing canine ITB. Although important in preventing infections, vaccination may not guarantee protection against development of signs, particularly in high-density populations. Because airborne transmission is common, dogs suspected of having contagious respiratory disease should be isolated when signs first develop in an effort to limit exposure to susceptible dogs. Thorough, routine cleaning of housing facilities, preferably using fresh sodium hypochlorite, chlorhexidine, or benzalkonium solution, is necessary to control the spread of ITB. Disinfection of surfaces is important to remove pathogenic viruses and bacteria; however, airborne spread from respiratory discharges of infected animals poses the greatest risk for exposure. Adequate ventilation, from 12 to 20 air exchanges per hour,^{6,26} is recommended in kennel or shelter facilities. To further limit exposure, relative humidity should be maintained between 50% and 65%, with ambient temperature between 21° C and 23.8° C. No evidence exists that IN vaccination, administered when clinical signs are exhibited, will alter the course of an outbreak.

Once an outbreak has developed, isolating or depopulating the entire facility for up to 2 weeks may be the only reasonable and most efficacious method of containing infections. This measure is necessary because clinically healthy previously infected dogs can be shedding organisms in low numbers. In addition to extensive cleaning, individual dogs are treated as necessary to manage clinical signs.

Animal facilities that maintain a large number of dogs, especially transient populations, are at considerable risk for canine ITB outbreaks. A reduction in the incidence of ITB has been observed in dogs whose vaccinations for all infections were current. However, attempts to prevent outbreaks through routine, widespread IN vaccines may be ineffective if vaccination and exposure are likely to occur within the same day. Furthermore, postvaccinal coughing or nasal discharge may preclude adoption of otherwise healthy dogs from impoundment facilities. In addition to vaccination, adequate housing, proper cleaning, and adequate ventilation are critical factors in

Infectious Diseases of the Dog and Cat, 3rd Edition

preventing outbreaks of ITB whenever dogs are housed within crowded environments. For further information, see [Chapter 98](#).

6.9 PUBLIC HEALTH CONSIDERATIONS

The zoonotic potential of canine *B. bronchiseptica* infection has been reviewed.^{16,19,58,59} Over the last several years, reports of human respiratory infections caused by *B. bronchiseptica* continue to appear in the human literature. At greatest risk are individuals who are immunosuppressed resulting from conditions related to alcoholic malnutrition, hematologic malignancy, long-term glucocorticoid therapy, concurrent human immunodeficiency virus infection, splenectomy, and pregnancy. As expected, individuals subjected to tracheostomy or endotracheal tube intubation are also at risk for infection. Humans with preexisting respiratory disease, such as chronic bronchitis, bronchiectasis, and pneumonia, are particularly susceptible. Although human bordetellosis has been associated with a variety of domestic and wildlife animal species, transmission of disease from pets to humans is largely circumstantial. In one instance, infection associated with exposure to rabbits was found to persist in a person with bronchopneumonia for at least 2.5 years.²⁴

Estimates suggest that up to 40% of immunocompromised adults living in the United States today have pets.² A logical assumption therefore is that, as pet owners, these individuals may be at increased risk of acquiring opportunistic zoonotic infections.* The risk of a child or immunocompromised adult becoming infected with pet-associated *B. bronchiseptica* infection must be considered small, particularly when exposure to a large number of dogs in kennels and animal shelters can be avoided. For further discussion concerning immunocompromised people and pets, see [Chapter 99](#).

7 CHAPTER 7 Nonrespiratory Parainfluenza Virus Infection of Dogs

Craig E. Greene

7.1 ETIOLOGY

Canine parainfluenza virus (CPiV) is a member of the family *Paramyxoviridae*, which includes canine distemper virus, simian virus 5 (SV-5), and human measles and mumps viruses. Human, simian, and canine type 2 parainfluenza viruses have all been called *SV-5-like viruses* because of their close antigenic relationship. Monoclonal antibody studies have shown minor antigenic differences between SV-5 isolates.¹¹ Whether different SV-5 isolates are transmitted among people, nonhuman primates, and dogs remains to be established. The virus associated with respiratory disease in dogs is CPiV,⁵ which causes an acute, self-limiting cough in the syndrome of canine infectious tracheobronchitis (ITB, see [Chapter 6](#)) and is recognized worldwide as an important cause of respiratory disease in dogs.^{1,10} Serologic studies indicate that the overall prevalence of CPiV in the canine population is high but variable. Experimental inoculation of CPiV in newborn pups can cause viral spread to internal tissues. Evidence shows that related but distinct paramyxoviruses may cause systemic or nonrespiratory infections in older dogs.⁶ In addition, parainfluenza virus was consistently isolated from the prostatic fluid of a dog.¹²

7.2 CLINICAL FINDINGS

A parainfluenza virus variant was isolated from the cerebrospinal fluid (CSF) of a 7-month-old dog with ataxia and paraparesis lasting 3 to 4 days.⁷ The dog had been vaccinated against canine distemper at 7.5 weeks of age. Gnotobiotic puppies inoculated intracerebrally with this virus isolate developed two forms of clinical illness.^{3,4} Some developed acute encephalitis characterized by seizures, myoclonus (involuntary rhythmic muscle contractions), and progressive neurologic signs within a few days after inoculation. Five of six inoculated dogs observed for 6 months after inoculation developed internal hydrocephalus, although clinical signs were not noted at the time. The hydrocephalus was thought to result from ependymitis with decreased absorption of CSF, with or without aqueductal obstruction (see [Chapter 84](#) for an additional discussion about this type of hydrocephalus from suspected infectious causes). Seven-week-old seronegative ferrets intracerebrally inoculated with this CPiV isolate have also been found to develop a self-limiting nonsuppurative ependymitis and choroiditis.² A 6-week-old puppy was found in extremis as a result of acute hemorrhagic enteritis.⁴ Although a paramyxovirus variant was isolated, it has not been confirmed that it was responsible for the clinical illness.

At present, it is uncertain whether the central nervous system or gastrointestinal forms of disease caused by paramyxoviral variants occur with any frequency under natural circumstances. Neurologic illness has been more commonly recognized as a complication of other paramyxovirus infections, such as with canine distemper in dogs (see [Chapter 3](#)) and in people with measles and mumps viruses (see [Chapter 25](#)). In laboratory rodents, other paramyxoviruses have been shown to produce encephalitis and hydrocephalus that are very similar to those that result when the paramyxoviral variant is injected into dogs. Naturally occurring encephalitis, periventriculitis, and hydrocephalus of a suspected bacterial origin have been described in young dogs (see [Periventricular Encephalitis, Chapter 84](#)).

Infectious Diseases of the Dog and Cat, 3rd Edition

7.3 DIAGNOSIS

Paramyxovirus-induced encephalitis or hydrocephalus may be confirmed serologically by the hemagglutination inhibition assay; however, because of the high prevalence of antibody in canine populations and the routine use of a vaccine for CPiV, confirmation requires demonstration of a rising serum antibody titer. CSF antibody titer to this variant virus was shown to remain persistently high in dogs after experimental infection.⁷ Viral isolation can be performed using CSF or brain tissue of infected dogs. In addition, direct fluorescent antibody methods can be used to detect viruses in nervous tissue. For cases of enteritis, virus isolation and electron microscopy of feces would be most valuable. Serologic techniques such as virus neutralization or HI must be used to distinguish these variant paramyxoviral strains from CPiV.

7.4 PATHOLOGIC FINDINGS

Gross pathologic findings have been identified only in experimentally infected dogs that became hydrocephalic. Moderately enlarged lateral and third ventricles are present. Microscopically, acute meningoencephalitis was characterized by multifocal neuronal necrosis, lymphoplasmacytic cellular infiltrates, and reactive gliosis. Focal ependymitis was also apparent. Flattening and discontinuities of the ependymal cells lining the ventricles were seen in dogs developing hydrocephalus. Ultrastructurally, the virus could not be found in the brains of dogs developing hydrocephalus and encephalitis that were examined 1 to 6 months after experimental infection. In the previously mentioned puppy with enteritis, the intestinal and gastric contents were blood tinged. Atrophy of small intestinal villi, mucosal congestion, and lymphoid necrosis were noted.

7.5 THERAPY AND PREVENTION

The prevalence of paramyxoviral variant diseases is unknown at present, and they have no known treatment. It is possible that the CPiV vaccine, which was developed for ITB (see [Chapter 6](#)), may help to prevent these other paramyxoviral diseases.

8 CHAPTER 8 Canine Viral Enteritis

Dudley L. McCaw

Johnny D. Hoskins

Since the late 1970s, viral enteritis has become recognized as one of the most common causes of infectious diarrhea in dogs younger than 6 months. Canine parvovirus (CPV)–1 and –2), canine coronavirus (CCV), and canine rotaviruses (CRVs) have been incriminated as primary pathogens. Astrovirus, herpesvirus, enteroviruses, calicivirus, parainfluenza viruses, and viruslike particles have been isolated from or identified in feces from dogs with diarrhea, but their pathogenicity is uncertain.^{21,29,51}

8.1 CANINE PARVOVIRAL ENTERITIS

8.1.1 Etiology

CPVs are small, nonenveloped, DNA-containing viruses that require rapidly dividing cells for replication (Fig. 8-1). As is the case with all parvoviruses, CPV-2 and -1 are extremely stable and are resistant to adverse environmental influences. CPV-2 is known to persist on inanimate objects, such as clothing, food pans, and cage floors, for 5 months or longer.

Most common detergents and disinfectants fail to inactivate CPVs. A noteworthy exception is sodium hypochlorite (1 part common household bleach to 30 parts water), which is an effective and inexpensive disinfectant. It is important that exposure to this disinfectant be prolonged (at least 10 minutes) and thorough.

Canine parvoviral enteritis is probably one of the most common infectious disorders of dogs. This highly contagious, often fatal disease is caused by CPV-2. Since its emergence in the late 1970s, CPV-2 has undergone genetic alterations in the dog, with development of new strains of the virus.^{90,91,93} In 1980, the original strain of CPV-2 evolved into type 2a (CPV-2a); and in 1984, another variant designated type 2b (CPV-2b) appeared. These CPV-2 alterations were associated with a genetic adaptation, enabling the parvovirus to replicate and spread more effectively in susceptible dogs. In the United States and Japan, CPV-2b has largely replaced those previously isolated strains, whereas in the Far East^{10,68} and Europe,^{17,26} both CPV-2a and -2b predominate.²⁴ In 2000, another strain was reported (CPV-2c), which was an adaptation that allowed infection of cats.⁴⁴ Although CPV-2c has been isolated only from leopard cats, infection in domestic cats and dogs is likely.⁴⁴ Genetic mutations in the structure of the surface transferrin receptor (TfR) of the virus has resulted in structural alterations that control the host adaptation of CPV strains.⁴¹ For a further discussion of CPV strains in cats, see Canine Parvovirus Infection of Cats in [Chapter 10](#).

8.1.2 Epidemiology

Natural CPV-2 infections have been reported in domestic dogs, bush dogs (*Speothos venaticus*), coyotes (*Canis latrans*), crab-eating foxes (*Cerdocyon thous*), and maned wolves (*Chrysocyon brachyurus*); and most if not all Canidae are susceptible. Experimental infections can be produced in domestic ferrets, mink, and cats; however, the infection is generally self-limiting. The original CPV-2 isolates produced only systemic and intestinal infections in dogs,¹²⁸ whereas the newer type 2a and 2b strains may infect felines under experimental^{68,73,131}

Infectious Diseases of the Dog and Cat, 3rd Edition

and natural^{71,127} circumstances (see [Chapter 10](#)). In domestic dogs, CPV-2 infection does not necessarily result in apparent disease; many dogs that become naturally infected never develop overt clinical signs. When the disease occurs, clinical illness is most severe in young, rapidly growing pups that harbor intestinal helminths, protozoa, and certain enteric bacteria such as *Clostridium perfringens*, *Campylobacter* spp., and *Salmonella* spp. In susceptible animals, the incidence of severe disease and death can be very high.

CPV-2 is highly contagious, and most infections occur as a result of contact with contaminated feces in the environment. In addition, people, instruments (equipment in veterinary facilities or grooming operations), insects, and rodents can serve as vectors. Dogs may carry the virus on their hair coat for extended periods. The incubation period of CPV-2 in the field is 7 to 14 days; experimentally, the incubation period has been found to be 4 to 5 days. With CPV-2a and -2b strains, the incubation period in the field can be as brief as 4 to 6 days.

Acute CPV-2 enteritis can be seen in dogs of any breed, age, or sex. Nevertheless, pups between 6 weeks and 6 months of age, and Rottweilers, Doberman pinschers, Labrador retrievers, American Staffordshire terriers, German shepherds, and Alaskan sled dogs seem to have an increased risk.^{25,39}

8.1.3

Pathogenesis

CPV-2 spreads rapidly from dog to dog via oronasal exposure to contaminated feces ([Fig. 8-2](#)). Virus replication begins in lymphoid tissue of the oropharynx, mesenteric lymph nodes, and thymus and is disseminated to the intestinal crypts of the small intestine by means of viremia. Marked plasma viremia is observed 1 to 5 days after infection. Subsequent to the viremia, CPV-2 localizes predominantly in the gastrointestinal (GI) epithelium lining the tongue, oral and esophageal mucosae, and small intestine and lymphoid tissue, such as thymus, lymph nodes, and bone marrow. It may also be isolated from the lungs, spleen, liver, kidney, and myocardium.¹³⁸

64

Normally, intestinal crypt epithelial cells mature in the small intestine and then migrate from the germinal epithelium of the intestinal crypts to the tips of the villi ([Fig. 8-3, A](#)). After reaching the villous tips, the intestinal epithelial cells acquire their absorptive capability and aid in assimilating nutrients. Parvovirus infects the germinal epithelium of the intestinal crypts, causing destruction and collapse of the epithelium (see [Fig. 8-3, B](#)). As a result, normal cell turnover (usually between 1 and 3 days in the small intestine) is impaired, and the villi become shortened. CPV-2 also destroys mitotically active precursors of circulating leukocytes and lymphoid cells. In severe infections, the results are often neutropenia and lymphopenia. Secondary bacterial infections from gram-negative and anaerobic microflora cause additional complications related to intestinal damage, bacteremia and endotoxemia, and disseminated intravascular coagulation (DIC).^{84,129,130} Active excretion of CPV-2 begins on the third or fourth day after exposure, generally before overt clinical signs appear. CPV-2 is shed extensively in the feces for a maximum of 7 to 10 days. Development of local intestinal antibody is most likely important in the termination of fecal excretion of parvovirus. Serum antibody titers can be detected as early as 3 to 4 days after infection and may remain fairly constant for at least 1 year.

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 8-1 Structure of parvovirus. (Courtesy University of Georgia, Athens, Ga.)

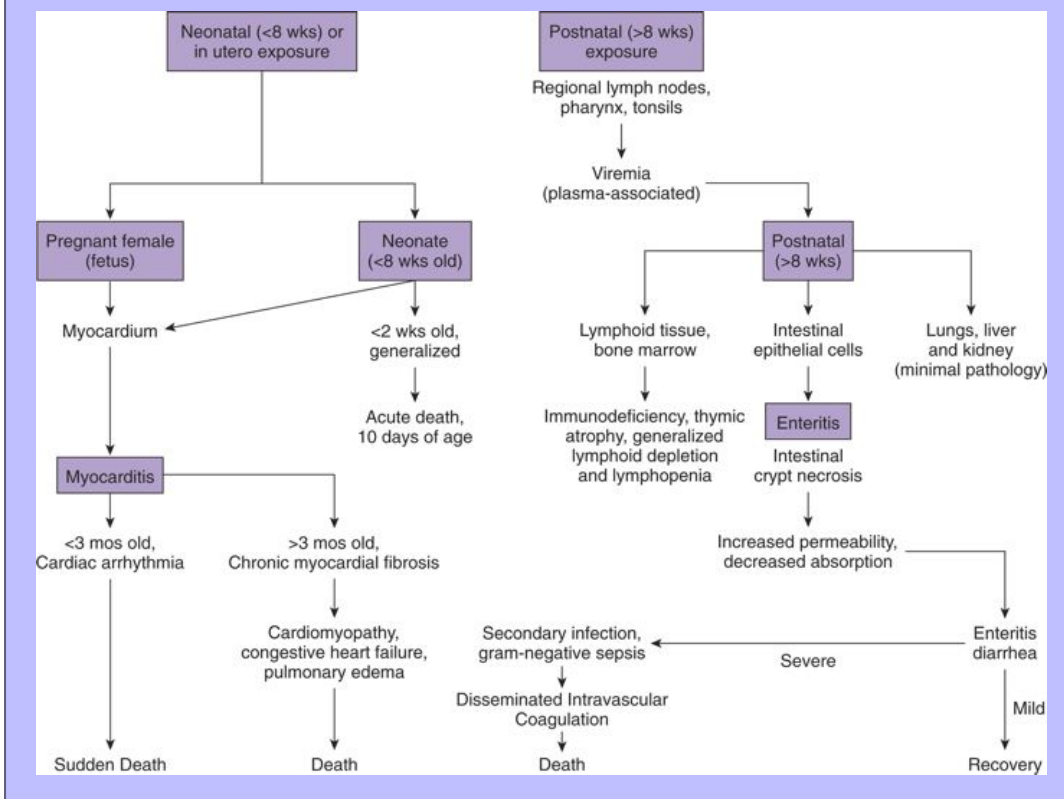

Fig 8-2 Sequential pathogenesis of CPV-2 infection.

Infectious Diseases of the Dog and Cat, 3rd Edition

8.1.4 Clinical Findings

CPV-2 infection has been associated with two main tissues—GI tract and myocardium—but the skin and nervous tissue can also be affected. In addition, other clinical complications of secondary infection or thrombosis can occur. A marked variation is found in the clinical response of dogs to intestinal infection with CPV-2, ranging from inapparent infection to acute fatal disease. Inapparent, or subclinical, infection occurs in most dogs. Severity of the CPV-2 enteritis depends on the animal's age, stress level, breed, and immune status. The most severe infections are usually in pups younger than 12 weeks because these pups lack protective immunity and have an increased number of growing, dividing cells.

64

65

Fig 8-3 Normal intestinal villus showing cellular differentiation along the villus. **B**, Parvovirus-infected villus showing collapse and necrosis of intestinal villus. (Courtesy University of Georgia, Athens, Ga.)

8.1.4.1 Parvoviral Enteritis

CPV-2 enteritis may progress rapidly, especially with the newer strains of CPV-2. Vomiting is often severe and is followed by diarrhea, anorexia, and rapid onset of dehydration. The feces appear yellow-gray and are streaked or darkened by blood (Fig. 8-4). Elevated rectal temperature (40° to 41° C [104° to 105° F]) and leukopenia may be present, especially in severe cases. Death can occur as early as 2 days after the onset of illness and is often associated with gram-negative sepsis or DIC, or both. Younger age, neutropenia, and Rottweiler breed have been associated with a poorer chance of survival (unpublished data).³¹

Infectious Diseases of the Dog and Cat, 3rd Edition

8.1.4.2

Neurologic Disease

Primary neurologic disease may be caused by CPV-2 but more commonly occurs as a result of hemorrhage into the central nervous system (CNS) from DIC or from hypoglycemia during the disease process, sepsis, or acid-base-electrolyte disturbances.¹ Concurrent infection with viruses such as canine distemper virus is also possible. Cerebellar hypoplasia, common in kittens prenatally or neonatally infected with feline panleukopenia virus, has not been adequately reported in pups with CPV-2 infection. CPV DNA was amplified using polymerase chain reaction (PCR) from brain tissue of two dogs with cerebellar hypoplasia, but time of exposure to CPV was not mentioned.¹¹⁴ CPV-2 has been identified in the CNS of cats (see Central Nervous System Infection in [Chapter 10](#)).

Fig 8-4 Dog with severe bloody diarrhea characteristic of severe parvoviral enteritis. (Courtesy University of Georgia, Athens, Ga.)

8.1.4.3

Cutaneous Disease

Erythema multiforme was diagnosed in a dog with parvoviral enteritis.²⁰ Skin lesions included ulceration of the footpads, pressure points, and mouth and vaginal mucosa. Vesicles in the oral cavity and erythematous patches on the abdomen and perivulvar skin were also present. Parvovirus was confirmed in the affected cells by immunohistochemistry.

65

8.1.4.4 Canine parvovirus–2 Myocarditis

CPV-2 myocarditis can develop from infection in utero or in pups younger than 8 weeks. All pups in a litter are usually affected. Pups with CPV-2 myocarditis often die, or they succumb after a short episode of dyspnea, crying, and retching. Signs of cardiac dysfunction may be preceded by the enteric form of the disease or may occur suddenly, without apparent previous illness. The spectrum of myocardial disease in individuals is wide and may include any of the following: acute diarrhea and death, without cardiac signs; diarrhea and apparent recovery followed by death, which occurs weeks or months later as a result of congestive heart failure; or sudden onset of congestive heart failure, which occurs in apparently normal pups at 6 weeks to 6 months of age. Myocarditis is still occasionally found in pups born to isolated, unvaccinated bitches¹³⁵ in contrast to its frequent occurrence during the widespread epizootic outbreaks of the late 1970s in CPV-naive dogs.¹ Myocarditis, with or without enteritis, has been associated with natural CPV-2a and -2b infections in 6- to 14-week-old dogs from Korea.¹³⁹ CPV infection appears not to be a common cause of heart disease because PCR analysis at necropsy of 27 dogs with either dilated cardiomyopathy or myocarditis did not detect CPV in any of the samples.⁶³

8.1.4.5 Thrombosis

Dogs with naturally occurring CPV-2 infections have clinical and laboratory evidence of hypercoagulability.⁸⁶ These dogs may develop thrombosis or phlebitis with catheters or visceral thrombi.

8.1.4.6 Bacteriuria

Asymptomatic urinary tract infection has been detected in approximately 25% of pups following CPV-2 enteritis.⁵⁰ This predisposition was attributed to fecal contamination of the external genitalia in association with neutropenia. Untreated subclinical urinary tract infection may lead to chronic urinary infection as an undesirable consequence.

8.1.4.7 Intravenous Catheter Infection

Bacteria from GI or environmental origin have been isolated from the intravenous (IV) catheters removed from dogs being treated for suspected parvoviral infections.⁵⁵ Most of these organisms were gram-negative types (*Serratia*, *Acinobacter*, *Citrobacter*, *Klebsiella*, and *Escherichia*). Most organisms were resistant to penicillins, first-generation cephalosporins, and macrolides while being susceptible to aminoglycosides, fluoroquinolones, chloramphenicol, potentiated sulfonamides, and clavulanate-potentiated penicillins. Despite the positive culture results of the catheter tips, none of the dogs showed systemic clinical signs of infection, and only one developed local phlebitis.

8.1.5 Diagnosis

The sudden onset of foul-smelling, bloody diarrhea in a young (under 2 years) dog is often considered indicative of CPV-2 infection. However, all dogs with bloody diarrhea (with or without vomiting) are not infected necessarily with CPV-2. Other enteropathogenic bacterial infections should also be considered (see [Chapter 39](#)). All clinical signs characteristic of CPV-2 infection are seldom present at any one time. Leukopenia, although not

Infectious Diseases of the Dog and Cat, 3rd Edition

found in all dogs, is usually proportional to the severity of illness and the stage of disease at the time the blood is taken. Abnormal coagulation test results may include prolongation of the activated partial thromboplastin time, increased thromboelastogram amplitude, and decreased antithrombin III activity.⁸⁶

Fecal enzyme-linked immunosorbent assay (ELISA) antigen tests are available for in-hospital testing for CPV-2 infection (see [Appendix 6](#)). These tests are relatively sensitive and specific for detecting CPV-2 infection.^{38,44,45,52} However, the period of fecal virus shedding is brief; CPV-2 is seldom detectable by 10 to 12 days after natural infection. This corresponds to 5 to 7 days of clinical illness. Positive results confirm infection or may be induced by all attenuated live CPV-2 vaccines (vaccine virus can yield a false-positive result in dogs 5 to 12 days after vaccination); negative results do not eliminate the possibility of CPV-2 infection. Generally, vaccine-induced reactions are weak positive compared with natural infection.

CPV-2 typically produces lesions in the jejunum, ileum, mesenteric lymph nodes, and other lymphoid tissues. CPV-2 can be isolated from these tissues or feces using tissue culture systems, if performed early. Later in the course of disease, virions become coated by antibodies and cleared. In most tissues, intranuclear inclusions are observed. In the glossal epithelium, these may appear as being within the cytoplasm, when in fact they originate in the nuclear space.⁴² Immunochemical methods can also be used to detect virus in tissue culture, electron microscopy (EM) scan of feces or tissues (see Pathologic Findings in this chapter). PCR has been used as a specific and sensitive means of detecting CPV in feces of infected dogs.^{68,73,132} This method can also help to differentiate between virulent and vaccine CPV strains.¹¹⁸

As a general rule, parvoviruses cause hemagglutination of erythrocytes. Inhibition of hemagglutination by CPV-2 antisera can be used to demonstrate serum antibody. The presence of high hemagglutination inhibition (HI) titer in a single serum sample collected after the dog has been clinically ill for 3 or more days is diagnostic for CPV-2 infection. Rising titers (seroconversion) can also be demonstrated when acute and 10- to 14-day convalescent serum samples are compared using either canine or feline parvovirus in HI and virus neutralization (VN) tests. ELISA tests are also available that permit distinction between IgG and IgM.¹¹¹ In-office ELISA test kits are commercially available for semiquantitative IgG and IgM measurements (Immunocomb, Biogal Labs, Megiddo, Israel)^{137,136} and for determining adequate IgG titers for vaccination (CPV/CDV Test Kit, Synbiotics, San Diego, Calif.). See [Appendix 6](#) for further information on these products.

8.1.6

Pathologic Findings

Early lesions are most pronounced in the distal duodenum; later, the jejunum is more severely affected. The intestinal wall is generally thickened and segmentally discolored, with denudation of intestinal mucosa and the presence of dark, sometimes bloody, watery material within the stomach and intestinal lumen ([Fig. 8-5](#)). In mild cases, the lesions are not easy to distinguish from those of nonspecific enteritis. Enlargement and edema of thoracic or abdominal lymph nodes have been observed.

The intestinal lesions are characterized by necrosis of the crypt epithelium in the small intestine. Intranuclear viral inclusion bodies may be seen in these epithelial cells and throughout the squamous epithelia of the upper GI tract.⁶² The pathologic changes may range from mild inflammation to diffuse hemorrhagic enteritis. The villi are shortened or obliterated, owing to lack of epithelial replacement by maturing crypt cells, resulting in collapse of the lamina propria ([Fig. 8-6](#)). Necrosis and depletion of the lymphoid tissue (e.g., Peyer's patches; mesenteric lymph nodes, thymus, and spleen) are present. Pulmonary edema or alveolitis may be observed in dogs dying of complicating septicemia.¹³⁰ Histologic examination is usually definitive; however, specific identification of

Infectious Diseases of the Dog and Cat, 3rd Edition

parvovirus in tissue specimens can be done by immunofluorescence or other immunochemical methods. Using	66
indirect fluorescent antibody (FA) testing, antigen in dogs with lethal CPV enteritis can be found in the dorsal	67
side of the tongue (96.3%), pharynx (81%), esophagus (50%), ventral tongue (20.4%), planum nasale (5.6%),	
small intestinal mucosa (85.2%), bone marrow (81.6%), spleen (79.6%), thymus (66.7%), mesenteric nodes	
(50.4%), palatine tonsils (58.5%), and myocardium (1.9%). ¹³⁸ In situ hybridization is a valuable specific tool for	
virus identification in formalin-fixed or wax-embedded tissue specimen. ¹³⁴

Parvoviral myocarditis, when present, is recognized grossly as pale streaks in the myocardium (Fig. 8-7). The myocardial lesions consist of a nonsuppurative myocarditis with multifocal infiltration of lymphocytes and plasma cells within the myocardium. Basophilic intranuclear inclusion bodies have been observed in cardiac muscle fibers, and parvovirus particles have been demonstrated by EM and by in situ hybridization¹³⁵ in the inclusion bodies.

Fig 8-7 Heart from a dog that died of the myocardial form of CPV-2 infection. Pale streaking of the myocardium is apparent. A similar lesion will be noted with CPV-1 infection in puppies younger than 3 weeks. (Courtesy Pfizer Animal Health, Lincoln, Neb.)

Infectious Diseases of the Dog and Cat, 3rd Edition

8.1.7

Therapy

The primary goals of symptomatic treatment for CPV-2 enteritis are restoration of fluid and electrolyte balance and preventing secondary bacterial infections. Antimicrobial agents, motility modifiers, and antiemetic agents are given in [Table 8-1](#). Fluid therapy is probably the single most important aspect of clinical management and should be continued for as long as vomiting or diarrhea (or both) persists. Hypoglycemia and hypokalemia are common and should be corrected through additions to the IV fluids. Antimicrobial agents are recommended because the combination of severe disruption of the intestinal epithelium allowing bacteria into the blood and peripheral neutropenia increases the risk of sepsis.¹⁰⁸ The most common bacteria appear to be *Escherichia coli* and *Clostridium perfringens*.^{129,130} The best antibacterial spectrum is provided by combination of a penicillin and an aminoglycoside. Before a nephrotoxic drug such as an aminoglycoside is administered, the patient should be fully hydrated. Antiemetic drugs are helpful to reduce fluid loss and decrease patient distress and allows for enteral nutrition. Metoclopramide hydrochloride and prochlorperazine have proved helpful in most dogs with persistent vomiting. The serotonin receptor antagonists are the most efficacious antiemetics.^{57,83} Ondansetron and dolasetron have both been used in dogs. Drug therapy to alter gut motility is seldom recommended in the treatment of CPV-2 enteritis. If needed, narcotic antispasmodics (e.g., diphenoxylate hydrochloride, loperamide hydrochloride) are preferred when motility modifiers are needed.

Although withholding food and water are general recommendations in treating GI diseases, including parvovirus enteritis, recent information suggests this is not necessary. When dogs with parvovirus enteritis were fed beginning on the first day of treatment (via nasoesophageal tube), their recovery time was shortened, and they maintained body weight when compared with dogs that were treated the conventional method of withholding food until signs had ceased for 12 hours.⁷⁵

After GI signs abate, a broad-spectrum dewormer and treatment for *Giardia* infection should be given. During the initial stage of CPV-2 enteritis, recommended adjunctive therapy has included transfusion of specific hyperimmune plasma or administration of antiendotoxin sera¹⁸ (see Passive Immunization, [Chapter 100](#), and Drug Formulary, [Appendix 8](#)). These adjuncts reportedly decrease mortality and the length of hospitalization¹⁸ but are expensive. A recombinant bactericidal-permeability-increasing (BPI) protein, which counteracts endotoxin, did not alter clinical outcome or survival in dogs naturally infected with CPV-2.⁸⁵ This result is despite increases in plasma endotoxin in affected animals.

- a Dose per administration at specified interval. For additional information on these drugs, see Drug Formulary, [Appendix 8](#).
- b Slow infusion can be used for severe vomiting.
- c Administered after correction of dehydration.
- d Administered over 4 hours.
- e SEPTI-SERUM; Immvac Inc., Columbia, MO.
- f Hetastarch or Dextran 70.

Recombinant human granulocyte colony-stimulating factor (G-CSF) has been advocated for the treatment of severe neutropenias induced by CPV-2 infection.²² However, supplementing recombinant human G-CSF to neutropenic pups with CPV-2 infection did not change any aspect of their clinical outcome.^{67,109,110} The lack of efficacy of exogenous G-CSF is probably the result of already existent high levels of endogenous G-CSF that are maximally stimulating the production of neutrophils.¹¹

Dogs with experimental and natural parvovirus infection have been treated with recombinant feline IFN- ω in high IV dosages (2.5×10^6 units/kg) beginning early (4 days or less after infection) in the course of parvoviral

Infectious Diseases of the Dog and Cat, 3rd Edition

infection.^{15,45,60,66} Reduced signs of clinical illness and mortality were observed in treated dogs. See Drug Formulary, [Appendix 8](#) for further information on its availability and usage.

Several therapies have been recommended and empirically would seem of benefit, but they have not been examined well enough to indicate that they are efficacious.⁵⁶ Some puppies are severely anemic, which may be the result of GI loss of blood caused by the parvovirus enteritis, or it might be unrelated to parvovirus such as parasitism. Transfusion of whole blood might benefit these puppies. Hypoproteinemia is present in some puppies. A whole blood transfusion will help resolve the problem, but if erythrocytes are not needed, a more appropriate therapy is plasma transfusion. Ideally, serum albumin concentration should be maintained at 2.0 g/dl or greater. If edema is present as a result of decreased proteins and is not corrected by a plasma transfusion, then synthetic colloid such as hetastarch should be considered. Colloids should not be given until dehydration is corrected. Glucocorticoids and flunixin meglumine may have beneficial effects in treating early sepsis or endotoxemia. These agents should not be used until dehydration is corrected, and repeated doses should not be given.

68

69

The use of hyperimmune plasma might be questioned because, at the time of clinical signs, the levels of antibodies are generally increased. However, pups that had a delayed or lower response are often more severely affected. Canine lyophilized IgG has been beneficial in treatment of dogs with naturally occurring CPV-2 infection.⁵⁸ Compared with control dogs, those receiving IgG as adjunctive therapy had reduced severity of disease, reduced cost of treatment, and reduced hospitalization time.

Pups that survive the first 3 to 4 days of CPV-2 enteritis usually make a rapid recovery, generally within 1 week in uncomplicated cases. Severely ill pups that develop secondary sepsis or other complications may require prolonged hospitalization.

8.1.8 Prevention

8.1.8.1 Immunity After Infection

A puppy that recovers from CPV-2 enteritis is immune to reinfection for at least 20 months and possibly for life. On reexposure to the various strains of CPV-2, protected pups will not have increased serologic titers, show overt signs of illness, or shed virus in the feces. In general, a good correlation exists between serum antibody titer, determined by either HI or VN testing, and resistance to infection. Serum antibody titers remain high for a prolonged period after CPV-2 enteritis, even if reexposure does not occur. If serum antibody titers become low, a localized infection is possible, but viremia and generalized illness are unlikely to develop. Although it may help in protection against entry of CPV-2, intestinal secretory IgA probably does not play a role in the longevity of protective immunity because intestinally derived antibody titers do not persist for longer than 15 days after infection.

8.1.8.2 Immunization and Duration of Immunity

Inactivated CPV-2 vaccines of sufficient antigenic mass protect dogs against wild-type CPV-2 exposure. If protective immunity is defined as complete resistance to subclinical infection, then that produced by most inactivated CPV-2 vaccines is short lived. Dogs vaccinated with inactivated CPV-2 vaccine can become subclinically infected as early as 2 weeks after vaccination. If a dog is given sequential doses of inactivated CPV-2 vaccine, however, a rapid secondary immune response is mounted, and the dog is protected for as long as 15 months.

Infectious Diseases of the Dog and Cat, 3rd Edition

Commercially prepared attenuated live and inactivated CPV-2 vaccines are available. These vaccines produce varying levels of protective immunity and are safe either alone or in combination with other vaccine components. Transient lymphopenia occurs 4 to 6 days after the administration of some attenuated live CPV-2 vaccines. Most attenuated live CPV vaccine strains replicate in the intestinal tract and are briefly shed in the feces. Although concern has been expressed about the possibility of attenuated CPV-2 vaccine undergoing reversion of virulence and causing apparent disease, experimental studies have shown that modified live virus (MLV) CPV-2 vaccines are safe.⁴⁹ The events following administration of attenuated live CPV-2 vaccines parallel those following wild-type CPV-2 infection. On day 2 after subcutaneous (SC) administration of vaccine, viremia and systemic distribution occur with shedding from GI tract on days 3 to 10. One difference between vaccine-induced and wild-type infections is that lower quantities of virus are shed after vaccination. Humoral immune responses to attenuated live vaccines that have been studied are similar to those observed with wild-type infection.

Serum antibody is usually detectable 3 days after vaccination, with levels rising rapidly to those observed after subsequent natural infection. Even if reexposure does not occur, protective antibody titers may persist for at least 2 years, and dogs exposed during this time should not become infected. Vaccination with potentiated attenuated CPV-2 vaccine has been shown to protect dogs on subsequent experimental challenge exposure.¹¹⁵ On the basis of serum antibody titers, in a veterinary hospital setting, 27% of the dogs being evaluated for revaccination had titers below the protective level for CPV-2.⁶⁵ Although serum antibody titers are not absolute indicators of protection, they have a good correlation with protection against CPV-2 infection (see also Canine Parvoviral Infection, [Chapter 100](#)). Even systemic chemotherapy for neoplasia in dogs did not affect serum CPV-2 antibody titers.³³

8.1.8.3

Attenuated Live CPV-2 Immunization

Contrary to publicized information, vaccination failure is not related to strain differences between field and vaccine strains. The primary causes of failure of vaccines are interfering levels of maternal antibody to CPV-2^{82,96} and lack of sufficient seroconversion to the CPV-2 vaccine administered. The age at which pups can be successfully immunized is proportional to the antibody titer of the bitch, effectiveness of colostral transfer of maternal antibody within the first 24 hours of life, and immunogenicity and antigen titer of the CPV-2 vaccine. Pups from a bitch with low protective titer of antibody to CPV-2 can be successfully immunized by 6 weeks of age, but in pups from a bitch with a very high titer to CPV-2, maternal antibody may persist longer.⁹⁶

Without knowledge of the antibody status of each puppy, recommending a practical vaccination schedule that will protect all of them is difficult. In addition, pups become susceptible to wild-type CPV-2 infection 2 to 3 weeks before they can be immunized. No vaccines are available that completely eliminate this window of susceptibility before pups become immunized.⁹⁶ With the *potentiated* vaccines presently available, which are more immunogenic than the original or *conventional* CPV vaccines, low levels of maternal antibody will not prevent successful response. Pups of unknown immune status can be vaccinated with a high-titer–attenuated live CPV-2 vaccine at 6, 9, and 12 weeks of age and then revaccinated annually.³⁷ A check for serum antibody level or an additional vaccination might be done at 15 to 16 weeks of age, especially in breeds that are at increased risk for CPV-2 enteritis.¹³ See discussion of parvoviral infection in [Chapter 100](#) for additional information.

Infectious Diseases of the Dog and Cat, 3rd Edition

8.1.8.4 Attenuated Live Canine Parvovirus–2b Immunization

Although not currently commercially available, experimental use of a modified live vaccine derived from CPV-2b produced higher antibody titers to CPV-2b and CPV-2 than did a vaccine derived from CPV-2.¹⁰² In addition, the CPV-2b vaccine was able to produce a titer increase in puppies with higher maternal antibody levels.¹⁰¹

8.1.9 Experimental Vaccines

A large number of genetically engineered vaccines have been developed in an attempt to improve the protection afforded by inactivated products while reducing the antigenicity of the potentiated vaccines. A DNA vaccine containing a plasmid encoding the full length of the viral protein (VP)1 region of CPV-2 protected 9-month-old pups from clinical signs and fecal shedding of virus experimental challenge-infection.⁴⁸ A vaccine based on a recombinant plant virus expressing the VP2 peptide, coded by a subset of the VP1 gene, protected against clinical disease, with limited fecal shedding following challenge.⁵³ Neither of these vaccines produced sterile immunity/as follows attenuated CPV-2 vaccination. Intranasal or SC vaccination of mice with a plant virus expressing a CPV-2 peptide elicited systemic and mucosal antibody responses.^{79,80}

69
70

8.1.10 Husbandry

CPV is one of the most resistant viruses to infect dogs. As a result, the hair coat and environment of the ill dog become contaminated. Diluted household bleach (1:30) with water should be applied to tolerable surfaces or used as a dip for animals leaving isolation facilities. Bleach should be added to washing of all utensils and bedding. The solutions require a 10-minute minimum exposure time. The shedding period is so short (under 4 to 5 days following the onset of illness) that the environment is of major concern. The virus can persist for months to years away from sunlight and disinfectants. Steam cleaning can be used for instantaneous disinfection of surfaces that do not tolerate hypochlorite. For further information on disinfection, see [Chapter 94](#).

8.1.11 Public Health Considerations

Studies have failed to find any evidence of human infection by CPV-2, even among kennel workers in heavily contaminated premises, although people apparently can act as passive transport vehicles for the virus between dogs. Although CPV-2 is not itself a human pathogen, extra care should always be practiced in handling fecal materials from diarrheic animals.

8.2 CANINE PARVOVIRUS-1 INFECTION

8.2.1 Etiology

In 1967, CPV-1 (also referred to as minute virus of canines [MVC]) was first isolated from the feces of military dogs. Physical and chemical properties of CPV-1 are typical of parvoviruses. CPV-1 is distinctly differentiated from CPV-2 by its host cell range, spectra of hemagglutination, genomic properties, and antigenicity.⁷ Using genetic analysis, it is most closely related to bovine parvovirus.¹¹⁷

Infectious Diseases of the Dog and Cat, 3rd Edition

CPV-1 can be propagated on the Walter Reed canine (WRC) cell line. By HI tests, CPV-1 is serologically distinct from parvoviruses of a number of other species. Apparently, CPV-1 and CPV-2 are different viruses; no homology in DNA-restriction sites between the two viruses has been demonstrated using several restriction enzymes.

8.2.2 Epidemiology

The domestic dog is the only proven host, although other *Canidae* are likely susceptible. Before 1985, CPV-1 was considered a nonpathogenic parvovirus of dogs. Since that time, clinical infections of CPV-1 in neonatal pups have been encountered by practicing veterinarians and diagnostic laboratory personnel. Serologic evidence indicates that its distribution is widespread in the dog population but is usually restricted to causing clinical disease in pups younger than 3 weeks,⁸ but disease has been reported in pups 5 weeks of age.¹⁰⁰ A reasonable assumption is that the spread is similar to that of CPV-2. Although it was first identified in the United States, isolations have been made worldwide,⁶⁹ and similar to CPV-2, it is likely ubiquitous.

8.2.3 Pathogenesis

The virulence of CPV-1 for dogs is uncertain; however, it has been identified by immunoelectron microscopy in the feces of pups and dogs with mild diarrhea. Between 4 and 6 days after oral exposure, CPV-1 can be recovered from the small intestine, spleen, mesenteric lymph nodes, and thymus. Histologic changes in lymphoid tissue are similar to those observed in pups infected with CPV-2 but less severe. In addition, CPV-1 is capable of crossing the placenta and producing early fetal death and birth defects.⁷ Experimental oronasal infection of neonatal specific pathogen-free (SPF) pups, with laboratory isolates from pups dying of enteric illness, produced only mild respiratory disease.⁸ Naturally induced disease in young pups has been characterized by enteritis, pneumonia, and myocarditis.⁴⁷ Naturally infected dogs have been shown to have a reduction in both numbers and killing activity of phagocytes.¹⁴

8.2.4 Clinical Findings

CPV-1 has been observed infrequently in field dogs with mild diarrhea, as well as in the feces of clinically healthy animals. Primarily, CPV-1 infection is a cause of enteritis, pneumonitis, myocarditis, and lymphadenitis in pups between 5 and 21 days of age.³¹ Many of these pups have mild or vague symptoms and eventually die, being classified as “fading pups.” Affected pups usually have diarrhea, vomiting, and dyspnea and are constantly crying. Some puppies have respiratory disease with no enteric signs.¹⁰⁰ Sudden death with few premonitory signs has also been observed. Because of transplacental infections, this virus can cause failure to conceive or fetal death or abortion.

8.2.5 Diagnosis

CPV-1 infection should be considered in young (under 8-week-old) pups with mild diarrhea that clinically or histologically resemble CPV-2 disease but are serologically CPV-2 negative, or in unexplained fetal abnormalities, in abortions, or in fading pups. CPV-1 will not cross react with any of the serologic or fecal detection methods for CPV-2. EM has observed CPV-1 in fecal and rectal swab samples from field dogs. Immunoelectron microscopy is necessary to distinguish CPV-1 from CPV-2. Inhibition of hemagglutinating activity in stool suspensions by specific antiserum is also diagnostic for CPV-1. To determine exposure, sera can

Infectious Diseases of the Dog and Cat, 3rd Edition

be tested for specific antibody with VN or HI tests. Because only the WRC cell line supports growth of CPV-1, the availability of virus isolation and serum VN tests is limited.

8.2.6 Pathologic Findings

Pathologic changes in nursing pups have included thymic edema and atrophy, enlarged lymph nodes, pasty soft stool in the intestinal tract, and pale gray streaks and irregular areas deep within the myocardium as found with CPV-2 (see Fig. 8-7). Histopathologic lesions are predominantly restricted to large intranuclear epithelial inclusions at the tips of the villi in the duodenum and jejunum. These inclusions are eosinophilic and often fill the nuclei. Other intestinal changes noted include crypt epithelial hyperplasia and single-cell necrosis of crypt epithelial cells. Lesions seen in other tissue include moderate to marked depletion or necrosis (or both) of lymphoid cells of Peyer's patches and thymus, severe pneumonitis with exudate in airways, and mineralized focal to diffuse areas of myocardial necrosis with cellular infiltration.

8.2.7 Therapy and Prevention

Once a diagnosis has been made, treatment of pups suffering CPV-1 infection is unrewarding because of the rapid progression of the disease. However, mortality may be reduced by ensuring that the environmental temperature of newborn pups is kept warm and by adequate nutrition and hydration. No vaccine is available at present.

8.2.8 Public Health Considerations

No known public health concern exists; however, extra care should always be practiced in handling sick pups and fecal material from diarrheic animals because other enteropathogens may be present.

70

71

8.3 CANINE CORONAVIRAL ENTERITIS

8.3.1 Etiology

CCV is a member of the virus family *Coronaviridae* belonging to the order *Nidovirales* (Fig. 8-8). Different coronaviruses of this family infect a large number of species, including humans, cattle, swine, dogs, cats, horses, poultry, rats, and mice (see Table 11-1). To date, several strains of CCV have been isolated from outbreaks of diarrheal disease in dogs. The virus genome is composed of a single-stranded RNA chain; replication occurs in the cell cytoplasm of the host. Coronaviruses are fairly resistant and can remain infectious for longer periods outdoors at frozen temperatures. The virus loses infectivity in feces after approximately 40 hours at room temperature (20° C) and 60 hours when refrigerated (4° C).¹²³ Coronaviruses can be inactivated by most commercial detergents and disinfectants.

8.3.2 Epidemiology

In 1971, a CCV was isolated from feces of military dogs that were suffering from suspected infectious enteritis. Since then, several outbreaks of contagious enteritis have occurred and a similar coronavirus has been isolated. The true importance of CCV as a cause of infectious enteritis in dogs is unknown; however, CCV was genetically detected³ or isolated⁷⁰ from 16% or 57%, respectively, of dogs with diarrhea in Japan. Serologic testing of Australian dogs showing signs of diarrhea revealed that 85% were positive for CCV-IgM antibodies,

Infectious Diseases of the Dog and Cat, 3rd Edition

which indicates recent infection.⁷⁸ Serologic information suggests that CCV has been present indefinitely in the dog population and is an infrequent cause of infectious enteritis. CCV is highly contagious and spreads rapidly through groups of susceptible dogs. Neonatal pups are more severely affected than those of weaning age and adult dogs. CCV is shed in the feces of infected dogs for weeks to months or longer, and fecal contamination of the environment is the primary source for its transmission via ingestion.¹²⁴

Fig 8-8 Structure of coronavirus. (Courtesy University of Georgia, Athens, Ga.)

8.3.3 Pathogenesis

The incubation period is short: 1 to 4 days in the field and only 24 to 48 hours experimentally. CCV can generally be isolated from the feces of infected dogs between 3 and approximately 14 days after infection.

After ingestion, CCV goes to the mature epithelial cells of the villi of the small intestine.^{124,125} After uptake of CCV by M cells in the dome epithelium of Peyer's patches virus and viral antigen is transported to the underlying lymphoid tissue. Uptake in the gut lymphoid tissue suggests that CCV may persist or become latent in dogs, similar to the situation for feline coronavirus. Genetic analysis suggested that nucleotide substitutions occurred in the transmembrane protein M gene during the time of clinical illness.¹⁰⁴ The virus also rapidly reproduces within epithelial cells and accumulates within cytoplasmic vacuoles. Virions from these vacuoles may be released directly into the external environment via the apical plasmalemma or may be released after lysis of the apical cytoplasm of infected cells. After production of mature virus, infected cells develop severe cytoplasmic changes, and the microvilli of the brush border become short, distorted, and lost. The overall result is that infected cells become lost from the villi at an accelerated rate and are replaced by increased replication rate of immature cells in the crypts of the mucosa. Crypt epithelium is not destroyed; on the contrary, hyperplasia develops. Affected villi become covered by low columnar to cuboidal epithelium, show variable levels of villous atrophy and fusion, and become infiltrated by mononuclear cells in the lamina propria. Unlike CPV infection, villus necrosis and hemorrhage are rare.

Infectious Diseases of the Dog and Cat, 3rd Edition

Dogs can have CCV and CPV infections simultaneously, and some studies suggest that CCV infection enhances the severity of CPV infection. Conversely, three of four puppies in a litter died from CCV enteritis 2 weeks after surviving CPV enteritis.¹⁰⁷ Concurrent infections with canine adenovirus-1 and CCV was suspected as the cause of severe enteric disease in an animal shelter.¹⁰⁴ Other enteropathogens such as *Clostridium perfringens*, *Campylobacter* spp., *Helicobacter* spp., and *Salmonella* spp. may increase the severity of CCV illness (see [Chapter 39](#)).

8.3.4

Clinical Findings

Differentiating CCV from other infectious causes of enteritis is difficult. Theories suggest that CCV infection is usually less dramatic than CPV-2 infection. The clinical signs can vary greatly, and dogs of any breed, age, and sex are affected. This finding contrasts with CPV infections in which affected dogs are usually younger than 2 years. Infected dogs usually have a sudden onset of diarrhea preceded sometimes by vomiting. Feces are characteristically orange in color, very malodorous, and infrequently contain blood. Loss of appetite and lethargy are also common signs. Unlike CPV-2 infection, fever is not constant, and leukopenia is not a recognized feature.

In severe cases, diarrhea can become watery, and dehydration and electrolyte imbalances can follow. Concurrent ocular and nasal discharges have been noted, but their relationship to the primary infection is unknown. Most of the dogs affected recover spontaneously after 8 to 10 days. When secondary complicating factors are present (parasites, bacteria, or other viruses), the disease can be significantly prolonged.

8.3.5

Diagnosis

Making a definitive diagnosis of CCV-induced disease is difficult. EM can detect CCV in fresh feces.

Approximately 1×10^6 virions are needed in unconcentrated fecal samples for identification of CCV by EM; thus false-negative findings are possible. Viral isolation is difficult because CCV does not grow well in tissue or cell culture systems. A highly sensitive reverse transcriptase PCR has been developed to detect CCV in fecal

71

specimens.^{28,99,106} Serum VN and ELISA tests for CCV antibody have been developed.¹¹¹ Positive CCV serum titers of affected dogs can only confirm exposure to CCV, and serum IgG titers have no relationship to protection as do intestinal secretory IgA titers.

72

8.3.6

Pathologic Findings

Mild infections are grossly unremarkable. In severe cases, the intestinal loops are dilated and filled with thin, watery, green-yellow fecal material. Mesenteric lymph nodes are commonly enlarged and edematous.

Atrophy and fusion of intestinal villi and a deepening of the crypts characterize the intestinal lesions of CCV. Also present are an increase in cellularity of the lamina propria, flattening of surface epithelial cells, and discharge of goblet cells. With well-preserved tissues, FA staining can enable specific detection of virus in the intestinal lesions.

8.3.7

Therapy

Deaths associated with diarrheal disease are uncommon but occur in pups as a result of electrolyte and water loss with subsequent dehydration, acidosis, and shock. Management must emphasize supportive treatment to maintain fluid and electrolyte balance as described for CPV-2 infection. Although rarely indicated, broad-spectrum

Infectious Diseases of the Dog and Cat, 3rd Edition

antimicrobial agents can be given to treat secondary bacterial infections. Good nursing care, including keeping the dogs quiet and warm, is certainly essential.

8.3.8 Prevention

Inactivated and MLV vaccines are available for protection against CCV infection.^{23,87} Two doses 3 to 4 weeks apart and annual revaccination are recommended for immunization of dogs regardless of age. These vaccines are relatively safe but provide incomplete protection in that they reduce but do not completely eliminate replication of CCV in the intestinal tract after challenge.^{88,89} Assessing the role of the CCV vaccines in protection against disease is difficult because CCV infections are usually inapparent or cause only mild signs of disease. For additional information on vaccination, see Coronavirus Infection in [Chapter 100](#).

8.3.9 Public Health Considerations

CCV is not believed to infect people. Coronaviruses are not strictly host specific; thus the possibility of human infection cannot be excluded. For this reason, extra care should always be practiced in handling sick pups and fecal material from diarrheic animals.

8.4 CANINE ROTAVIRAL INFECTION

8.4.1 Etiology

Rotaviruses are recognized as important enteric pathogens in many animal species and in people. They are sometimes referred to as duovirus, reovirus-like, and rotalike virus agents. Currently, rotaviruses are classified as distinct members of the family *Reoviridae*. CRV is a double-stranded RNA, nonenveloped virus that is approximately 60 to 75 nm in diameter ([Fig. 8-9](#)). CRV is resistant to most environmental conditions outside the host.

Rotaviruses have been isolated in tissue cultures or observed by EM of specimens from many species, including mice, monkeys, calves, pigs, foals, lambs, humans, rabbits, deer, cats, and dogs.

8.4.2 Epidemiology

Rotaviruses are transmitted by fecal-oral contamination. The viruses are well adapted for survival outside the host and for passage through the upper GI tract. Serum antibodies to rotavirus have been identified in dogs and cats of all ages.

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 8-9 Structure of rotavirus. (Courtesy University of Georgia, Athens, Ga.)

8.4.3 Pathogenesis

Rotaviruses infect the most mature epithelial cells on the luminal tips of the small intestinal villi, leading to mild-to-moderate villous atrophy. Infected cells swell, degenerate, and desquamate into the intestinal lumen, where they release a large number of virions that become sources of infection for lower intestinal segments and for other animals. Necrosis of rotavirus-infected cells is most pronounced 18 to 48 hours after oral infection. Necrotic cells are rapidly replaced by immature crypt epithelium. Clinical signs result primarily from the villous atrophy, leading to mild to moderate maldigestion and malabsorption and osmotic diarrhea.

8.4.4 Clinical Findings

Most clinical rotaviral infections have been demonstrated in the feces of pups younger than 12 weeks, with mild diarrhea. Some cases of severe fatal enteritis associated with CRV have been reported to occur in pups as young as 2 weeks. The clinical signs are usually not as severe as those for the other canine enteric viruses (CPV-2 and CCV). A watery to mucoid diarrhea is usual, and this lasts for 8 to 10 days. The pups usually remain afebrile. CRV may contribute to enteric disease in mixed viral infections.

8.4.5 Diagnosis

Most pathogenic rotaviruses share common group-specific internal capsid antigens that can be detected by many methods, including commercial fecal ELISA (Rotazyme, Abbott Labs, N. Chicago, Ill.; Enzygnost, Behring Inst., Marburg, Germany) and latex agglutination (Rotalex, Orion Diag, Helsinki, Finland; Slidex Rota-kit,

Infectious Diseases of the Dog and Cat, 3rd Edition

Biomerieux, Marcy-l'Etoile, France) tests used to diagnose human rotavirus infection (see also [Appendix 6](#)).¹¹¹ Rotaviruses can also be identified in fecal specimens by EM, although care must be taken to differentiate rotaviruses from the apparently nonpathogenic reoviruses occasionally present in dog feces. EM improves specificity of the test. Testing for seroconversion is possible but not widely available.

72

8.4.6 Pathologic Findings

73

Pathologic changes are limited to the small intestine, consisting of mild to moderate villous blunting. The virus can be detected in frozen sections by fluorescent antibody techniques.

8.4.7 Therapy and Prevention

Most dogs recover naturally from their infection. Treatment, if needed, consists solely of symptomatic therapy as described for CPV-2 enteritis. No vaccines are available for CRV, and current estimates of the frequency and severity of the disease do not appear to justify vaccine development.

8.4.8 Public Health Considerations

Rotaviruses are generally host specific; however, the various strains cannot be easily distinguished, and the possibility of human infection cannot be eliminated. Rotaviral infections in people usually occur in young infants and children (younger than 4 years). Poor sanitation and hygiene, as exist in developing countries, increase the prevalence of infection. Persons handling feces from diarrheic dogs should take routine precautions.

8.5 OTHER VIRAL ENTERITIDES

A large number of other viruses have been identified in feces of dogs both with and without diarrhea. For the most part, the pathogenicity and importance of these viruses as causes of infectious enteritis remain unknown. Based on work in other species, some viruses may be true enteric pathogens, whereas others are most likely incidental findings.

Astrovirus-like particles have been reported in the stools of clinically healthy and diarrheic dogs. Astroviruses are known to cause enteritis in other species, such as swine, but whether this is either true or common in the dog is unknown. The viruses have also been identified in diarrheic cats (see [Chapter 12](#)).

A herpesvirus antigenically related to feline herpesvirus has been isolated from a dog with diarrhea, but Koch's postulates have not been fulfilled.⁵¹ Similarly, the importance of serologic reactivity of some dogs to human echoviruses and coxsackieviruses is unclear (see also Enteroviral Infections, [Chapter 24](#)).

An apparently specific canine calicivirus has been isolated on several occasions from the feces of dogs with enteritis, sometimes alone and sometimes in conjunction with other known enteric pathogens.^{72,113} Similarly, an antigenically distinct parainfluenza virus, isolated from a dog with bloody diarrhea, was believed to be causal (see [Chapter 7](#)).

The study of viral enteritis in dogs is in its infancy. Undoubtedly, there are other viruses that affect the GI tract of dogs, but they remain to be discovered and characterized.

9 CHAPTER 9 Canine Viral Papillomatosis

Michelle Wall

Clay A. Calvert

9.1 ETIOLOGY

The papillomavirus was first described in 1933 when Shope discovered the agent responsible for cutaneous papillomas in the cottontail rabbit.¹⁹ Multiple canine papillomas in dogs are uncommon, comprising less than 12.5% of canine skin tumors.²⁰ Benign mucocutaneous tumors of epithelial origin are caused by infectious papillomavirus of the *Papovaviridae* family. The papilloma viruses are categorized with the polyomaviruses to form the papovaviruses. Members of this family are small (33 to 60 nm), naked, ether-resistant, double-stranded circular DNA tumor viruses, similar in structure to but larger than parvoviruses; they form crystalline structures within the nuclei of infected cells.^{22,34} These viruses lack a lipid envelope and are acid stable and relatively thermostable, which may explain much of their inherent resistance.³⁴ Papillomaviruses are naturally oncogenic, producing benign warts, and are usually species and site specific. Cross-species infection of horses by bovine papillomaviruses type 1 and type 2 have been reported.¹³ Most isolated viruses lack serologic cross-reactivity. Although antigenically distinct, papillomaviruses of humans, cattle, horses, dogs, and cats share at least one group-specific determinant. Inoculation of canine oral papillomavirus (COPV) into kittens, mice, rats, guinea pigs, rabbits, and nonhuman primates has failed to produce papillomas. Tumors can be transmitted experimentally within the species of origin by scarification with whole cells or cell-free filtrates. A distinct papillomavirus has been identified in cutaneous papillomas of cats (see [Chapter 20](#)) and dogs.^{26,41} The close genetic relationship between feline and canine papillomas compared with those of other species supports the hypothesis that papillomaviruses have coevolved with vertebrates during host evolution.^{49,52}

74

9.2 EPIDEMIOLOGY

Papillomas (also referred to as *warts*, *verruca vulgaris squamous cell papillomas*, or *cutaneous papillomatosis*) may be either (1) naturally occurring noninfectious or virus-induced solitary tumors or (2) transmissible virus-induced multiple tumors. The virus is transmitted by direct and indirect contact, but damaged epithelial surfaces may be necessary for successful inoculation.^{3,16} The papillomavirus must overcome the host's immune response to replicate and produce clinical infection, so the significance of these warts is greater in immunocompromised patients.^{13,34} Four or more separate papillomaviruses may infect dogs, usually without papilloma development. Numerous clinical syndromes and symptoms have been described in dogs with papillomavirus: oral papillomatosis, venereal papillomas, cutaneous papillomas, cutaneous inverted papillomas, multiple papillomas of the footpad, and papillomavirus-associated canine-pigmented plaques.

Most infectious papillomas undergo spontaneous regression, but occasionally papillomavirus infections persist or lesions recur, especially when the host is immunocompromised and the immune system cannot eliminate the virus (e.g., in a dog with concurrent infections). Dogs with granulocytic ehrlichiosis had remission of oral papillomatosis after treatment.⁵⁰ Malignant transformation into squamous cell carcinoma has been reported in various species, especially cattle. Progression to sarcoma tumors has also been reported in horses, donkeys, and mules as a result of bovine papillomavirus infection.¹⁸

Infectious Diseases of the Dog and Cat, 3rd Edition

The association of human papillomavirus and bladder cancer remains unresolved,^{24,37} but strong evidence supports the role of human papillomavirus in cancer of the anogenital tract.²² The human papillomavirus is a critical factor in the development of cervical cancer.⁴ Progression of the papillomavirus to carcinoma can occur in dogs, although malignant transformation is uncommon. Reports have been made of a beagle with oral papillomatosis and a collie with an oral and a corneal papilloma that experienced malignant transformation.^{1,54} The interaction of certain chemicals, genetic background, or other carcinogens with papillomavirus-infected cells is believed to produce the potential for malignant transformation; for example, human laryngeal papillomas exposed to irradiation and bladder tumors in cattle exposed to bracken fern create the potential for transformation.^{8,13}

9.3 PATHOGENESIS

The life cycle of the papillomavirus is closely associated with the differentiating epithelial cell, and infections with papillomavirus are usually confined to the epidermis and epithelium.³⁹ Papillomavirus infects basal keratinocytes of the stratum germinativum; the basal cell is the only cell in the squamous epithelium that is capable of undergoing division.⁵⁵ Once it has infected the basal layer, the virus expresses itself in the basal and suprabasal layers, undergoes genome replication in the granular and spinous layers, packages its DNA in the squamous layers, and releases a new infectious virus with the keratinized squames.¹³ The first tissue response to COPV infection is an increase in mitotic activity, resulting in acanthosis and hyperkeratosis. As the disease progresses, some infected cells begin producing virus. These cells develop inclusion material but do not undergo cytoplasmic differentiation. Cytoplasmic degeneration and cell death ensue with viral persistence in strands of keratin; however, the majority of basal layer cells differentiate into keratogenetic normal cells. Spontaneous tumor regression is the usual course. The virus is latent in the basal layers, although complete viral particles may be identified at the granular level.

The incubation period of COPV is usually 4 to 8 weeks postinoculation. Concentration of COPV in the inoculum may influence subsequent tumor growth and regression in various ways. Papillomavirus infection delays the activation of the host's immune system. The virus targets end-stage differentiating cells and is often protected from systemic immune defenses, and the production of papillomavirus is not accompanied by inflammation.³⁴ Dogs given small doses of virus develop more papillomas and have delayed regression compared with dogs given larger doses of virus. Antibodies to papillomavirus are produced, but they do not correlate with growth or regression. Once regression occurs, subsequent immunity develops.

The mechanisms resulting in spontaneous regression or spread of papillomas are unknown. Papilloma regression is thought to be associated with the presence of CD4⁺ and CD8⁺ lymphocytes. These cells, especially the CD4⁺ cells, activate macrophages, inhibit viruses via cytokines, kill keratinocytes, or all of these.³⁴ Virus-neutralizing antibody inactivates COPV in sensitized animals but does not inhibit established virus or papillomas. Serum from dogs whose papillomas have undergone spontaneous regression usually not only fails to produce tumor regression but also can enhance tumor growth in naive dogs. Passive transfer of serum immunoglobulins from immune dogs may occasionally protect naive dogs.^{34,48} Failure of protection by serum immunoglobulins from dogs that have undergone spontaneous regression may be the result of the induction of blocking antigen-antibody factors that impede cytotoxic lymphocyte action on target cells. Severe oral papillomatosis occurs in beagles with IgA deficiency.⁴⁷ Cellular immune mechanisms may be more important in inhibiting the development of early papillomas in dogs. Regression is enhanced by the injection of immune lymphocytes from dogs in which COPV has regressed. In contrast, COPV papillomatosis spread from the oral cavity throughout the haired skin of a Shar-pei dog given glucocorticoids.⁴⁷ Multiple cutaneous papillomas caused by a new papillomavirus developed in a boxer

Infectious Diseases of the Dog and Cat, 3rd Edition

dog receiving long-term glucocorticoid therapy, and similar associations were recognized in dogs with hypogammaglobulinemia, IgM deficiency, impaired T-cell responses, and high dose, long-term cyclosporine administration.^{7,9,26,40} In humans, increased prevalence of papillomatosis is associated with defects in the cell-mediated or humoral immune system as well.

Puppies inoculated with COPV develop hyperplastic and neoplastic lesions at sites other than the oropharyngeal mucosa. Lesions have included epidermal hyperplasia, epidermal cysts, squamous papilloma, basal cell epithelioma, and squamous cell carcinoma; however, very few inoculations were associated with these extraoral lesions.

9.4 CLINICAL FINDINGS

Oral papillomas occur on the oral, labial, and pharyngeal mucosa, as well as on the tongue, on the hard palate, and on the epiglottis; it rarely occurs in the esophagus (Fig. 9-1). Oral papillomatosis of young dogs (with a median age of 1 year) is a contagious viral disease.²⁷ The lesions typically begin as white, smooth, flat, shiny plaques that progress, usually 4 to 8 weeks postinfection, to pedunculated or cauliflower-like masses.^{13,27} The oral form is usually a self-limiting disease, although the lesions may persist without spontaneous regression or spread to other areas of the body.³⁹

(Courtesy Patrick Hensel and Tracy Gieger, University of Georgia, Athens, Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Ocular papillomas can occur on the conjunctivae, cornea, and eyelid margins (Fig. 9-2). Ocular papillomas are less common than oral papillomas and are caused by a virus that is similar in structure to the oral papillomavirus.

Virus-induced cutaneous papillomas are uncommon and usually solitary lesions caused by a subtype of the canine papillomavirus; they are not associated with the papovavirus. Although usually solitary, the cutaneous lesions may be multifocal and are often found elsewhere on the body (Fig. 9-3). COPV inoculated into the skin of the face may produce a papilloma, but attempts to produce a tumor by inoculating the skin of the abdomen or back with COPV have usually failed.

Dogs older than 2 years of age seldom develop oral papillomas, and older dogs appear to be resistant to COPV infection. Ocular papillomas occur most often in dogs 6 months to 4 years of age but have been reported in dogs as old as 9 years. The susceptible age range of dogs with cutaneous papillomas is broader. Cutaneous papillomas occur in older dogs and appear to be more common in males.³⁹ The Kerry blue terrier and the cocker spaniel have been reported to be overrepresented.^{39,41} The cutaneous warts are distinct from the oral form and usually occur on the head, feet, and eyelids. In Australia, cutaneous papillomas of the distal limbs and interdigital pad area in racing greyhounds occur in dogs 12 to 18 months of age.¹⁴

Cutaneous inverted papillomas usually occur on the ventrum and inguinal regions.¹¹ They have been reported to occur in dogs from 8 months to 7 years of age.^{11,41} These small, firm, raised masses appear as cup-shape lesions with a central core of keratin that have a small pore opening to the skin surface.²⁷ Their surface is similar to that of an intracutaneous cornifying epithelioma, but they have a papillary projection of epidermis into the lumen that epitheliomas do not possess.¹¹ Single or multiple lesions may develop, and they are covered by skin with a central pore opening to the surface.

Multiple papillomas affecting the footpads have been described in adult dogs.³⁹ The lesions are very firm and hyperkeratotic. They can occur on more than one foot and often cause lameness (Fig. 9-4). They do not seem to be associated with a virus.

Papillomavirus-associated canine-pigmented plaques have been documented in several miniature schnauzers and pugs during young adulthood.³² These lesions often progress over time and do not regress. Potential for malignant transformation exists.

Although oral papillomatosis is the most common clinically relevant disease, other forms are recognized. Oral papillomatosis is a contagious, usually self-limiting disease affecting the oral mucosa, labial margins, tongue, palate, pharynx, and epiglottis. Initially, oral papillomas are pale, smooth, elevated lesions, but they soon become cauliflower-like, with fine, white, stringy projections. Early tumors appear to “seed” the rest of the susceptible oral tissues. Recognition of the lesions usually occurs while the numbers of tumors are still increasing. Halitosis, ptyalism, hemorrhage, and oral discomfort are clinical signs observed by the owners of affected dogs. These lesions often bleed when traumatized. As many as 50 to 100 tumors are often present at the time of diagnosis (see Fig. 9-1, C and D).

Papillomavirus infections usually regress spontaneously, but the time to regression varies from weeks to years. Regression typically occurs within 4 to 8 weeks. Oral papillomas usually regress after 4 to 8 weeks, although they may persist for up to 24 months. Cutaneous papillomas may persist for 6 to 12 months before undergoing spontaneous regression. Occasionally, incomplete regression occurs, and a few papillomas persist indefinitely. Dogs

Infectious Diseases of the Dog and Cat, 3rd Edition

affected by persistent papillomas often have many large tumors and may become malnourished. Secondary bacterial infection of large, persistent, and ulcerated tumors is common and characterized by a mucopurulent discharge.

Fig 9-2 Eyelid papilloma in a dog.

Fig 9-3 Multiple papillomas on the (A) lateral flank and (B) caudal thigh of two different dogs. (Courtesy Patrick Hensel, University of Georgia, Athens, Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Ocular papillomas tend to persist longer than oral papillomas and are usually less numerous. When COPV was inoculated into the eyelids of dogs, only 50% of the dogs developed papillomas, the incubation period was longer than it is in the oral cavity, and the tumors persisted longer than they do in the oral cavity.⁵³ Experimentally papillomavirus isolated from ocular lesions can produce oral papillomatosis, but it has not been proven that this occurs naturally.²⁷

9.5 DIAGNOSIS

The diagnosis of papillomatosis is based on the epidemiology and gross appearance of the tumors. Ocular papillomas are usually biopsied and examined histologically because they are not as morphologically distinct as oral papillomas. Microscopic features of papillomas include marked epidermal hyperplasia on fibrovascular stalks. Small, intranuclear, basophilic inclusions may be noted and in some cases, keratinocytes within the papillomas may contain large eosinophilic cytoplasmic inclusions.¹⁵ Cutaneous papillomas, usually morphologically distinct, are often excised for aesthetic reasons and examined microscopically. Cutaneous papillomas can occur at many sites, most often on the lower extremities, often in the interdigital areas and footpads, and occasionally subungually. The viral cause can be confirmed by immunohistochemistry staining for viral antigen, electron microscopy findings demonstrating the virus, or polymerase chain reaction and in situ hybridization techniques to detect papillomavirus DNA.*

* References 7,15,39,42,47,51.

9.6 THERAPY

Treatment is not indicated if only a few papillomas are present because they are usually self-limiting, and afterward dogs are immune to reinfection.³⁹ However, the patient should be frequently monitored to determine whether the tumor numbers are increasing. Spontaneous regression is the usual course, but treatment may be indicated when tumors persist; when large, multiple tumors produce pharyngeal obstruction; when problems eating occur; and for

Infectious Diseases of the Dog and Cat, 3rd Edition

aesthetic reasons. Treatment efficacy is often difficult to determine because of the high incidence of spontaneous regression.

The ideal therapy remains unknown because of the lack of sufficient knowledge regarding papillomavirus. Surgical excision, cryosurgery, and electrosurgery are acceptable modes of oral tumor treatment. Surgical removal, freezing, or simply crushing 5 to 15 of the tumors may induce spontaneous regression, presumably a result of antigenic stimulation. Laser therapy has been effective in the treatment of several resistant human warts and has been described for human recurrent respiratory papillomatosis.¹⁷ Oral papillomatosis has been unsuccessfully treated with a CO₂ laser.²⁵ Although autogenous vaccines are commonly recommended, their efficacy in dogs is questionable, and they are often not effective against persistent papillomatosis. Recombinant vaccines have been shown to induce regression in several species including the dog and can be used prophylactically to prevent mucosal infections with COPV.^{3,23,25,47} It has been demonstrated that systemic immunization with COPV L1 protein can induce a humoral response that will provide protection against oral papillomatosis.⁴⁸ The vaccines may also play a role in decreasing the development of squamous cell carcinomas. In a case report of a 16-month-old Siberian husky that did not respond to surgical therapy, an autogenous vaccine appeared to induce regression of the resistant oral papillomas, and high circulating neutralizing antibodies against COPV were produced.²⁵ The titers appeared to be correlated with regression of the oral papillomas.²⁵ Anecdotal reports have been made of success with the use of autogenous vaccines. Additional studies should be performed regarding the effectiveness of recombinant COPV vaccines because the development of neoplasms has been reported to occur at the injection site of live COPV vaccines in dogs.^{8,28,45} Cutaneous papillomas that arise as a result of glucocorticoid-induced immunosuppression may regress once this therapy is discontinued.

Surgical excision or cryosurgery is effective for papillomas of the conjunctiva or eyelid. Cryosurgery is not recommended for corneal papillomas. Care should be taken to prevent spread of the virus to adjacent ocular tissues, and cryosurgery or possibly laser therapy may offer an advantage in this regard.

Systemic and intralesional (bleomycin) chemotherapy using single-agent vincristine, cyclophosphamide, or doxorubicin has been ineffective in the majority of dogs treated. Topical application of 5-fluorouracil (0.5% solution) has been used successfully in humans with numerous cutaneous warts, a treatment that may be useful for cutaneous lesions in dogs. However, ingestion of 5-fluorouracil can result in local irritation and severe systemic toxicity. The retinoid etretinate has been useful in the treatment of a few dogs with cutaneous papillomatosis. Widespread papillomavirus-associated canine-pigmented plaques have been effectively treated with etretinate (1 mg/kg orally every 24 hours).^{32,33} Possible retinoid toxicity can include conjunctivitis, pruritis, vomiting, diarrhea, joint stiffness, pedal and mucocutaneous erythema, hyperactivity, and teratogenicity. Interferons (IFNs) have been administered parenterally and intralesionally to affected humans until regression occurs. Low doses of oral IFNs rather than high doses of parenteral IFNs are more commonly used in pets and less expensive, but not likely to be effective. In vitro studies of IFN therapy have shown a reduction in the papillomavirus in mouse cells transformed by bovine papillomavirus-1.³² The immune modulator Acemannan (*Acemman Immunostimulant*, Carrington Labs, Irving, Tex.) has been administered intralesionally to cause regression of fibrosarcomas and might be an alternative to IFN therapy. Photodynamic therapy has induced good responses for several types of skin cancer and may play a role in future treatment of canine papillomas. Dogs recovering from oral papillomatosis are immune, as are most dogs older than 2 years (see Interferons, [Chapters 2 and 100](#); Acemannan, [Chapter 100](#); and Drug Formulary, [Appendix 8](#) for additional information on administration and precautions of these drugs).

77

78

Infectious Diseases of the Dog and Cat, 3rd Edition

9.7 PREVENTION

Protection against viral challenge with COPV has been achieved by sequential immunization doses via DNA delivery of a plasmid encoding COPV major capsid L1 protein or oncoproteins E1 or E2 to cutaneous and oral mucosal sites in beagles.^{31,43,44} Codon-optimized E1 gene sequences (but not wild-type gene sequences) provided complete protection after DNA vaccination of beagle dogs with COPV.³¹ Both cell-mediated and humoral immune responses were detected. No vaccine is commercially available.

¹⁰ CHAPTER 10 Feline Parvovirus Infections

Craig E. Greene

Diane D. Addie

^{10.1} ETIOLOGY

Feline panleukopenia is caused by a small, serologically homogeneous parvovirus (feline panleukopenia virus [FPV]), with single-stranded DNA. Genetically, structurally, and antigenically, it is closely related to blue fox parvovirus (BFPV), mink enteritis virus (MEV), and canine parvovirus (CPV) ([Table 10-1](#)).³⁸ In addition, CPV strains 2a and 2b have been isolated from healthy cats³⁹ and from those with signs of feline panleukopenia (see later discussion, Canine Parvoviral Infection, and [Chapter 8](#)).^{40,59} In contrast, FPV has limited replication in dogs after experimental inoculation.⁶¹ FPV is very stable, able to survive for 1 year at room temperature in organic material on solid fomites. It resists heating to 56° C for 30 minutes and remains viable for longer periods at lower temperatures. The virus survives disinfection with 70% alcohol and various dilutions of organic iodines, phenolics, and quaternary ammonium compounds. FPV is inactivated by bleach (6% sodium hypochlorite), 4% formaldehyde, and 1% glutaraldehyde in 10 minutes at room temperature.

^{10.2} EPIDEMIOLOGY

FPV can cause disease in all members of the family Felidae. Some Viverridae, Procyonidae, and Mustelidae, including the binturong, raccoon, coatimundi, ring-tailed cat, and mink, are also susceptible (see [Table 100-20](#)). The virus is ubiquitous because of its contagious nature and capacity for persistence in the environment. Virtually all susceptible cats are exposed and infected within the first year of life. Unvaccinated kittens that acquire maternally derived antibody (MDA) through colostrum are usually protected for up to 3 months of age (though longer duration of MDA to 20 weeks sufficient to interfere with vaccination has been reported).² Most infections are subclinical, inasmuch as 75% of unvaccinated, clinically healthy cats have demonstrable antibody titers by 1 year of age. Seasonal variations in the incidence of panleukopenia and disease outbreaks presumably parallel increases in the number of susceptible newborn kittens. Although panleukopenia is regarded as a condition of unvaccinated random-source cats, infection has been reported in kittens born into pedigree breeding cats from well-vaccinated queens.^{1,2,7}

A perception exists among veterinary practitioners that the prevalence of FPV infection in cats has diminished over the last two decades. Reasons for this decrease may be the more widespread vaccination of cats and the use of modified live virus (MLV) vaccines, which may cause virus shedding, thereby immunizing exposed cats. Secondly, the newly emerging CPV-2 strains infecting cats may offer some cross-protection against FPV infection. FPV may be more adapted to its host; however, other prenatal or neonatally acquired forms of disease such as neurologic or cardiac manifestations are occurring (see later discussion under Pathogenesis).

Because of its short shedding period, but long environmental survival, FPV is most commonly transmitted by indirect contact of susceptible animals with contaminated premises. It is shed from all body secretions during active stages of disease but is most consistently recovered from the intestine and feces. Virus shedding usually lasts 1 to 2 days, but cats can shed virus in their urine and feces for a maximum of 6 weeks after recovery.⁹ FPV is maintained in the population by its environmental persistence rather than by prolonged viral shedding. In utero transmission

Infectious Diseases of the Dog and Cat, 3rd Edition

occurs. The virus has been isolated for a maximum of 1 year from the kidneys of neonatally infected kittens, but shedding does not occur. Owners who lose a kitten to feline panleukopenia should *not* introduce a new kitten into the household without having it vaccinated.

Fomites play a relatively important role in disease transmission because of prolonged survival of the virus on contaminated surfaces. Vehicles for exposure include contaminated litter trays, clothing, shoes, hands, food dishes, bedding, and infected cages. Transmission also probably occurs via flies and other insect vectors during warm periods.

10.3 PATHOGENESIS

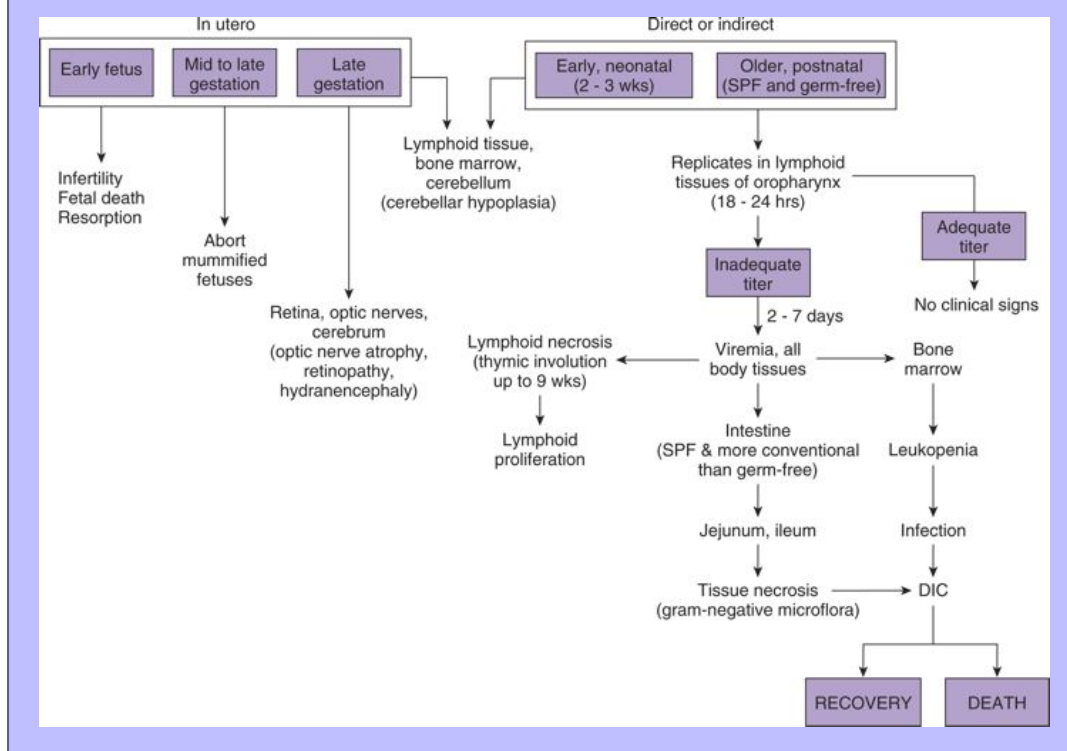

As a parvovirus, FPV requires rapidly multiplying cells for successful infection, and the distribution of lesions within a prospective feline host occurs in tissues with the greatest rate of mitotic activity (Fig. 10-1). Lymphoid tissue, bone marrow, and intestinal mucosal crypts (intestinal glands) are most commonly invaded in adult animals. Late prenatal and early neonatal infections in cats result in some lymphoid and bone marrow lesions, but the central nervous system (CNS), including the cerebrum, the cerebellum, the retina, and optic nerves, can be affected.

10.3.1 Systemic Infections

Experimental infections have been produced in specific pathogen-free (SPF) and germ-free kittens. Clinical severity of infection is milder in these animals compared with that in field cases and in experimentally infected conventional cats, suggesting that co-pathogenic factors may play a role in the natural disease. The virus undergoes replication in lymphoid tissues of the oropharynx 18 to 24 hours after intranasal (IN) or oral infection. A plasma-phase viremia, occurring between 2 and 7 days, disseminates the virus to all body tissues, although pathologic lesions primarily occur in tissues with the highest mitotic activity. Lymphoid tissue undergoes initial necrosis followed by lymphoid proliferation. Thymic involution and degeneration are found in germ-free and SPF cats infected up to 9 weeks of age. Decreased T-cell responsiveness has been reported in FPV-infected cats, but no interference in humoral immune responses occurs. Cats surviving infection have a decrease in viremia corresponding to a rapidly rising virus neutralization (VN) serum antibody titer by 7 days postinoculation (PI).

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 10-1 Pathogenesis of feline panleukopenia. *SPF*, specific pathogen-free; *DIC*, disseminated intravascular coagulation.

During intestinal infection, the virus selectively damages replicating cells deep in the crypts of the intestinal mucosa. Differentiated absorptive cells on the surface of the villi are nondividing and are not affected. Shortening of the intestinal villi results from damage to the crypt cells, which normally migrate up the villi, replacing absorptive cells. Damage to the intestinal villi results in diarrhea caused by malabsorption and increased permeability (see Fig. 89-6, C).

SPF kittens have more severe intestinal lesions compared with germ-free kittens. The proliferation rate of crypt epithelium is faster in SPF kittens as a result of indigenous microflora or their metabolic by-products, which stimulate the turnover rate of intestinal epithelial cells. The extent of damage throughout the intestinal tract parallels the presence of FPV, and lesions are milder in the colon, where epithelial mitotic rates are slower than they are in the small intestine. The jejunum and ileum are more affected than the duodenal segment, which may reflect lower number of indigenous microorganisms in the proximal small bowel.

SPF and conventional cats with panleukopenia are also susceptible to secondary bacterial infections with enteric microflora. Gram-negative endotoxemia, with or without bacteremia, is a common complication of systemic FPV infection. Disseminated intravascular coagulation (DIC), a frequent complication of endotoxemia, can also develop with feline panleukopenia.

80

81

Infectious Diseases of the Dog and Cat, 3rd Edition

10.3.2 Co-infections

Concurrent infections with co-pathogens can increase the severity of FPV infections in cats, similar to the situation in dogs with parvoviral infection. Intestinal cell replication increases during insults to the bowel mucosa, which can increase the virulence of parvoviruses that infect rapidly dividing cells. Dual infection with *Clostridium piliforme*, the causative agent of Tyzzer's disease, was found in kittens (see also [Chapter 39](#)).³²

Co-infections with salmonellae and FPV have also been described in purebred catteries, with severe mortality.¹⁴ FPV may be an immunosuppressive agent in these enteric bacterial co-infections given that it causes both leukopenia and bowel injury, which allows bacterial proliferation.

10.3.3 In Utero Infection

Early in utero infection can produce a spectrum of reproductive disorders in the pregnant queen, including early fetal death and resorption with infertility, abortions, or the birth of mummified fetuses. Closer to the end of gestation, infections will result in birth of live kittens with varying degrees of damage to the late-developing neural tissues. FPV produces variable effects on animals from the same litter. Some kittens are apparently unaffected owing to either innate resistance or the acquisition of maternal antibody, but they may harbor virus subclinically for up to 8 to 9 weeks in some cases.⁹

10.3.4 Central Nervous System Infection

The CNS, optic nerve, and retina are susceptible to injury by virulent or vaccine strains of FPV during prenatal or early neonatal development, and, of CNS lesions, cerebellar damage has been most commonly reported. This predilection for cerebellar disease may be explained by the fact that in cats the cerebellum develops during late gestation and early neonatal periods. FPV interferes with cerebellar cortical development, resulting in reduced and distorted cell layers. The cerebellum can be affected by infections occurring as late as 9 days of age. Polymerase chain reaction (PCR) has confirmed that parvoviral DNA can be found in the cerebellum of cats with cerebellar hypoplasia.⁴⁸ Other CNS lesions can be produced by earlier prenatal infections. Lesions of the spinal cord and cerebrum, including hydrocephalus, hydranencephaly, and optic nerve and retinal abnormalities, can occur (see Clinical Findings later in this chapter).^{19,53} Purkinje's cell degeneration in the cerebellum was described in one adult feral cat with systemic FPV infection.¹³ Unexpectedly, parvoviruses appear to be capable of replicating in neurons, which are considered to be terminally differentiated cells. Cats that had died of various diseases including panleukopenia had parvovirus detected histochemically in their brains.⁶² These cats did not have the clinical signs of cerebellar hypoplasia nor were they of that susceptible age group. Viral nucleic acid was found by in situ hybridization to be in brain nuclei, especially in the diencephalic areas. Some of the virus appeared to be CPV-2 of the old antigenic type. The clinical significance of this neuronal infection is unknown.

10.3.5 Myocarditis and Cardiomyopathy

Myocarditis in people and animals can be induced by a large number of viruses. Myocarditis was one of the early-recognized features of CPV-2 infections in dogs, and it continues to be a feature of CPV-1 infection in dogs (see [Chapter 8](#)). With CPV-2, a lack of maternal immunity, during the early epidemic period of the late 1970s and before the advent of available vaccines, resulted in increased susceptibility of the fetus to infection. FPV likely infects kittens born to queens that were exposed to the virus during pregnancy. Hearts from cats dying of idiopathic hypertrophic, dilated, and restrictive forms of cardiomyopathy were examined by PCR for

Infectious Diseases of the Dog and Cat, 3rd Edition

genomic evidence of FPV, feline calicivirus (FCV), feline herpes virus (FHV)-1 and feline coronavirus (FCoV).³⁶ Only FPV was identified in a significant number of the hearts. These data suggest that FPV is important in the pathogenesis of this disease in cats.

10.4 CLINICAL FINDINGS

The frequency with which cats show evidence of clinical disease with FPV is much less than the number of cats infected with the virus. This fact is supported by the high prevalence of FPV antibodies in the cat population. Subclinical cases, more common in older susceptible cats, remain unrecognized. Severe clinical illness is the rule in young unvaccinated kittens; the highest morbidity and mortality occurs between 3 and 5 months of age. Sudden neonatal or adolescent death (fading kittens) has been observed in kittens of 4 weeks to 12 months of age from households of vaccinated pedigree cats.² In one study in the United Kingdom, FPV was the cause of 25% of kitten mortality.⁷

The disease has an acute self-limiting course, and other diseases probably cause chronic leukopenia or diarrhea. In the most peracute form, cats may die within 12 hours, as if poisoned, with little or no premonitory signs. They may be found in terminal stages of septic shock, being profoundly dehydrated, hypothermic, and comatose.

The acute form is most common, with fever (40° to 41.6° C [104° to 107° F]), depression, and anorexia occurring within 3 to 4 days before presentation. Vomiting, which develops during the illness in most cats, is frequently bile-tinged and occurs unrelated to eating. Extreme dehydration, sometimes exhibited by the cat crouching with its head over the water dish, may occur as a nonspecific feature of this disease (Fig. 10-2). Diarrhea occurs with less frequency. When it is present, the diarrhea usually occurs somewhat later in the course of illness.

On abdominal palpation, the intestinal loops may have a thickened, ropelike consistency, and discomfort is commonly noted. Mesenteric lymphadenomegaly is usually present, whereas peripheral lymph nodes are not enlarged. Oral ulceration, bloody diarrhea, or icterus may be noted in complicated infections. Petechial and ecchymotic hemorrhages may be found in cats with complicating DIC, although cats do not frequently show overt signs of hemorrhage, even with marked thrombocytopenia.

81

82

Fig 10-2 Cat with head hanging over water bowl, a frequent but nonspecific finding in panleukopenia and other acute causes of gastroenteritis. (Courtesy University of Georgia, Athens, Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 10-3 Kitten with congenital feline panleukopenia and cerebellar hypoplasia showing marked ataxia. (Courtesy University of Georgia, Athens, Ga.)

Severe dehydration associated with anorexia, vomiting, and diarrhea can lead to progressive weakness, depression, and semicoma. Cats become hypothermic during the terminal stages of the illness. They can die suddenly from complications associated with secondary bacterial infection, dehydration, and DIC. Animals that survive infection for longer than 5 days without developing fatal complications usually recover, although recovery frequently takes several weeks.

Queens infected or vaccinated during pregnancy may show infertility or abortion of dead or mummified fetuses, but clinical signs are never exhibited in the aborting female. Some kittens in a litter may be born with ataxia, incoordination, tremors, and normal mental status typical of cerebellar disease (Fig. 10-3). They walk with a broad-based stance with hypermetric movements, and they frequently show intention tremors of the head. Tremors and incoordination are absent when kittens are at rest. Not all kittens in a litter are affected or have the same degree of neurologic deficits.⁵³ Signs of forebrain damage include seizures, behavioral changes, and relatively normal gait despite postural reaction deficits. Affected kittens with minimal cerebellar dysfunction can compensate to a degree with time and may make suitable pets with subtle residual deficits.

Retinal lesions may be visible on fundic examination of kittens affected with neurologic signs or as an incidental finding in clinically normal cats. These areas of retinal degeneration appear as discrete, gray foci with darkened margins, and retinal folding or streaking may be seen (Fig. 10-4).

10.5 DIAGNOSIS

10.5.1 Clinical Laboratory Findings

A presumptive diagnosis of systemic feline panleukopenia is usually made based on clinical signs and the presence of leukopenia. Leukocyte counts during the height of severe infection (days 4 to 6 of infection) are usually between 50 and 3000 cells/ μ l. Less affected animals have counts between 3000 and 7000 cells/ μ l. Leukopenia, from which the disease derives its name, is not pathognomonic for FPV infection alone and may not occur in all cases. The severity of leukopenia usually parallels that of clinical illness, and leukopenia also

Infectious Diseases of the Dog and Cat, 3rd Edition

develops in infected germ-free and SPF cats. In FPV, neutropenia develops first, as neutrophils exude into the infected gut, then followed by leukopenia from bone marrow suppression, a resurgence of leukopoiesis characterized by neutrophilia with a left shift follows in cats that recover. As in dogs, CPV infection of cats leads to lymphopenia. Subsequent examination of the leukocyte count in 24 to 48 hours in recovering FPV-infected cats will show a rebound in leukocyte numbers.

Fig 10-4 Dark foci in the retina from a kitten with hydranencephaly and optic nerve hypoplasia as a result of in utero FPV infection. (Courtesy Charles Martin, Athens, Ga.)

Feline salmonellosis with overwhelming septicemia may mimic feline panleukopenia with the presence of leukopenia and acute gastrointestinal (GI) illness. Fecal culture may be helpful under these circumstances (see [Chapter 39](#)).

A transient decrease in absolute reticulocyte count and a mild (5% to 10%) decrease in hematocrit have been found during the viremic period in experimentally infected kittens. Because of the sudden onset of the disease and relatively long life span of erythrocytes, marked anemia is also less common in panleukopenia unless intestinal blood loss is severe. A persistent, nonregenerative anemia and leukopenia are more suggestive of feline leukemia virus (FeLV) infection (see Diagnosis, [Chapter 13](#)).

Thrombocytopenia is a variable feature of feline panleukopenia and may be found with other coagulation abnormalities in cats that develop DIC. Thrombocytopenia, resulting from direct bone marrow injury, can also occur in association with leukopenia early in the course of infection.

Biochemical findings in FPV infections are usually nonspecific. Increases in alanine aminotransferase (ALT) and aspartate aminotransferase (AST) activities or bilirubin can reflect hepatic involvement, but elevations are mild

Infectious Diseases of the Dog and Cat, 3rd Edition

to moderate and icterus is rare. Azotemia is frequently present from prerenal or nonrenal causes such as dehydration, although the virus can produce minimal renal pathologic effects.

Magnetic resonance imaging or computed tomographic scanning can be used to visualize cerebral or cerebellar cortical defects in cats with neurologic signs resulting from in utero infections.⁵³

10.5.2 Serologic Testing

These procedures are available for the properly equipped diagnostic and research laboratory, although they are rarely indicated for clinical practice. Serum VN is the most common method. Twofold serial dilutions of antisera are performed against precalculated amounts of FPV. Virus and sera are incubated before inoculation of the cell culture. Cultures can be examined for specific cytopathic changes and inclusion bodies produced by the virus. The first sample is taken as soon as possible during the illness, and the second is taken 2 weeks later. A fourfold rise in VN titer is indicative of acute infection. Complement fixation (CF) titers also can be performed. Hemagglutination inhibition (HI) and hemagglutination tests can be performed using some strains of FPV, which, as with CPV, will variably agglutinate porcine erythrocytes at 0° C but at pH 6.4 rather than 7.2. The variation is usually related to individual variation among pig erythrocytes in the test. A fourfold rising titer is considered indicative of active infection. VN and HI titers have been used as the reference standards for protection against infection.^{34,51} Minimum titers (greater than 1:10) that correlate with resistance to challenge infection have been determined in these studies. The highest titers are consistent with natural exposure to virus, as few cats mount these titer responses after vaccination. In one study,³⁴ the enzyme-linked immunosorbent assay (ELISA) method was too sensitive in that positive titer results were detected in a low number of unvaccinated cats that were not protected following challenge infection.

10.5.3 Fecal Enzyme-Linked Immunosorbent Testing

ELISA for CPV antigen, in feces or intestinal contents, is a sensitive and practical indicator of FPV infection in kittens.^{1,2,12} Commercially available kits are available for this purpose (see [Appendix 6](#)). Results using fecal ELISA kits for CPV have varied between these commercial assays² so that preliminary evaluation is advisable. Assays have also been performed on tissue specimens taken at necropsy. These are homogenized, and the supernatant has been applied directly on the test strip.² However, it must be borne in mind that FPV may be detectable only in the feces by ELISA kits for 24 to 48 hours PI and that by the time clinical signs occur, the virus is no longer detectable. The virus can be detected for longer periods using viral isolation; however, this method is not clinically practical. For these reasons, antibody testing or histology (or both) is also recommended.

10.5.4 Viral Isolation

Feline cells are required to support viral replication in cell cultures, and frequent mitosis is needed to ensure a continuing infection, although FPV has been shown to replicate in cells in which DNA synthesis has been blocked. Cytopathic effects, required to substantiate the presence of the virus, are more easily demonstrated in young, rapidly multiplying cells. Plaque-detection methods are possible when certain cell types and cell synchronization are used. Virus can be isolated from the urine and feces of kittens surviving experimental in utero inoculation at 3 and 6 weeks after birth, respectively. Using PCR, attenuated FPV has been detected in tissues for at least 19 days after vaccination.⁸ Direct culture from trypsinized lung and kidney tissues allows improved isolation of the virus for up to 70 days. Virus has been isolated by direct culture for up to 1 year from the lungs and kidneys of prenatally infected kittens, despite a high level of circulating antibody. Virus can be

Infectious Diseases of the Dog and Cat, 3rd Edition

found in the CNS for at least 22 days after neonatal infection and thereafter persists in Purkinje's cells. Direct fluorescent antibody (FA) testing can be used to detect virus in cell cultures and from tissues (usually intestine) of infected cats within 2 days after infection. Monoclonal antibodies can be used to distinguish FPV from CPV strains, as can PCR followed by restriction enzyme digestion analysis.^{2,22,50}

10.5.5 Genetic Detection

PCR has been used to identify FPV in intestinal and tissue samples from cats.^{14,33,36,53} This technique is especially valuable in localized tissue infections, given that viral quantities are low. It also can be used on formalin-fixed, paraffin-embedded tissues. Because carnivore parvoviruses can cross-infect multiple species, genetic detection permits specific identification of the viral strain.

10.6 PATHOLOGIC FINDINGS

Gross pathologic changes in naturally infected cats are usually minimal. The intestinal tract is obviously dilated; the bowel loops are firm and may be hyperemic (Fig. 10-5) with petechial and ecchymotic hemorrhages on the serosal surfaces. The feces frequently have a fetid odor when blood is present. Prenatally infected cats may have a small cerebellum, hydrocephalus, or hydranencephaly (Fig. 10-6). Thymic atrophy, present in all infected neonates, is the only gross finding in germ-free kittens.

Histologic abnormalities in the intestine include dilated crypts, with sloughing of epithelial cells and necrotic debris into the lumen (Fig. 10-7). Crypt-lining cells may slough completely in some cases so that only the basement membrane remains. Shortening of villi occurs secondary to the necrosis of crypt cells. The most severe histologic lesions are found in the jejunum and ileum; the duodenum and colon are less severely affected. Focal damage is most prominent around lymphoid follicles in the submucosa of the small intestine. Lymphocytic infiltrations are conspicuously absent from all tissues, and lymphocyte depletion is present in the follicles of lymph nodes, Peyer's patches, and spleen. Lymphoid atrophy is present with concomitant mononuclear phagocyte hyperplasia. FeLV-associated enteritis has been confused with FPV enteritis, being described as a panleukopenia-like syndrome. In cats with FPV infection, mucosal infiltration is mild, caused by the absence of leukocytes, and T cells predominate.³³ In contrast, cats with FeLV-associated enteritis have marked mucosal infiltrates associated with mononuclear and T cells.

83

Fig 10-6 Cerebellar hypoplasia in a brain from a cat with in utero FPV infection.

84

Infectious Diseases of the Dog and Cat, 3rd Edition

Histologic abnormalities in the cerebrum of prenatally or neonatally infected kittens can include dilation of the ventricles and disruption of the ependymal cells with malacia of subcortical white matter. Cerebellar degeneration is marked by disorientation and reduced population of the granular and Purkinje's cell layers. Myelin degeneration can be found predominantly in the lateral funiculi of the spinal cord.

Eosinophilic intranuclear inclusions can be found in FPV infection, although they are transient and are frequently absent with routine formalin fixation. Bouin's or Zenker's fixatives must be used. Electron microscopic (EM) findings indicate that the inclusions correspond with sites of virus replication. As with CPV infection, EM can detect viral particles in intestine and fecal specimens. Immunohistochemical staining can be used to detect virus in tissue specimens.

10.7 THERAPY

Mortality caused by FPV infection can be avoided with appropriate symptomatic therapy and nursing care. Cats that can be kept alive for several days with supportive measures usually develop adequate immune defense mechanisms to overcome the infection. Parenteral fluid therapy is employed to replace lost electrolytes, counteract dehydration, and replace daily maintenance needs. Oral intake of food and water should be withheld during this time to lessen vomiting and slow the bowel mitotic activity that is necessary for viral replication. Fluid volumes that must be replaced as a result of vomiting and diarrhea can be calculated by evaluating the cat's state of hydration. Additional maintenance needs from insensible losses are administered at a rate of 44 ml/kg/day. Balanced isotonic fluid replacement with lactated Ringer's solution is desirable, and potassium supplementation may be beneficial. Fluids can be administered subcutaneously (SC) unless severe dehydration associated with reduced peripheral vascular circulation occurs for which intravenous (IV) therapy is required.

Fig 10-7 Microscopic appearance of the jejunum from a cat with FPV infection. Dilated crypt lumina and collapsed villi are visible in the lower part of the figure; there is sloughing of epithelial cells. Necrotic debris and overlying inflammatory exudate are present in the intestinal lumen in the upper part of the figure (H and E stain, $\times 100$). (Courtesy University of Georgia Athens, Ga.)

Antiemetics may be required to control persistent vomiting ([Table 10-2](#)). The use of anticholinergic medications is controversial and is contraindicated because they produce sustained ileus of the bowel. Metoclopramide given parenterally works best. GI protectants such as kaolin-pectin and bismuth subsalicylate have been recommended to coat the bowel but cannot be given to vomiting animals. Bismuth compounds have the added a theoretic advantage

Infectious Diseases of the Dog and Cat, 3rd Edition

of reducing increased intestinal secretion and resulting diarrhea. Glucocorticoid therapy should not be selected routinely at antiinflammatory or higher dosages because of its immunosuppressive effects.

Plasma or blood transfusion therapy may be required in cats that develop severe anemia, hypotension, or hypoproteinemia (plasma protein less than 5.0 g/dl). A platelet count and activated coagulation time should be evaluated before administration of blood products in cases of ongoing DIC. Low-dose SC heparin therapy (50 to 100 U/kg given every 8 hours) can be administered simultaneously with transfusion if thrombocytopenia and severe incoagulability are present. Antiserum or high-titer parvoviral antiserum from vaccinated or recovered cats is beneficial if given after exposure and before clinical signs are noted. After signs are observed, it is too late.

84

Table 10-2 Drug Therapy for Feline Panleukopenia

85

DRUG	DOSAGE ^a (mg/kg)	ROUTE	INTERVAL (HOURS)	DURATION (DAYS)
Antiemetics				
Metoclopramide	0.2–0.4 ^b	PO, SC	6–8	prn
	1–2	IV	24 ^c	prn
Thiethylperazine	0.5–5.0	IM, SC	8	prn
Trimethobenzamide	3.0	IM, SC	8	prn
Antimicrobials				
Ampicillin, amoxicillin	15–20	IV, SC	6–8	prn
Cephapirin	10–30	IV, SC, IM	6–8	prn
Gentamicin	2	IV, SC, IM	8	prn ^d
Interferon- ω	2.5×10^6 units/kg	IV	24	prn

PO, By mouth; SC, subcutaneous; IV, intravenous; IM, intramuscular; prn, as needed.

- a Dose per administration at specified interval. For additional information on these drugs, see Drug Formulary, [Appendix 8](#).
- b Should not be given in conjunction with other motility modifiers.
- c Total dose IV not to exceed 1 to 2 mg/kg/day; this dose may be divided as multiple bolus infusions throughout the day.
- d Renal function (blood [serum] urea nitrogen [BUN], urine casts) should be closely evaluated, and the drug should not be continued for longer than 7 to 10 days at this dosage.

Broad-spectrum antibiotics, such as ampicillin or cephalosporin, are administered to control secondary bacterial infection resulting from virus injury to the intestinal mucosa (see [Table 10-2](#)). Parenteral therapy is preferred because of continued vomiting. A combination of a penicillin or cephalosporin derivative with parenteral aminoglycosides may be required for cats that are septic or moribund. Caution must be taken with aminoglycosides, because of their nephrotoxic potential, and with quinolones, because of cartilaginous toxicity in growing animals and retinal toxicity, especially in cats (see Antibacterial Chemotherapy, [Chapter 34](#), and Drug Formulary, [Appendix 8](#)). One rationale for antibiotic therapy in this disease is to reduce the mitotic activity of the bowel epithelium by decreasing intestinal microflora, because germ-free animals have been shown to have a mild form of disease.

Combination B-vitamin therapy should be given parenterally to all cats with feline panleukopenia because of decreased food intake from anorexia, high requirements for B vitamins, and loss in diuresis to prevent development of thiamine deficiency. Low-dose oral or parenteral diazepam (2.5 mg total) can be used intermittently, a few minutes before feeding, to stimulate the appetite of anorectic cats that are not vomiting. IV recombinant feline interferon used to treat CPV reduced mortality 6.4-fold,¹¹ and no reason can be found to think that it would not be equally effective in feline parvovirus infections.

Infectious Diseases of the Dog and Cat, 3rd Edition

Response to therapy can be followed by monitoring the total and differential leukocyte counts because a resurgence of leukopoiesis occurs within 24 to 48 hours. Bizarre forms of leukocytes can be detected in the blood and bone marrow.

After the nursing period, the cat can be started on oral alimentation by frequent feedings of small quantities of bland baby food, broth, or blended food. Eventually, the cat may be fed larger quantities of solid foods. Semimoist foods have lower residue and help firm the feces of cats with persistent diarrhea. On rare occasions, cats that refuse to eat after several days should be force-fed by mouth or by pharyngostomy or gastrostomy tube or given diazepam, as indicated previously.

10.8 PREVENTION

10.8.1 Maternal and Passive Immunity

Colostrum antibodies to feline panleukopenia have a half-life of 9.5 days (see [Tables 100-2](#) and [100-4](#)). MLV vaccines and inactivated tissue culture (TC)–origin vaccines are both ineffective when maternal-derived antibody VN titers, as measured by some laboratories, are greater than 1:10. Successful vaccination without maternal antibody interference can be achieved by 12 to 14 weeks of age in most cases (range is 6.8 to 18.8 weeks), depending on the antibody titer in the queen. Kittens with VN titers from 1:10 to 1:30 cannot be successfully vaccinated but are susceptible to infection with FPV. Similar to pups infected with CPV, kittens can still be infected with FPV before the time they are immunized, although this problem has not been as widely recognized. Recovery from natural infection with virulent virus probably results in lifelong immunity.

Therapeutic passive immunity has been used to prevent panleukopenia. Homologous antisera from cats with a high titer to infection will provide immunity according to the titer of the product and the amount administered. The recommended dose is 2 ml per kitten given SC or intraperitoneally (IP). Because administered immunoglobulins persist for up to 2 to 4 weeks, the neonatal vaccination series must be delayed. Passive administration of antisera is recommended for use *only in exposed susceptible* (unvaccinated) cats that require immediate protection or in colostrum-deprived kittens, with subsequent vaccinations at 2 to 3 or 4 to 5 weeks of age with inactivated or MLV vaccines, respectively. Newborn kittens are immunologically competent to FPV and can respond with neutralizing antibodies at 7 to 12 days of age.

10.8.2 Active Immunization

Active immunization has been the most important factor in reducing the incidence of the disease. Both inactivated and MLV products have been effective in preventing this disease. TC-origin-inactivated products can break through maternal immunity as early as MLV vaccines. Unlike MLV products, they have the advantage of being safe in pregnant queens and in kittens younger than 4 weeks. Inactivated vaccines may be given to febrile kittens when an effective immune response is doubtful. No danger exists of postvaccinal virus spread or clinical illness as a result of reversion to virulence, although the suspicion is that inactivated products can contain live virus. The major disadvantage of these products is that, in the absence of maternal antibody, two injections are required to achieve a titer that can be obtained from one injection of MLV product. Protection with inactivated vaccines does not consistently occur until 3 to 7 days after the second vaccination. Antibody titers to inactivated vaccine have been adequate for protection by 2 weeks after the first vaccination but have been greatly boosted by the second injection. Cell-mediated immune (CMI) responses to FPV were stimulated as early as 3 days after the second of two doses of adjuvant inactivated FPV vaccine. Long-term duration of immunity studies show protection against challenge infection after 7.5 years in cats that were vaccinated as kittens.⁵² The inactivating

85

86

Infectious Diseases of the Dog and Cat, 3rd Edition

agents used in some of these vaccines are also irritating to cats. With cloning of FPV into bacterial plasmids, developing a more purified subunit vaccine against this infection may be possible. A raccoon poxvirus-vector, recombinant FPV vaccine has protected cats against challenge infection.²³

MLV vaccines produce more rapid and effective immunity than do inactivated virus vaccines. In the absence of maternal antibodies, one injection of any of the currently available MLV products for panleukopenia will produce a protective titer or HI or serum neutralizing titers greater than 1:8 to 1:10^{34,52} in a previously unvaccinated cat; however, a second vaccination is recommended. Oral vaccination with MLV vaccine is ineffective, whereas IN or aerosol exposure to vaccine produces an active immune response. MLV vaccines are recommended in contaminated areas such as shelters and infected catteries or in outbreaks to provide faster protection. MLV vaccines should be avoided in immunosuppressed cats because of the risk of vaccine-induced disease (see [Chapter 100](#)).

Colostrum-deprived kittens can be vaccinated regardless of age, but MLV products should be avoided in kittens younger than 4 weeks because of the danger of producing cerebellar degeneration. Colostrum-deprived kittens younger than 4 weeks at first presentation should receive at least two inactivated FPV vaccines 2 to 3 weeks apart. If 4 weeks or older, these kittens can receive one MLV-FPV vaccine with an optional one given 2 to 3 weeks later.

Initial vaccinations for nursing kittens are generally begun at 8 to 9 weeks of age and are followed by at least one more MLV product or two more inactivated vaccines, depending on which type of antigen is used. Subsequent vaccines should be given 2 to 4 weeks thereafter; the last vaccine is given at 12 to 20 weeks of age. In situations of apparent vaccine breaks or kitten mortality, prior or subsequent vaccinations in the initial series might be considered.² Panleukopenia vaccines are usually given SC. Combined vaccines that contain FPV and rabies or feline respiratory viruses have been marketed. See Feline Panleukopenia in [Chapter 100](#) and [Appendix 2](#) for overall vaccination recommendations for prevention of this disease.

Annual vaccination against panleukopenia is recommended and performed by most veterinarians, although it is probably not essential. Actually, one MLV product or two inactivated vaccines may produce lifelong immunity. Two inactivated vaccines given at 8 and 12 weeks to SPF kittens isolated in a barrier-maintained research facility produced high persistent VN antibody titers for at least 6 years.⁵⁰⁻⁵² In all likelihood, revaccination produces an anamnestic response and presumably is not harmful. After the kitten series, and a first booster 1 year later, triennial vaccination in conjunction with the rabies vaccine offers adequate protection.⁵⁰

Proper disinfection procedures are essential to prevent or control an outbreak owing to the high resistance of FPV. Household bleach diluted 1:32 (1 oz/gallon) should be used on all cages, feeding dishes, floors, and holding areas, in addition to general cleansing. In cat holding facilities, all new cats should be vaccinated on arrival with MLV products and kept in disinfected cages separate from the resident cats for several days.

10.8.3 Control of Outbreaks

Disease clusters of FPV infection in cats have been described in recent years. In some cases, this incidence has been in catteries with currently vaccinated pedigree cats.^{2,7} Such outbreaks can develop because of inherent immunodeficiency associated with young age, inbreeding, maternal antibody interference, or a highly contaminated environment. Some of the kittens were infected before they could be successfully immunized as a result of maternal antibody blockade, coupled with a highly contaminated environment. An early vaccination of kittens beginning at 6 weeks of age, instead of the conventional 8- to 9-week age period, was shown to induce a

Infectious Diseases of the Dog and Cat, 3rd Edition

response in a significant proportion of kittens by 9 weeks of age. It did not interfere with subsequent response to vaccination at 9 and 12 weeks.¹⁰ Furthermore, cases in which outbreaks are noted in older kittens, vaccination should be continued beyond 12 weeks, with an additional dose at 18 to 20 weeks to obtain seroconversion.² Other outbreaks have occurred in large congregations of cats in humane society or animal control facilities.⁷ These outbreaks usually occur in young cats that have been born or brought into these facilities. Use of inactivated vaccines has been one contributing factor to outbreaks in these highly contaminated environments. Protection with inactivated vaccines is generally delayed for 2 to 3 weeks after the second vaccine in nave kittens. These cats are generally exposed and infected before immunity can develop. Use of MLV vaccines at the time of entry, and before exposure, may help control such outbreaks. In some instances, these outbreaks might relate to infection with CPV-2 variants (see later discussion) because these may infect cats with preexisting immunity to FPV. Generally, infections with these strains are mild, even in nave cats; however, laboratory challenge studies with CPV-2 strains may not always reflect natural circumstances.

IN vaccination for parvoviral infections are not as effective as parenterally administered vaccines. Parvoviruses cause a systemic viremia in their host, and circulating antibody has a major role in immunity and clearing the virus from the body. During viremia, parvoviruses cause cytolysis and subsequently spread extracellularly and must escape to new dividing cells, thereby becoming exposed to circulating antibody. An outbreak of salmonellosis and panleukopenia was reported in a purebred cattery where IN trivalent vaccine was used.¹⁴

10.9 CANINE PARVOVIRAL INFECTION IN CATS

10.9.1 Etiology

Parvoviruses as a group are relatively stable. Viruses isolated for many decades appear to be homogeneous. The basic parvoviral gene sequence has a common ancestral sequence; however, viruses isolated from particular carnivore hosts are very closely related and have only minor differences. This relationship suggests that host adaptations have been constant and evolving with time. FPV was the only type parvovirus recognized to infect cats until the mid 1940s. An outbreak of enteritis and mortality in mink was ascribed to a virulent closely related mutant MEV. Both FPV and MEV are closely related and are divided into at least three subtypes; the first two are commonly isolated from mink. The original CPV-2 strain, detected in the mid to late 1970s, was thought to have originated from an FPV or closely related parvoviral strain of mink or other carnivore. CPV-2 differed in two specific epitopes on its cell surface and its ability to cause hemagglutination (HA) of feline erythrocytes at specific pH. The HA specificity is determined by binding of a specific viral epitope to N-glycolylneuraminic acid, a sialic acid present on feline blood group-A erythrocytes, but not on dog erythrocytes. In cell culture, feline and canine parvoviruses replicate in most feline cells; however, only CPV-2 and its variants replicate in dog cells. FPV can replicate in dog thymus and bone marrow cells, but no other canine tissues. Therefore infections of dogs with FPV are self-limiting and do not spread. The CPV-2 mutation was associated with the ability of this virus to replicate in the canine gut and associated lymphoid tissues, with transmission to other hosts via excreta. The ability to infect and spread in cats was lost.

Since its evolution and host adaptation to dogs, CPV-2 in domestic and wild dog populations spread throughout the world between 1974 and 1978. Genetic analysis indicated that alterations in four sequences in the viral capsid protein gene were responsible for this change in host specificity. Since that occurrence, CPV has undergone several changes in the ancestral sequence with the origination of three new variants to date. CPV-2a was recognized, as the predominant isolate between 1979 and 1981. It had five to six amino acid differences on the nucleocapsid surface, which can be detected by monoclonal antibody and later by genetic analysis (see [Table 10-1](#)). CPV-2b was first detected beginning in 1984, and, although all three strains co-exist, it is currently the

Infectious Diseases of the Dog and Cat, 3rd Edition

predominant worldwide isolate from dogs.⁴⁶ Unlike CPV-2, CPV-2a and CPV-2b strains readily replicate in feline ileum and lymphoid tissues. A new CPV-2c variant having two subtypes (a and b) was isolated from leopard cats in southeast Asia.^{28,29} These subtypes have not been isolated from naturally infected cats or dogs and may represent an offshoot mutation.

One of the confusions with the parvoviral nomenclature for carnivores is that viruses have been named according to the host from which they were isolated, rather than their genetic relatedness. Because of the close genetic relationship, and spread of many of these isolates between hosts, a newer designation must be devised. With the present system, CPV-2a and CPV-2b might be termed as variants of FPV in their behavior, even though they cannot be distinguished from identical isolates made from dogs. Therefore the designated terms as listed in [Table 10-1](#) should be used to describe certain genetic, antigenic, and host range differences between various isolates.

The nature of host specificity has been elucidated through genetic analysis and x-ray crystallography. Regions in the capsid structure located around VP2 residues can influence canine transferrin receptor and affect the host cell species of infectivity.^{17,25,26} Mutations in the genes controlling these capsid moieties and selective pressures allow the parvoviruses to evolve and infect new hosts.²⁴

10.9.2 Epidemiology

CPV-2 and its newer strains are actually host range variants of FPV. CPV-2 does not replicate in cats, but CPV-2a and -2b do so very efficiently. CPV-2a and -2b have been isolated from between 10% and 20% of domestic cats with naturally occurring parvoviral disease from Germany.⁵⁹ In such areas, FPV is still the major parvovirus infecting cats. In southeast Asia, CPV-2a, -2b, and -2c strains predominate in isolations from large exotic cats.^{42,56} One supposition is that large felids are more susceptible to CPV than they are to canine distemper virus.⁵⁶ Another theory is that these large cats were not vaccinated and that the subtypes 2a and 2b can spread more effectively because of the wider reservoir host range. Under these conditions, domestic and exotic cats likely acquire their CPV-2a and -2b infections from an environment that is contaminated by dog feces. Isolations from domestic and exotic cats have varied between these two strains, according to the predominant strain in the local dog population. Levels of CPV-2 strain shedding by cats (0.5 to 2.0 log₁₀) are lower than those found with similar infections in dogs (6 to 9 log₁₀), although they are sufficient to infect susceptible in contact cats. Nevertheless, infected dogs are more likely to disseminate virus in the environment and be reservoirs for feline infection. A prediction for the future is that CPV-2a and -2b will replace FPV and CPV-2 as the predominant carnivore parvoviruses worldwide.³⁰

10.9.3 Clinical Signs

CPV strains 2a and 2b can induce disease in infected cats with signs similar to those of feline panleukopenia.^{8,37,43,47} The natural infection has often been asymptomatic as have the experimental infections of SPF cats.^{40,59} However, the development of clinical illness may relate to the general condition of the cats involved at the time of exposure. Laboratory experiments with parvoviruses in SPF animals do not always match corresponding disease in conventional animals or in those animals that acquire infection in nature. Host factors are likely important because infections with CPV-2a, -2b, and -2c have been clinically significant in exotic felids.^{29,43,56}

Given that clinical signs are milder or unapparent in CPV-2a or -2b-infected cats as compared with those with FPV infection, the suspicion was that CPV-2 strains were less virulent. Of the new strains, CPV-2c appears to be

Infectious Diseases of the Dog and Cat, 3rd Edition

relatively the most pathogenic.²⁹ In SPF cats, those inoculated with CPV-2c became clinically ill with leukopenia and diarrhea.⁴³ Correspondingly, more severe signs were noted in FPV-infected cats while signs were milder or absent in CPV-2a-infected cats.

10.9.4 Diagnosis

Pronounced lymphopenia and mild leukopenia have been observed in cats challenged with CPV, similar to the leukocyte alterations with this infection in dogs.⁸ This condition contrasted to the marked leukopenia and mild lymphopenia observed in corresponding cats challenged with FPV.

Antibody titers in serum to CPV-2a, -2b, and -2c cross react with those to FPV. Titers would be lower between the heterologous agents; however, this would not be clinically detectable unless multiple viruses were used as antigen simultaneously. Parvo-ELISA test kits can be used to detect parvoviruses; however, the levels of virus in stool using one kit was 2.76 log₁₀ lower than those found with corresponding FPV infection in cats.⁸

Carnivores that recover from parvoviral infections generally stop shedding virus once high levels of serum antibodies are present. Although they may persist for variable periods, tissues and secretions of recovered animals are cleared of virus. Surprisingly, CPV-2a and -2b strains have been isolated from the peripheral blood mononuclear cells of clinically healthy cats with high VN antibody titers against FPV.^{28,29,37} Whether these infections are associated with intermittent or chronic virus shedding is uncertain.

10.9.5 Therapy

CPV infections in cats have been reported to be milder than those associated with FPV infection. Treatment would be identical with that for treating feline panleukopenia (see the previous section on Therapy).

87

88

10.9.6 Prevention

CPV and FPV viruses cross-react with VN and HI antibody titers. Lower cross-reactivity of these antibodies are observed against CPV strains in cats experimentally inoculated with FPV or vaccinated with inactive FPV vaccines, as compared with cats being challenged with CPV strains.⁴² Vaccination of large cats in zoos against feline parvovirus is recommended to produce immunity against that infection and protect against heterologous infection with CPV-2a and -2b. FPV vaccines may have a short duration and partial protection against CPV-2 strain infections.

Attenuated FPV vaccines have protected domestic cats from clinical illness and virus shedding following challenge with CPV-2b isolates at 2 weeks after vaccination.⁸ Similar challenge studies have not been performed with inactivated vaccines, and longer-term challenge studies are not available. Cheetahs have been infected with CPV strains despite FPV vaccination.⁵⁶ In vitro, a cross-neutralization study following inactivated FPV vaccination indicated antibodies developed against FPV, CPV-2a, -2b, and -2c.⁴² However, the antibody titers against the CPV strains were considerably lower. CPV-2c had the lowest degree of cross-reactivity with FPV, which may explain the higher degree of virulence of this CPV-2 strain for cats. Interestingly, cats infected with CPV-2c have had high cross-reactive titers against CPV-2a and -2b. Specific vaccines against CPV-2 strains may be needed to protect domestic and exotic cats in the future. A CPV-2c strain would be a logical candidate for the antigen.

Infectious Diseases of the Dog and Cat, 3rd Edition

11 CHAPTER 11 Feline Coronavirus Infections

Diane D. Addie

Oswald Jarrett

The clinical condition of feline infectious peritonitis (FIP) was first described in the 1960s.⁸² Subsequent studies of the lesions of FIP by electron microscopy (EM) incriminated a coronavirus. FIP is the major infectious cause of mortality in cats.¹⁸⁴ A possible explanation for an apparent increase in the prevalence of FIP is that management of the domestic cat has changed.^{141,143} With the introduction of cat litter, more cats have been kept permanently indoors, exposing them to large doses of feline coronavirus (FCoV) in the feces, which would previously have been buried outdoors. More and more cats are spending part of their lives in multicat crowded environments such as at cat breeders or shelters, which increases their stress and chance of exposure to pathogens while in such an environment.

11.1 ETIOLOGY

FCoVs belong to the order Nidovirales and family *Coronaviridae*. The coronaviruses are large, enveloped, positive-stranded RNA viruses. The major viral proteins are the spike (S), nucleocapsid (N), and membrane (M). Until the emergence of the severe acute respiratory syndrome (SARS) caused by SARS coronavirus (SARS-CoV), coronaviruses were divided into three groups. It has been debated whether SARS-CoV belongs to the second group or forms a different, fourth group.^{54,110,156,169} Rota et al¹⁵⁶ found no genetic similarities between SARS-CoV and FCoV, but Stavrinides and Guttman¹⁶⁹ demonstrated that SARS-CoV S protein is a mosaic of group I CoVs and an avian CoV. They found many similarities between the S of type II FCoV strain 79-1146²⁸ and the Urbani SCoV strain (except for a 200-base-pair region that was similar to an avian sequence). At the time of writing, the SARS-CoV is thought to have originated from the masked palm civet cat (*Paguma larvata*), which is not a feline but is a member of the mongoose family (Viverridae). Nevertheless, cats may become infected with SARS-CoV experimentally¹¹⁹ and naturally; a single cat from a household of infected people seroconverted (though remained healthy). The consensus is that people cannot get SARS from their pet cats (*Felis catus*).

FCoVs are in group I of *Coronaviridae*, the same group as transmissible gastroenteritis virus (TGEV), porcine respiratory coronavirus canine coronavirus (CCV),^{75,121,127} and human bronchitis, coronavirus serotype 229E (HCoV 229E).¹⁷ A comparison of these viruses and their pathogenicity for cats is summarized in [Table 11-1](#).

89

11.1.1 Types I and II Feline Coronaviruses

The isolation of FCoV in cell culture is very difficult.⁶⁸ Laboratory strains of FCoV can be classified into types I and II according to their growth characteristics in cell culture, cytopathogenicity, and comparative degree of neutralization by antisera to canine coronavirus.^{84,143,185} Type I is wholly feline, whereas type II FCoVs are genetically more closely related to CCV than are type I FCoVs.^{67,127,185} Type II FCoVs have arisen by recombination between type I FCoV and CCV.^{67,68,127,185} Most of the spike of the type II FCoV is CCV spike.⁶⁷ Type I is the more prevalent type in field infections.^{9,68,74} Each type is capable of causing a spectrum of clinical signs in cats, ranging from asymptomatic infections to diarrhea to FIP.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 11-1 Features of Coronaviruses That Infect Cats

VIRUS	HOST	VIRUS INFECTS CATS	CATS DEVELOP FIP	SEROCONVERTS CATS	COMMENTS AND REFERENCES
FCoV	Cat	+	± ^a	+	Designation for coronaviruses that cause asymptomatic infections, diarrhea, or FIP in cats; previously called "FECV" and "FIPV"; can infect newborn pigs, producing lesions similar to mild TGEV. ¹⁴⁵
CVLP	Cat	+	— ^b	—	Observed in feces of cats ^{26,85} ; not cross reactive with FCoV; not believed to cause disease in cats ^{85,145} but has been associated with diarrhea ^{12b} ; may be excreted for 12 months after infection. ⁸⁵
CCV	Dog	+	— ^c	+	Causes diarrhea in dogs; infected cats seroconvert but are clinically normal after oronasal exposure ⁹ ; cats develop effusive FIP after IM or IP inoculation ¹²¹ ; shed from oropharynx but not feces of experimentally infected cats for 1 week; ⁹ vaccines given IM can cause ADE in cats, ^{83,121} and one caused FIP-like signs in dogs.
TGEV	Pig	+	—	+ ^d	Causes vomiting and diarrhea in piglets younger than 1 month; replicates in villous tip epithelium of SI; mutation in 1980 caused new variant—porcine respiratory coronavirus ⁸⁴ ; can subclinically infect cats but no ADE with subsequent FCoV infection ¹⁸ ; serologic cross-reactive with CCV and FCoV.
SCoV	Human	+	—	+	No clinical signs in cats; seroconversion by 28 days after infection; virus detected in oropharyngeal and nasal swabs 4 and 6 days after infection, respectively, but not in rectal swabs. ¹¹⁹
HCV-229E	Human	+	—	+	Causes common cold in people and nonsymptomatic feline infection with minimal viral replication and no ADE. ⁹

FCoV, Feline coronavirus; CVLP, coronavirus-like particles; CCV, canine coronavirus; TGEV, transmissible gastroenteritis virus; SCoV, severe acute respiratory syndrome coronavirus; HCV-229E, human coronavirus-229E; ADE, antibody-dependent enhancement; +, occurs; ±, variable occurrence; —, = does not occur.

a Diarrhea or FIP.

b Nonsymptomatic or diarrhea. Virus may be excreted in feces for up to 12 months.

c Oronasal infection. Virus is shed from oropharynx but not feces for 1 week although asymptomatic virus can cause FIP if given parenterally.

d Diarrhea and lesions indistinguishable from mild TGEV infection. In the 1980s a new TGEV variant called porcine respiratory coronavirus was developed.

Infectious Diseases of the Dog and Cat, 3rd Edition

11.1.2 Biotypes Feline Enteric Coronavirus and Feline Infectious Peritonitis Virus

Laboratory strains of FCoV vary in their ability to cause disease when administered to cats.¹⁷ Some laboratory isolates are unable to cause FIP when inoculated intraperitoneally (IP) into cats and are named feline enteric coronavirus (FECV). It was once thought that these viral strains did not leave the gut, but it is now known that they can. It was previously believed that in nature two biotypes of FCoV existed: feline infectious peritonitis virus (FIPV) and FECV, with differing potential for causing disease. In fact, it is now believed that all natural FCoV infections have the potential to cause FIP, although they do so in only approximately 10% of infected cats.

Differing cell tropism of either enteritis- or peritonitis-producing viruses has been suggested as a possible explanation of different manifestations of disease: FECV replicates in enterocytes, causing diarrhea or asymptomatic infection, whereas FIPV replicates in macrophages, leading to systemic infection and FIP. One theory is that for FIP to occur, a mutation must occur in an FECV to permit replication in macrophages.^{170,184} Detection of messenger RNA (mRNA) in circulating monocytes is evidence that the virus is infecting cats systemically and is replicating. A reverse transcriptase polymerase chain reaction (RT-PCR) that detects mRNA was positive in 94% of 49 confirmed cases of FIP and in none of 12 cats with histologically confirmed non-FIP disease. However, 6% of 326 clinically healthy cats had positive test results.¹⁶⁴ Whether detection of mRNA is predictive of development of FIP in the healthy cat remains to be seen.

Comparison of the genomes of FIPV and FECV laboratory strains WSU 79-1146 and WSU 79-1683 revealed a deletion of the 7b open reading frame (ORF) in FECV strain 79-1683, which was postulated to account for the FECV's lack of virulence.⁶⁸ However, ORF7b deletions readily arise during in vitro passage,⁶⁸ and intact 7b genes have been found in most FECV isolates,^{68,184} indicating that deletions in ORF7b are not a universal distinguishing property of FECVs.⁶⁸ Deletions, or nonsense mutations, in the ORF3c of FIPVs are more consistently found in pathogenic strains, having been found in 11 of 13 laboratory strains of FIPV that were compared with the corresponding FECVs from which they had arisen.¹⁸⁴ Deletions turning FECVs into FIPVs make more sense as frequent naturally occurring events than insertions, which would be required to turn FECVs into FIPVs if the 7b theory had been correct. The 7b protein is a secreted, nonstructural glycoprotein whose function is unknown.¹⁸⁴ However, deletions in the 7b gene do seem to correlate with attenuation of virulence, and it has been postulated that it modulates the inflammatory or immune response.⁶⁸

If the mutation hypothesis of FCoV to FIPV is correct, no two cases of FIP are caused by genetically identical viruses. An alternative to the mutation theory is that kittens developing FIP do so because they are subjected to a large viral dose at a time in life when their still undeveloped immune systems are also coping with other infections and the stress of vaccination, rehoming, and neutering.^{12,41,68} Furthermore, pedigree kittens and certain large cats (cheetahs¹⁹) may also be genetically predisposed to developing FIP.³⁹ Preliminary studies failed to show any association of FIP or resistance to FCoV infection with the class II feline leukocyte antigen DRB.⁷ Researchers will explore other genetic markers for susceptibility in attempts to help cat breeders develop lines not susceptible to FIP.

Clearly, wherever natural FCoV infection exists, so does the potential for the development of FIP.¹² In accordance with the guidelines set forth in the Fifth International Symposium on Coronaviruses,¹¹³ the generic term *feline coronavirus (FCoV)* is used when discussing the virus, unless it is meaningful to differentiate FECV

Infectious Diseases of the Dog and Cat, 3rd Edition

and FIPV. *Feline infectious peritonitis (FIP)* is used to denote the multisystemic disease state associated with viral dissemination.

11.2 PATHOGENESIS

Cats become infected with FCoV by ingestion and possibly by inhalation of virus. The receptor for the type II FCoV is an enzyme, aminopeptidase-N, found in the intestinal brush border.¹⁸ The type I FCoV receptor is unknown.⁷¹ Type II FCoV probably replicates in the small intestinal epithelial cells. The main site of type I FCoV viral replication is unknown but is likely to be in the ileum and colon.⁶⁶ Virus is shed in feces from 2 days postinfection.^{11,65,171} In early infection, virus may replicate in the tonsils^{145,171} and oropharynx¹⁴⁰ and is shed in the saliva¹¹⁷ for only a few hours or days.⁶

Although the etiology of FIP is still uncertain, it is an immune-mediated disease involving virus or viral antigen, antiviral antibodies, and complement. A more appropriate name would be *feline coronaviral vasculitis*. Cats that have no anti-FCoV antibodies do not develop FIP, and if FCoV-seropositive cats are decompartmented using cobra-venom factor, FIP does not ensue. Complement fixation leads to the release of vasoactive amines, which cause endothelial cell retraction and thus increased vascular permeability. Retraction of capillary endothelial cells allows exudation of plasma proteins, hence the characteristic protein-rich exudate that develops in effusive FIP.¹⁷

Two possible explanations describe the development of FIP once virus has become systemic. The first is that FCoV is distributed throughout the body by infected monocytes/macrophages; the second is that FIP is an immune complex disease. FCoV-infected monocytes attach to the endothelium of affected blood vessels, extravasate,^{100,104} and enable virus to enter the tissues.¹⁴³ The virus attracts antibodies, complement is fixed, and more macrophages and neutrophils are attracted to the lesion.¹⁴³ Circulating immune complexes have been demonstrated in cats with FIP,⁶⁰ but FIP is atypical of an immune complex disease in that joints and skin are rarely affected.

Effusive FIP is the acute form, usually occurring 4 to 8 weeks after infection or a stressful event, although it can occur terminally in cases of noneffusive FIP, the chronic form of the disease, which occurs weeks to months postinfection. Cats that develop effusive FIP may have a large quantity of virus, leading to the destruction of many blood vessels and the formation of many pyogranulomata. Noneffusive FIP may result from a partially successful cell-mediated immune (CMI) response¹⁴³ or from fewer but often larger pyogranulomata.

The clinical and pathologic signs that occur in FIP are direct consequences of the vasculitis and organ damage that result from damage to the blood vessels that supply them. In effusive FIP, many blood vessels are affected, hence the exudation of fluid and plasma proteins into the body cavities. In noneffusive FIP, the clinical presentation depends on which organs are damaged by the FIP pyogranulomata.

Some viruses have immunomodulating effects on their hosts, which moderate the body's attempts to eliminate the virus. Cats with FIP are lymphopenic, and lymphoid depletion is evident in spleen and lymph nodes. In particular, the number of CD4+ lymphocytes in tissues decreases during the evolution of FIP lesions, most likely because of an increased lymphocyte apoptotic rate. In contrast, cats who survive FCoV infection develop follicular hyperplasia in the peripheral lymph nodes.¹³⁷ Haagmans et al⁵⁷ showed that FCoV-infected cells released a substance that caused apoptosis in bystander T lymphocytes in lymph nodes. The nature and function of this protein has not yet been defined. Possible candidates are the proteins of the FCoV genes 3a-c and 7a-b because

Infectious Diseases of the Dog and Cat, 3rd Edition

these genes are rapidly lost from viruses grown in cell culture with no loss of ability to replicate, indicating that their function is in the cat's body, perhaps as a virokinge.

11.2.1 Protective Immune Response to Feline Coronavirus Infection

The mechanism by which cats are protected against developing FIP is not understood. It is generally assumed cats do not develop FIP because of a successful CMI response and that a humoral response is harmful. Evidence from experimental infections show that cats surviving a challenge mount a greater CMI response than those who succumb.³¹ However, clearance of natural infections also correlated with the presence of a humoral immune response to the FCoV spike protein,⁵³ and it is known that kittens are protected by maternally derived antibody.⁴ Therefore it is possible that some antibody protection also occurs. Humoral immunity associated with secretory IgA is suspected to be important in preventing initial infection of epithelial cells.⁴ In exposed cats, seroconversion occurs within 18 to 21 days after infection.

90

91

The role of other biologic substances in protecting cats against FIP is also unknown: four surviving cats had a transient rise in serum amyloid A (SAA); whether this increase and the decrease in α -acid glycoprotein (AGP) seen in these cats had some protective role has been questioned.⁴⁷ The biologic function of AGP is not completely known. AGP is a natural antiinflammatory and immunomodulatory agent. The immunomodulatory function of AGP is affected by its carbohydrate composition.^{16,43} The Sialyl Lewis X form of AGP is induced during inflammation and ameliorates complement and neutrophil-mediated injuries, whereas the non-Sialyl Lewis X form does not.⁴³ Moreover, Sialyl Lewis X is the ligand for the cell adhesion molecules involved in adherence of monocytes to endothelial cells,⁴³ and one of the earliest stages of the pathogenesis of FIP is the adhesion of FCoV-infected monocytes to the endothelium in FIP vasculitis. It is possible that development of FIP has little to do with the virus and everything to do with the AGP response of the cat.¹

11.2.2 Antibody-Dependent Enhancement of Feline Infectious Peritonitis

Antibody-dependent enhancement (ADE) is a phenomenon that has foiled many attempts to find a successful FIP vaccine.^{132,143,161,180} A greater proportion of cats that had been vaccinated with trial vaccines developed FIP than cats in the unvaccinated control group also exposed to a laboratory strain of FCoV—usually the very virulent 79-1146 type II strain. The proposed mechanism is that antibody facilitates the uptake of FCoV into macrophages.* Cats with ADE develop disease in fewer than 12 days, whereas controls take 28 days or more.¹⁶¹ By contrast, field studies have shown that seropositive pet cats that were naturally reinfected by FCoV showed no evidence of ADE.⁹ Indeed the opposite occurred, because many of the cats that had become seropositive after natural infection appeared to be immune.¹² The mortality rate of cats that were in contact at the time of initial FCoV infection was 14%, compared with about 8% at the time of reinfection.¹² In practical terms a seronegative cat introduced into a household in which FCoV is endemic has a 1 in 6 chance of developing FIP, whereas a seropositive cat has a 1 in 12 chance. Cats are at greatest risk of developing FIP in the first 6 to 18 months after infection, and the risk decreases to about 4% 36 months after infection.¹² Olsen provided an excellent review of ADE of FIP.¹³²

* References 23, 24, 29, 73, 131, 133, 134.

Infectious Diseases of the Dog and Cat, 3rd Edition

11.2.3 Viral Shedding

It is likely that when naive cats in a multicat household first encounter FCoV, most become infected because they seroconvert. FCoV is shed mainly in the feces. In early stages of infection, it may be found in saliva for hours or days⁶ and possibly in the respiratory secretions and urine.^{65,171} It is possible that viral shedding of types I and II are different; laboratory strains, which are typically type II, are shed for only a couple weeks,¹⁷¹ whereas in natural infection, type I virus is shed by 65% of cats for 2 to 3 months and longer by many cats. Thirteen percent of naturally infected cats become lifelong carriers.⁶ A curious feature of lifelong carrier cats is that they shed the same strain of virus continuously in the feces until death, and they rarely develop FIP.⁹ Detection of carrier cats requires positive fecal RT-PCR test results for 9 months (Table 11-2). Cats that are eliminating FCoV may shed virus intermittently or at undetectable levels toward the end of infection.⁶⁶ Virus is maintained in the cat population by chronic carrier cats and through reinfection of transiently infected cats.⁹

The stress of entering a rescue shelter increases viral shedding 10^1 - to 10^6 -fold.¹⁴⁷ However, the stress of pregnancy and lactation did not cause infected queens to shed more virus.⁴⁰ Of cats with naturally occurring FIP, 42% to 75% shed virus.¹¹ Because RT-PCR cannot measure the viability of the detected organism, the infectivity of the shed virus cannot be absolutely ascertained. However, a correlation between strong RT-PCR results and infectivity has been made.⁴⁰

Although serologic testing has limitations, it is clear that seronegative cats, as determined by a *reliable* diagnostic test, do not shed FCoV,^{4,40} whereas approximately one in three FCoV-seropositive cats do shed virus.⁴ Cats with higher antibody titers are more likely to shed virus,^{6,140} although cats with relatively low indirect fluorescent antibody (FA) titers of 1:40 to 1:80 have a 26% to 39% chance of shedding FCoV.^{4,5,6,65} Evidence of viral shedding is never a good reason to euthanize a cat because most FCoV shedders stop within a few months, and less than 10% develop FIP.⁵ In addition, if a cat has survived one exposure to FCoV, it may be better to use it for breeding rather than introduce new susceptible animals that may not be resistant, because a genetic element may play a role in susceptibility to FCoV infection.³⁹

11.2.4 Transmission

Transmission is primarily indirect through contact with virus-containing feces or fomites. The major sources of FCoV for uninfected cats are litter trays shared with infected cats.¹⁴⁴ In new infections, transmission through sneezed droplets, sharing food bowls, and mutual grooming are also possibilities but only for a matter of hours. FCoV is a relatively fragile virus, but in dry conditions it has been shown to survive for up to 7 weeks outside the cat.¹⁶⁰ Transmission through lice or fleas is considered unlikely.¹⁷ Although documented, transplacental transmission is extremely uncommon because most kittens that are removed from contact with adult virus-shedding cats at 5 to 6 weeks of age do not undergo seroconversion.⁴

Whether FCoV transmission in cats shows is unknown. In one survey, showing cats appeared to be of minor significance in FIP incidence,⁹⁰ whereas in another survey 84% of cats at shows in the United Kingdom were found to be seropositive.¹⁶⁷

Infectious Diseases of the Dog and Cat, 3rd Edition

11.3 CLINICAL FINDINGS

11.3.1 Initial Feline Coronavirus Infection

Most FCoV infections are subclinical. When FCoV first infects cats, they may have a brief episode of upper respiratory tract signs or diarrhea, although these signs are usually not severe enough to warrant veterinary attention. Kittens infected with FCoV generally have a history of diarrhea and occasionally of stunted growth and upper respiratory tract signs.⁴

11.3.2 Coronaviral Enteritis

FCoV can cause transient and clinically mild diarrhea,¹⁴³ vomiting, or both in cats. However, occasionally the virus can be responsible for a severe acute or chronic course of vomiting or diarrhea with weight loss, which may be unresponsive to treatment and continue for months.¹⁰³

11.3.3 Feline Infectious Peritonitis

Two basic forms of FIP—effusive (wet) and noneffusive (dry)—have been characterized. Approximately half the cats with FIP are younger than 2 years,^{61,70} but cats of any age can be affected. Evaluation of the history of cats with FIP typically reveals that they lived in a multicat environment in the previous year, usually in cat breeders or rescue facilities. Occasionally, they have been to a boarding cattery, cat show, or veterinary clinic.

91

Cats that have spent several years in a single-cat environment are extremely unlikely to have FIP. Nevertheless,

92

FIP, especially the noneffusive form, can incubate for months or even years.¹⁷⁵ Cats with FIP usually have a history of stress in the previous few months.^{117,153} Those with effusive FIP are usually taken to their veterinarians within 4 to 6 weeks of arriving in a new home, elective surgery, or a similar stressful situation, whereas cats with noneffusive FIP develop disease after a greater interval. Clinical signs may reflect the specific organ systems involved.

^a Author's (DDA) data from a household of cats in which FCoV was successfully eradicated by isolating cats that had eliminated FCoV infection from those who were still shedding virus. The shaded boxes indicate when a cat was moved to another household. By August 1997 the carrier cat was identified as Sooty, and in April 1998 she was rehomed. Note that occasionally cats with antibody titers of less than 100 were shedding FCoV. Newcomers Tabby and Ginger were prevented from becoming infected by being isolated from infectious cats.

11.3.3.1 Effusive Feline Infectious Peritonitis

Cats with effusive FIP have ascites (although very few owners notice the abdominal distension [Fig. 11-1]),¹⁵³ thoracic effusion (Fig. 11-2), or both. The cat may be bright or dull, anorexic, or eating normally. Abdominal swelling with a fluid wave, mild pyrexia (39° C to 39.5° C), weight loss, dyspnea, tachypnea, scrotal enlargement, muffled heart sounds, and mucosal pallor or icterus may be noted. In one survey, FIP

Infectious Diseases of the Dog and Cat, 3rd Edition

accounted for 14% of cats with pericardial effusion, second only to congestive heart failure (28%).¹⁵⁸ Abdominal masses may be palpated, reflecting omental and visceral adhesion, and the mesenteric lymph node may be enlarged.

11.3.3.2 Noneffusive Feline Infectious Peritonitis

Signs of noneffusive FIP are often vague and include mild pyrexia, weight loss, dullness, and depressed appetite. Cats may be icteric. Abdominal palpation usually reveals enlarged mesenteric lymph nodes¹⁰¹ and may also reveal irregular kidneys or nodular irregularities in other viscera. If the lungs are involved, the cat may be dyspneic, and thoracic radiographs may reveal patchy densities in the lungs.¹⁷⁷

Cats with noneffusive FIP frequently have ocular lesions. The most common ocular sign in FIP is iritis, manifest by color change of the iris. Usually all or part of the iris becomes brown, although occasionally blue eyes appear green. Iritis may also manifest as aqueous flare, with cloudiness of the anterior chamber, which in some cases can be detected only in a darkened room using focal illumination. Large numbers of inflammatory cells in the anterior chamber settle out on the back of the cornea and cause keratic precipitates, which may be hidden by the nictitating membrane (Fig. 11-3). Some cats hemorrhage into the anterior chamber. If the cat has no sign of iritis, the retina should be checked because FIP can cause cuffing of the retinal vasculature, which appears as fuzzy grayish lines on either side of the blood vessel (Fig. 11-4).

92

Occasionally, pyogranulomata are seen on the retina, or the vitreous appears cloudy. Retinal hemorrhage or detachment may also occur¹⁷³ but is more commonly a sign of hypertension. Similar ocular signs can also be caused by infections with *Toxoplasma* organisms, feline immunodeficiency virus (FIV), feline leukemia virus (FeLV), or systemic fungi (see Chapter 93).^{112,173}

93

Fig 11-3 Keratic precipitates on the cornea (*arrows*) in noneffusive FIP. The nictitating membrane (*N*) has been deflected down to enable visualization of the precipitates. (Courtesy Diane Addie, University of Glasgow, Glasgow, Scotland.)

Of cats with FIP, 12.5% have neurologic signs¹⁵³; signs are variable and reflect the area of central nervous system (CNS) involvement. With noneffusive FIP, 25% to 33% of cats have neurologic abnormalities.³⁷ The most common clinical sign is ataxia followed by nystagmus and then seizures.¹⁰⁸ When FIP causes meningitis, the signs reflect damage to the underlying nervous tissue: incoordination, intention tremors, hyperesthesia, behavioral changes, seizures, cranial nerve defects, and unexplained fever. When the FIP lesion is a pyogranuloma on a peripheral nerve or the spinal column, lameness, progressive ataxia, or paresis (tetraparesis, hemiparesis, or paraparesis) may be observed. Cranial nerves may be involved, causing symptoms such as visual deficits and loss of menace reflex,¹⁰⁸ depending on which cranial nerve is damaged.

In a study of 24 cats with FIP and neurologic involvement, 75% were found to have hydrocephalus on gross or histologic postmortem examination.¹⁰⁸ Because other diseases such as cryptococcosis, toxoplasmosis, and lymphoma have not been reported to cause hydrocephalus, detecting it on a computed tomography scan is highly suggestive of a diagnosis of neurologic FIP.^{108,37} Meningeal and periventricular contrast enhancement may also be observed.

Infectious Diseases of the Dog and Cat, 3rd Edition

11.3.3.3 Colonic or Intestinal Feline Infectious Peritonitis

Occasionally, the primary or only organ affected by FIP granulomas is the intestine. Lesions are most commonly found in the colon or ileocecolic junction but may also be in the small intestine.^{61,178} Cats may have various clinical signs as a result of this lesion—usually constipation, chronic diarrhea, or vomiting.^{61,178} Palpation of the abdomen often reveals a thickened intestine. A hematologic finding may be increased numbers of Heinz bodies.

11.3.3.4 Clinical Signs in Neonatal and Prenatal Kittens

FIP is the second most common infectious cause of death in kittens after weaning²⁰ but causes no deaths from birth to weaning (“fading kittens”). However, FCoV infection does result in stunting of kittens, increased incidence of diarrhea, and upper respiratory signs. FCoV does not cause infertility.

93

94

Fig 11-4 The retina of a cat with noneffusive FIP. The photograph is in focus but appears cloudy because of the high-protein exudate into the vitreous. Cuffing of the retinal blood vessels appears as grayish lines on either side (*arrowheads*) Retinal blood vessels can be seen disappearing into pyogranulomata (*P*) (Courtesy John Mould, Herefordshire, U.K.)

Infectious Diseases of the Dog and Cat, 3rd Edition

11.3.3.5 Nondomestic Felidae

FCoV can be an important pathogen for domestic and exotic Felidae. Enteric coronavirus infections have produced chronic weight loss, diarrhea, and anorexia. In a survey of captive felids, more than 50% had positive test results for infection based on fecal PCR and serologic testing for type I and type II coronavirus.⁹² Mortality from FIP has been observed among captive exotic felids, with cheetahs (*Acinonyx jubatus*) having the highest risk for clinical illness. Necrotizing colitis caused by FCoV is a major health problem in these cats.⁹²

11.4 DIAGNOSIS

11.4.1 Coronaviral Enteritis

No specific tests exist for coronaviral enteritis, and FCoV can only be assumed to be the cause of diarrhea in FCoV-seropositive or RT-PCR fecal-positive cats in which other infectious or dietary causes have been eliminated. Even biopsy is of limited use because the histopathologic features of villous tip ulceration, stunting, and fusion are nonspecific. FCoV infection may only be confirmed if immunohistochemical or immunofluorescent staining of gut biopsies is available.

11.4.2 Feline Infectious Peritonitis

Good clinical skills are more important for diagnosing FIP than for diagnosing any other disease. Positive predictive value (PPV) and negative predictive value (NPV) rises in populations in which the prevalence of a disease is higher; therefore available tests are more valuable for clinicians who have already narrowed down the diagnosis to FIP and a few other conditions by a thorough clinical examination and patient history.

At the time of writing and despite what manufacturers may claim, no single diagnostic test for FIP is commercially available; histopathology is still the gold standard. However, two tests are promising. One involves detection of mRNA in circulating monocytes,¹⁶⁴ and another is detection of FCoV in macrophages in effusions, although a negative result does not rule out FIP.^{60,139}

It is often helpful to consider effusive and noneffusive FIP in different ways, although they do not overlap and each may progress to the other. Various schemes and algorithms have been devised that give high PPVs of an FIP diagnosis.^{117,153,163} An algorithm for the diagnosis of FIP is presented in [Table 11-3](#) and is used in the rest of this section.

11.4.3 Clinical Laboratory Findings

The typical hematologic changes in effusive and noneffusive FIP are lymphopenia¹³⁵ and neutrophilia with a left shift. In noneffusive FIP, cats have a nonregenerative anemia (hematocrit [HCT] < 30%) associated with chronic inflammation; cats that are constipated from granulomatous colitis have an increase in Heinz bodies in the erythrocytes.

An important feature of FIP is hyperglobulinemia ([Fig 11-5](#)). The albumin-globulin (A:G) ratio is a useful diagnostic tool, especially when measured in the effusion. Total protein in the effusion should be greater than

Infectious Diseases of the Dog and Cat, 3rd Edition

3.5 g/dl, and an A:G ratio less than 0.4 indicates that FIP is very likely.¹⁶³ The serum A:G ratio decreases in FIP because as the albumin level remains normal or falls slightly and globulin levels increase, possibly through stimulation of B cells by interleukin-6, which is produced as part of the disease process.⁵⁰ Thus the total serum protein level is often high. FIP should be suspected when serum protein electrophoresis reveals a polyclonal hypergammaglobulinemia. (Differential diagnoses include lymphosarcoma, multiple myeloma or other plasma cell neoplasm, chronic infection, or FIV.^{108,118})

Measurement of AGP is helpful in the diagnosis of FIP.³² It is an acute-phase protein that exists in higher levels in several infectious diseases of cats and is therefore not specific for FIP. However, AGP levels in the plasma or effusions are usually greater than 1500 µg/ml in FIP, a level that helps distinguish FIP from other clinically similar but noninflammatory conditions such as cardiomyopathy and neoplasia. Cats with FIP have a tenfold increase in SAA compared with FCoV-exposed cats.⁴⁷ Reference concentrations are less than 20 µg/ml; in cats with FIP, they can increase to 80 µg/ml.

Other biochemical alterations reflect damage to the organs containing FIP lesions and are not specifically useful for diagnosing FIP. However, they may help the clinician determine whether treatment is worthwhile. Hyperbilirubinemia may be observed and frequently is a reflection of hepatic necrosis. Despite this fact, the alkaline phosphatase and alanine transaminase activities are often not increased as dramatically as they are with cholestatic disorders such as cholangiohepatitis and hepatic lipidosis. Analysis of cerebrospinal fluid (CSF) from cats with neurologic signs may reveal elevated protein levels (56 to 348 mg/dl, with normal being less than 25 mg/dl)¹⁰⁸ and pleocytosis (100 to 10,000 nucleated cells/ml—neutrophils, lymphocytes, and macrophages).¹⁰⁸ Similar findings may be apparent in aqueous humor of cats with uveitis. CSF may be difficult or impossible to withdraw as a result of inflammatory cell accumulation.¹⁰⁸

11.4.4 Effusion

The next most useful step in diagnosis is to sample the fluid, which in FIP may be clear, straw colored, and viscous and because of the high protein content may froth when shaken (Fig. 11-6). The effusion may clot when refrigerated. If the sample is bloody, pus filled, chylous, or foul smelling, then FIP is unlikely,¹⁵³ although in rare cases it can appear pink and chylous.¹⁵⁹ The effusion in FIP is classified as a modified transudate in that the protein content is usually very high (>3.5 g/dl), reflecting the composition of the serum, whereas the cellular content approaches that of a transudate (<5000 nucleated cells/ml).¹²⁴ The protein content of the effusion is high because of the increased levels of gamma globulins, thus a low A:G ratio in an effusion is highly predictive of FIP. An A:G ratio of more than 0.8 almost certainly excludes FIP,¹⁶³ and with values between 0.45 and 0.8, FIP remains a possibility.^{117,165} An A:G ratio of less than 0.45¹⁶⁶ in an effusion with greater than 3.5 g/dl of total protein and low cellularity, consisting of predominantly neutrophils and macrophages, is diagnostic of effusive FIP.¹⁵³ The main diseases with similar fluids are lymphocytic cholangitis and occasional tumors, usually of the liver. Cytology of the effusion, as well as radiographic and ultrasonographic findings, may help to differentiate neoplasia, which in addition to cardiomyopathy and liver disease is the condition most often mistaken for effusive FIP.^{70,163} Adding a small drop of fluid to a 98% acetic acid solution can cause a precipitate because of the high protein content, and the procedure is easily performed in the veterinary office. A negative result is useful in ruling out FIP.⁶⁰

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 11-3 Algorithm for the Diagnosis of Feline Infectious Peritonitis

PARAMETER	LIKELIHOOD	^a PROCEED TO
A. Presenting Signs		
1. Nonspecific illness, anorexia, chronic recurrent, antibiotic-unresponsive pyrexia, with or without weight loss	>3	>B
2. Abdominal distention or dyspnea	>3	>B
B. Environment		
1. Single-cat household more than 1 year	>1	>C,H
2. Multicat household, cat breeder, humane shelter, in previous 6–12 months	>3	>C
3. Stressed in previous 1–12 months (e.g., was rehomed, was neutered, gave birth, visited veterinarian)	>3	>C
C. Clinical Signs		
1. Ascites with or without thoracic or pericardial effusion	>3	>D3,D4,D5
2. No effusion		
a. Systemic: depression, icterus, renal failure, diarrhea or constipation; neurologic or ocular signs	>3	>D1,D2
b. Neurologic: ataxia, nystagmus, seizures, tremor, paresis or paralysis, circling, menace deficit, behavioral changes, head tilt, magnetic resonance imaging suggesting periventricular contrast enhancement, ventricular dilatation, and hydrocephalus	>3	>D1,D2,D3
c. Ocular: iritis, uveitis, keratic precipitates, aqueous flare, retinal vascular cuffing, nystagmus, blindness	>4	>D1,D2
d. No ocular findings	>1	>E1,H2
e. Computed tomography scan: hydrocephalus	>5	>G
D. Laboratory Findings		
1. Hematologic findings		
a. Lymphopenia, nonregenerative anemia, left shift neutrophilia	>3	>D2,E1,F3a
2. Blood biochemistry		
a. A:G ratio <0.45	>5	>E1,F3a
High globulin ($\geq 35\text{g/L}$ or $\geq 3.5\text{g/dl}$)		
High $\alpha 1$ -acid glycoprotein ($>1500\text{ mg/ml}$)		
b. A:G ratio 0.45–0.8	>3	>E1,F3a
Moderate globulin ($25\text{--}35\text{g/L}$ or $2.5\text{--}3.5\text{g/dl}$)		
c. A:G ratio >0.8	>0,1	>H
Low globulin ($<25\text{g/L}$ or $\leq 2.5\text{g/dl}$)		
d. Normal $\alpha 1$ -acid glycoprotein ($<500\text{ mg/ml}$)	>0	>H
3. Effusion		
a. Clear, straw colored, clots on standing, froths if shaken	>4	>D4,D5
b. Pus, chyle (milky), or blood	>1	>H, \pm F2
4. Cytology of effusion		
a. Low cellularity (<5000 nucleated cells/ml); cells mostly macrophages and neutrophils	>5	>E,F2
b. High cellularity, bacteria present, mitotic figures present, or mainly lymphocytes	>0	>H
5. Biochemistry of effusion		
a. High total protein ($>3.5\text{g/dl}$)	>5	>E,F2
A:G ratio <0.45		
$\alpha 1$ -acid glycoprotein $>1500\text{ mg/ml}$		
b. A:G ratio 0.45–0.8	>3	>E
c. Albumin $>48\%$, low globulins ($<32\%$)	>1	>H
d. Albumin-globulin ratio >0.8	>0	>H
6.a. Rivalta test positive	>2	>D7
b. Rivalta test negative	>0	>H
7. Immunofluorescence of macrophages in effusion		
a. Positive	>5	>G
b. Positive	>3	>E,H

Fig 11-5 Serum electrophoretic pattern from a cat with FIP hyper β and γ globulinemia. (Courtesy University of Georgia, Athens, Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Positive staining of FCoV-infected macrophages from an effusion is diagnostic of FIP, but a negative result does not rule it out (Fig. 11-7).^{60,139} One difficulty with this test is that often the effusion has few macrophages.

11.4.5 Serologic Testing

Serologic testing for diagnosis of FIP has been frequently criticized. However, it has an important role in the diagnosis and management of FIP when certain methodologies are used and results are properly interpreted. 96

Serologic testing for FIP can be useful if the laboratory is reliable and consistent and the test results have been correlated with clinical findings. However, in one study a single serum sample was divided and sent to five different laboratories in the United States and yielded five different results.¹⁴⁹ Methodologies and antibody titer results may vary among laboratories, but each should have established two levels. One is the least significant level of reactivity (or *low* positive titer value) and another is the *high* antibody titer value. High titers have been correlated with a greater chance of FCoV shedding. (Antibody titers expressed in this chapter are those established by the authors' laboratory in Glasgow, Scotland.) When searching for a reliable laboratory, repeat samples from the same animal should be sent without warning to the same laboratory and an FCoV-referenced laboratory for comparison. Serum or plasma samples store well at -20°C without loss of antibody titer. An in-house test—the FCoV Immunocomb (Biogal Galed Laboratories Kibbutz Galed, M.P. Megido Israel)—compared favorably with the gold standard immunofluorescent antibody test.⁸ (See Appendix 5 for a listing of some established laboratories for the immunofluorescent antibody test.) 97

Fig 11-6 Body cavity effusion from a cat with FIP. Note froth and opacity from high protein content. (Courtesy University of Georgia, Athens, Ga.)

Fig 11-7 Direct immunofluorescent staining of abdominal effusion showing intracellular coronavirus in a cat with FIP. (Courtesy Wayne Roberts, University of Georgia, Athens, Ga.)

It has been said that more cats have died of FCoV-antibody test results than of FIP.¹⁴² At times, clinicians have mistakenly equated a positive antibody titer result with a diagnosis of FIP, which is partly the fault of kit manufacturers who specifically call their tests “FIP tests,” when in fact they actually detect FCoV or FCoV antibodies. In addition, FCoV tests are often requested for inappropriate reasons. Five major indications for FCoV antibody testing exist as outlined below.

11.4.5.1 Diagnosis of Feline Infectious Peritonitis or Coronaviral Enteritis

Serologic tests are very useful for cats with suspected FIP, but clinicians should be aware of their limitations. First, many healthy cats and cats with conditions other than FIP are seropositive. Second, some cats with effusive FIP appear to have low titers or be seronegative because large amounts of virus in their bodies are binding to antibody, making them unavailable to bind the antigen in the serologic test. Although exceptions have been reported,^{108,168} cats with noneffusive FIP usually have a high FCoV-antibody titer and are rarely seronegative, thus coronavirus serology can usually be used to rule out a diagnosis of FIP in suspected noneffusive cases. The presence of a high FCoV-antibody titer in a sick cat from a low-risk, one- or two-cat household is also unusual; it is a stronger indicator of a diagnosis of FIP than the same antibody titer in a cat from a multicat household in which FCoV is likely to be endemic.

Infectious Diseases of the Dog and Cat, 3rd Edition

Serologic testing should only be performed to diagnose FIP in conjunction with a compatible history, clinical signs, and examination of the effusions or blood for high globulins and a low A:G ratio (see [Table 11-3](#)). Serologic tests performed on ascites or thoracic effusions yield the same results as when done on blood samples provided they have high protein concentrations that approximate blood. Seronegative cats with suspected effusive FIP can be examined further for the presence of virus by RT-PCR³³ when available.

Occasionally, healthy cats are considered to have noneffusive FIP simply because they are seropositive and have no ascites. This assumption is incorrect because cats with noneffusive FIP are clinically ill.

Cats with neurologic FIP had higher antibody titers but lower FCoV loads than cats with generalized FIP.⁴² Measurement of antibodies to FCoV in CSF has been reported to assist in the diagnosis of neurologic FIP.³⁷ The ratios of serum protein to CSF protein and serum FCoV antibody to CSF-FCoV antibody were always equal to or greater than one. None of eight control cats with nonneurologic FIP had anti-FCoV antibodies in the CSF. Unfortunately, these control cats were experimentally infected and had relatively low serum antibody titers to FCoV. Nonspecific leakage of serum proteins into CSF cannot be eliminated. It can only be controlled by (1) considering the CSF titer in light of increased CSF cellularity that suggests nonspecific leakage or (2) comparing a ratio of the CSF-serum titers to another infectious agent (antibody indexing). Seronegativity in diarrheic cats rules out FCoV as a cause; however, FCoV may or may not be a cause of diarrhea in seropositive cats.

11.4.5.2

Contact with Suspected or Known Viral Excretor

Testing of a cat that may have been exposed to FCoV is usually done for one of two reasons. First, the owner wants to know the prognosis for an exposed cat. Second, the owner wants to obtain another cat and needs to know whether the exposed cat is shedding FCoV. In either case, it is very likely that the cat will be seropositive because 95% to 100% of cats exposed to FCoV become infected and seroconvert approximately 18 to 21 days after exposure. The owner should be advised of this possibility and reassured that it does not necessarily indicate a poor prognosis. Most cats infected with FCoV do not develop FIP, and many in households of less than 10 cats eventually clear their infection and become seronegative within a few months or years. Adult cats can be retested using the same laboratory every 3 to 6 months until the antibody titer falls threefold to fourfold. Kittens and adults that have been exposed only once often have a quicker reduction in antibodies and may be tested every 1 to 2 months. Some cats remain seropositive for years but are not necessarily virus shedders. A rise in antibody titer or maintenance at a high level does not necessarily indicate a poor prognosis for the cat. Of 50 cats tested by the authors, antibody titers remained at 1:640 or greater on at least three occasions, yet only four cats died of FIP. However, in an endemic infection, a constant low titer of 1:20 or less is highly indicative that a cat will not develop FIP.

97

98

The aim of serotesting and segregating cats is to prevent exposure of cats that have eliminated infection to chronic virus-shedding cats. The lowest dilution of sample that a laboratory considers *positive* (the least significant level of reactivity [LSLR]) in its diagnostic test should be ascertained. Laboratories have different techniques, and the LSLR level can vary from 1:10 to 1:100. If a laboratory uses an LSLR serum dilution of less than 1:100 as negative, some cats that are excreting FCoV will not be identified—FCoV excretors with indirect FA titers as low as 1:40 have been found.^{4-6,65} Cats with sera that are nonreactive at lower dilutions by the indirect FA test (i.e., dilution of less than 1:10) are unlikely to shed FCoV. Approximately one third of seropositive cats excrete virus,^{4,5} so if a cat is seropositive, it is unwise to obtain another cat unless it also has antibodies. After 3 to 6 months, the antibody titer can be rechecked to determine whether it has become

Infectious Diseases of the Dog and Cat, 3rd Edition

negative. In a stable, isolated population of fewer than 10 cats that are mixing together, in which half remain seronegative, it is reasonable to infer that the other cats are probably not excreting virus.

11.4.5.3 Cat Breeder Requests Testing

Cat breeders often request that their cats be screened for FCoV antibodies before mating. Such testing is worthwhile only if a reliable test is used and the laboratory's negative LSLR is low (i.e., less than a titer of 1:10 or 1:20). If the cat is seronegative, it can be safely mated with another seronegative cat. If the cat is seropositive, it can be mated with a seropositive cat; isolation and early weaning should prevent the resulting kittens from becoming infected.^{3,4,69} Alternatively, a breeder may prefer to isolate a seropositive cat, wait 3 to 6 months, and retest in the hope that it will have become seronegative.

11.4.5.4 Screening a Cattery for Feline Coronavirus

FCoV infection is highly contagious. If many cats are housed in a group, then a random sampling of three to four cats indicates whether FCoV is endemic. If cats are housed individually, it may be necessary to test them all. Cats in households with fewer than 10 cats (that do not take in any new cats) and in those in which the cats are isolated from each other in groups of three or less often eventually lose their FCoV infection.⁵² Retesting is worthwhile *only* if the cats are kept in these small groups and not commingled. Testing every 3 to 16 months establishes the loss of infection because antibody titers fall, and an increasing proportion of cats become seronegative if not reexposed to infection (see [Table 11-2](#)).

11.4.5.5 Screening a Cat for Introduction into a Feline Coronavirus-Free Cattery

Once a cattery has been established as FCoV seronegative, it can be maintained FCoV free by testing and isolating new cats before they are introduced. Seropositive cats should never be introduced; for the safety of other cats, it should be assumed that they are shedding FCoV.

11.4.6 RT-PCR Testing

PCR is a highly sensitive technique for amplifying and detecting small amounts of DNA (see Molecular Diagnosis, [Chapter 1](#), and [Fig. 1-3](#)). Because FCoV is an RNA virus, a DNA copy must first be made using the enzyme RT.

Viral detection is clinically useful to veterinarians in two areas: (1) confirming the presence of FCoV in cats that appear to have FIP but are seronegative and (2) detecting viral shedding for epidemiologic purposes.^{6,9,40,66} Viral detection in body tissues or fluids is not a useful prognostic indicator in the healthy cat because FCoV has been detected in the blood of healthy FCoV-seropositive cats.⁶⁵ However, virus was detected in 13 brains of 17 cats with neurologic FIP,⁴² so a positive result was useful but a negative result did not rule out FIP. In addition, the absence of FCoV in the blood stream does not mean a cat is not going to develop FIP.³⁶ False-negative results can also be generated in the laboratory by accidental introduction of (or not inhibiting) enzymes that destroy RNA (ribonucleases, or RNases). Detection or absence of FCoV in the feces or saliva is not helpful as a prognostic test but is a useful research tool. Cats that are chronic FCoV shedders are not at special risk of developing FIP,^{9,40} but they make it difficult to contain infections in a cattery. However, lifelong FCoV shedders can only be identified by nine consecutive monthly positive RT-PCR fecal tests.⁶

Infectious Diseases of the Dog and Cat, 3rd Edition

11.4.7 Antigen Detection in Tissues

Viral detection by direct FA and immunohistochemistry can be applied to effusion, cytologic, or biopsy specimens but requires a specialized laboratory. Immunofluorescence can confirm the presence of FCoV in macrophages in the effusions of cats with wet FIP.¹³⁹ Both tests are commercially available (see [Appendix 6](#)) and are confirmatory tests in cases in which the histologic findings are not typical of FIP.^{174,187} FCoV antigen has been detected in swabs made from the nictitating membranes of cats with FIP⁸⁰; however, these results have not been confirmed by other laboratories.¹⁷⁴

11.5 PATHOLOGIC FINDINGS

The essential lesion of FIP is the pyogranuloma. In effusive FIP, all the surfaces of the abdominal contents, thoracic contents, or both can be covered in small (1- to 2-mm) white plaques ([Figs. 11-8 and 11-9](#)). Few other diseases have similar lesions, although occasionally miliary tumors or systemic mycoses can appear. In noneffusive FIP, gross pathologic lesions can be much more variable; however, the kidney is frequently affected and should be examined carefully for pyogranulomata in the cortex ([Fig. 11-10](#)). In colonic FIP the colon may be thickened and have a gross appearance that is similar to alimentary lymphosarcoma.⁶¹ In some cats, abnormalities are minimal, and a diagnosis can be made only by histologic examination. In the meninges, gross changes are often minimal or consist of hyperemia of the surfaces; however, histologic lesions are characterized by diffuse meningeal infiltration with pyogranulomatous inflammation ([Fig. 11-11](#)). To diagnose FIP definitively, vasculitis must be demonstrated. The lesion consists of an arteriole or venule bordered by a central area of necrosis that is surrounded by a perivascular infiltration of mononuclear cells, proliferating macrophages and lymphocytes, plasma cells, and neutrophils. Immunohistochemistry used to demonstrate the presence of virus in the lesions is the absolute gold standard.

In cats with coronavirus diarrhea, FCoV can infect the mature columnar epithelium of the tips of the villi of the alimentary tract, resulting in sloughing of the villous tips. FCoV can be demonstrated in the epithelial cells by immunohistochemical staining or immunofluorescence.¹⁴⁰ Mild to moderate villous atrophy may be seen, and villi may be fused.¹⁴⁰

98

99

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 11-9 Omentum of a cat with effusive FIP. Note gelatinous appearance and small, white perivascular pyogranulomata (*arrows*) typical of effusive FIP on gross postmortem examination.

11.6 THERAPY

Various drugs are available for treatment of FIP ([Table 11-4](#)). For additional information, an excellent review of therapy by Richard Weiss has been written.¹⁸⁸ No antiviral drugs targets FCoV; however, much work has been done on the viral enzyme 3C-like protease of the coronavirus,^{13,14,62,64} and anticoronaviral drugs are being developed for use in people with SARS.

11.6.1 Clinical Category

11.6.1.1 Healthy Feline Coronavirus-Seropositive Cat

No evidence suggests that any treatment of a healthy seropositive cat could prevent development of FIP. Treatment with glucocorticoids could conceivably prevent clinical signs from occurring, but immunosuppression might have the opposite effect and precipitate onset of clinical FIP. However, because stress is a common factor in the development of FIP in infected cats,¹⁵³ avoiding unnecessary stress such as rehoming, elective surgery, or placement in a boarding cattery may be beneficial.

11.6.1.2 Coronaviral Enteritis

Most cases of coronaviral diarrhea are self-limiting. Cats with chronic diarrhea in which other possible causes have been eliminated, that are seropositive for FCoV, or in which FCoV has been detected in the feces can only be treated supportively using fluid-electrolyte replacement and restricted caloric oral diet with living natural yogurt or with probiotics (see [Chapter 89](#)), as appropriate.¹⁴³ No specific antiviral treatment

Infectious Diseases of the Dog and Cat, 3rd Edition

has yet been demonstrated to cure this condition. Some cats respond to low doses of prednisolone (0.5 to 1 mg/day per cat).

Fig 11-10 Bisected kidney of a cat with noneffusive FIP showing pyogranulomata (*arrows*)

Fig 11-11 Histopathologic section of surface of cerebellar cortex from a cat with meningeal inflammation from dry FIP (H and E stain, $\times 100$). (Courtesy University of Georgia, Athens, Ga.) Algorithm for the Diagnosis of Feline Infectious Peritonitis

Infectious Diseases of the Dog and Cat, 3rd Edition

11.6.1.3 Clinical Feline Infectious Peritonitis

Because FIP is an immune-mediated disease, treatment is aimed at controlling the immune response to FCoV, and the most successful treatments consist of relatively high doses of immunosuppressive and antiinflammatory drugs and feline interferon- ω . Rest, avoidance of stressful situations, and a high-protein diet may also help cats with mild clinical signs.¹⁴³

11.6.2 Prednisolone

Prednisolone is the main immunosuppressant used in the treatment of FIP. It is safe, tends to make the cat feel better, and stimulates the cat's appetite. Prednisolone suppresses the humoral and CMI response. One cat with noneffusive FIP treated with prednisolone alone survived for 10 months. Prednisolone has the advantage of also being the treatment for lymphocytic cholangitis, which can be mistaken for FIP; when the diagnosis is in doubt, prednisolone can be given. A cat with lymphocytic cholangitis has a good chance of recovery, whereas a cat with FIP will die.

99

100

Table 11-4 Drug Therapy for Feline Infectious Peritonitis

DRUG	DOSAGE	ROUTE
Antiinflammatory		
Drugs^a		
Prednisolone	2–4 mg/kg/day, reducing by half every 10 days until stabilization or remission	PO
Feline interferon- ω (Virbagen Omega, Carros, France)	1 \times 10 ⁶ U every other day for five injections then once or twice weekly or 50,000 U daily until total remission of clinical signs	SC PO
Human interferon- α (Roferon, Roche Pharmaceuticals, Nutley, N.J.)	<i>Effusive FIP</i> : 2 \times 10 ⁶ IU/kg/day <i>Noneffusive FIP</i> : 30 IU/day for 7 days at alternate weeks	IM PO
Thromboxane synthetase inhibitor (ozagrel hydrochloride)	5 mg/kg twice daily	SC
Supportive Drugs^b		
Aspirin	10 mg/kg every 48–72 hr	PO
Ampicillin	50 mg three times daily	PO
Anabolic steroids	Routine dosage	IM, PO
Ascorbic acid	125 mg twice daily	PO
Vitamin A (not beta-carotene form)	200 IU/kg/day	PO
Vitamin B ₁ (thiamine)	100 μ g/day	PO

a Use either prednisolone and interferon or thromboxane synthetase inhibitor from Antiinflammatory Dugs and any or all of the drugs Supportive Drugs.

b Use of all or a combination of these drugs is recommended. (See Drug Formulary, [Appendix 8](#) for additional information on each drug. See also Weiss R: *In August JR (ed): Consultations in feline internal medicine*. WB Saunders, 1994, pp 3–12.)¹⁸⁸

Prednisolone should never be used in cats with septic peritonitis or pleurisy, which is why cytology is a very important part of FIP diagnosis. The effusion of a cat with sepsis has many more leukocytes, and an attentive cytologist can detect the bacteria or fungi.

Infectious Diseases of the Dog and Cat, 3rd Edition

The dosage is 2 to 4 mg/kg/day given orally, with a gradually reducing dose every 10 to 14 days until the optimal dosage for the cat is determined by continued response to treatment. Cats on immunosuppressive drugs should also be given broad-spectrum antibiotics if secondary bacterial infections arise and possibly given l-lysine (see [Chapters 16](#) and [93](#)) to prevent recrudescence of latent herpesvirus.

11.6.3 Thalidomide

The rationale of using thalidomide in the treatment of FIP is to reduce inflammation and the humoral immune response to FCoV while leaving the CMI (antiviral) response intact. Only four cats with FIP have been treated with thalidomide, and all died. However, one with a thoracic effusion did eliminate his effusion and was in remission for 3 months. To be effective, thalidomide needs to be used very early in the disease before too many blood vessels became damaged.

The owner's consent must be obtained for treatment with this drug because it is not licensed for use in cats. The dose is 50 to 100 mg and should be given at night. It should *not* be given to pregnant cats because it is teratogenic.

11.6.4 Interferon

11.6.4.1 Feline Interferon- ω

Recombinant feline IFN- ω (Virbagen Omega, Virbac SAs Carros, France) is available in some countries and has been used in treatment of FIP.⁸⁷ Because it is a homologous protein, it is likely to have a more sustained effect than the human recombinant proteins.

IFN- ω initially was given subcutaneously at 1×10^6 MU/kg every other day and then once weekly or 50,000 U orally per cat for variable period if remission was seen. Cats were also treated with glucocorticoids: (1) 1 mg/kg dexamethasone administered intrathoracically or by IP injection or (2) prednisolone. Oral prednisolone was initially given at 2 mg/kg once daily, and the dosage was gradually tapered to 0.5 mg/kg every other day after remission.⁸⁷

Using this combined drug protocol, 4 cats of 12 completely recovered, and 2 survived for 4 and 5 months, respectively. All cats that recovered completely had the effusive form and were relatively older cats (older than 4 years). Unfortunately, this study did not have a control group (i.e., a group of cats that had similar presenting signs and were treated conventionally), so the efficacy of the treatment cannot be wholly evaluated. However, histologic examination showed the cats that did succumb had FIP, and the same diagnostic criteria were used for all cats.

At the time of writing, data are being collated about the effectiveness of feline IFN- ω in the treatment of FIP. It seems to help approximately one third of FIP cases treated.

11.6.4.2 Human Interferon- α

For noneffusive FIP, 30 IU/day of human interferon- α (IFN- α) for 7 days at alternate weeks is given by mouth. In effusive FIP, the same oral dosage can be used, or larger doses of IFN (10^4 to 10^6 IU/day) can be

Infectious Diseases of the Dog and Cat, 3rd Edition

given by intramuscular (IM) injection. After 6 to 7 weeks, if the cat is still alive, IFN no longer works at this dose because the cat makes antibodies against it (see Drug Formulary, [Appendix 8](#)).

11.6.5 Vitamins and Antioxidants

- **Vitamin A**, an antioxidant, is given at a dosage of 200 IU/day orally (by mouth or in food). Cats cannot metabolize the β -carotene form, so it must be given as fish oil (e.g., halibut liver oil). Too much vitamin A can cause excessive deposition of bone at the joints, so this supplement should not be used for more than 4 to 6 weeks. 100
101
- **Vitamin B₁ (thiamine)** has been used at a dosage of 100 μ g/day orally (by mouth or in food).
- **Vitamin B complex** is a good appetite stimulant and can be obtained from health food shops or pharmacists. The dosage that is recommended by the manufacturer for children can be used for cats.
- **Vitamin C (ascorbic acid)**, at a dosage of 125 mg twice daily, can be given by mouth or in food. Vitamin C is an antioxidant. Given over a long period, vitamin C can cause a predisposition for developing oxalate crystals in the urine.
- **Vitamin E**, at a dosage of 25 to 75 IU per cat twice daily, is given orally (by mouth or in food). Vitamin E is an antioxidant.
- **Anabolic steroids** are used for appetite enhancement and anticatabolism, especially if evidence of renal failure exists.
- **Thromboxane synthetase inhibitors** have been used in two cats with abdominal effusions. Ozagrel hydrochloride (5 to 10/mg/kg twice daily) and prednisolone (2 mg/kg/day) were used with success.¹⁸⁶

11.6.6 Monitoring Treatment and Prognosis

Regardless of the treatment chosen, it is important to monitor each cat's progress. Regular checks every 7 to 14 days of the HCT, globulins, A:G, AGP, and the cat's weight serve as indicators of the cat's progress. Later, examinations could be performed only monthly if the cat is improving. It is not worthwhile to measure the FCoV-antibody titer more often than every month because no discernible difference within a shorter period can be detected. The AGP should be the first to decrease if treatment is having a positive effect because AGP is a measure of inflammation. Positive signs also include decreasing globulin levels, increasing A:G and HCT, the appearance of reticulocytes in blood smears, and weight gain. Negative signs are AGP remaining high, globulins staying high or increasing, A:G decreasing, and weight loss. When the HCT becomes less than 20% and is nonregenerative (i.e., no reticulocytes are seen on blood smear examination), the cat should probably be humanely euthanized if its quality of life is impaired. Clearly, if the cat is distressed at any point in the treatment, euthanasia should be considered. Cats with effusive FIP usually only survive a few days—weeks at best. Cats with noneffusive FIP can survive many weeks or months, although after neurologic signs begin, death usually ensues fairly rapidly.

11.7 PREVENTION

More than any other factor, management of kittens determines whether they become infected with FCoV.^{3,4,41,69} Kittens of FCoV-shedding queens should be protected from infection by maternally derived antibody until they are

Infectious Diseases of the Dog and Cat, 3rd Edition

at least 5 to 6 weeks old. A protocol for the prevention of FCoV infection in kittens is presented in [Table 11-5](#). When reliable serologic tests are available, kittens should be tested when older than 10 weeks to ensure that isolation and early weaning have been effective. Infected kittens younger than 10 weeks may not yet have seroconverted.⁴ A protocol for minimizing the spread of FCoV in catteries is presented in [Table 11-6](#).

Many attempts have been made to develop effective vaccines, but unfortunately most have failed because of ADE.^{161,180} However, a vaccine, Primucell, was produced (Pfizer Animal Health, New York, N.Y.) incorporating a temperature-sensitive mutant of the FCoV strain DF2-FIPV, which could replicate in the cool lining of the upper respiratory tract but not at the higher internal body temperature.^{22,44-46} This vaccine, administered intranasally, produces local immunity at the site where FCoV first enters the body—the oropharynx—and also induces a long-lasting CMI response. The vaccine has been available in the United States since 1991 and has been introduced in some European countries.³⁶ The two concerns about this vaccine are its safety and efficacy.

The safety concern is whether the vaccine can cause ADE. Although some experimental vaccine trials have recorded ADE on challenge,^{122,162} the overwhelming evidence from field studies is that Primucell is safe.^{36,150} In two double-blind trials (one of 609 cats and one of 500 cats), the animals were vaccinated with either Primucell or a placebo, and in both trials fewer FIP deaths occurred in the Primucell-vaccinated group than the placebo group.^{36,150} Clearly, Primucell afforded protection from FIP and did not cause ADE. Furthermore, immediate side effects from vaccination such as sneezing, vomiting, or diarrhea were not statistically different between the vaccinated group and the placebo group.³⁶

Primucell vaccination causes seroconversion, and although it may be at a lower level than that caused by natural infection, it can still cause low positive antibody titers. Cats shed vaccine virus oronasally for up to 4 days.²² The recommendation for vaccination is to give two doses 3 weeks apart from 16 weeks onward. Although Primucell is recommended to be given to cats at least 16 weeks old, it has also been administered to 9-week-old kittens and found to be safe. In these kittens the vaccine did not prevent infection; however, the amount of FCoV isolated from the gut and mesenteric lymph nodes was significantly reduced.^{86,154} Primucell seems to be safe to administer to pregnant cats and does not affect kitten mortality or reproductive capability in breeding colonies.^{44,154}

Primucell is also safe to administer simultaneously with other vaccines or to FeLV-infected cats.⁴⁴ Annual boosters are recommended. Because mucosal immunity is involved, the duration of protection after natural exposure or vaccination is short lived in most cats after virus is cleared, and reinfection is possible. Vaccine must be given periodically to maintain this immunity.

101

102

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 11-5 Protocol for Prevention of Feline Coronavirus Infection in Kittens

STEP	DESCRIPTION
Prepare kitten room.	1. Remove all cats and kittens 1 week before introducing new queen. 2. Disinfect room using 1:32 dilution of sodium hypochlorite (bleach). 3. Dedicate separate litter trays and food and water bowls to this room, and disinfect with sodium hypochlorite. 4. Introduce single queen 1–2 weeks before parturition.
Practice barrier nursing.	1. Work in the kitten room before tending other cats. 2. Clean hands with disinfectant before going into kitten room. 3. Have shoes and coveralls dedicated to the kitten room.
Wean and isolate kittens early.	1. Test queen for FCoV antibodies either before or after she gives birth. 2. If queen is seropositive, she should be removed from the kitten room when the kittens are 5–6 weeks old. 3. If the queen is seronegative, she can remain with the kittens until they are older.
Test kittens.	1. Test kittens for FCoV antibodies after 10 weeks of age.

The efficacy has been questioned because the vaccine strain is a serotype II coronavirus, and the serotype I coronavirus is more prevalent in field isolates. A double-blind trial of 609 16- to 53-week-old vaccinated pet cats was conducted in Switzerland.^{36,116} At the start of the trial, 358 cats were seropositive. Up to 150 days after vaccination, the number of cats that developed FIP was not significantly different. However, after 150 days, only one FIP-associated death in the vaccinated group of cats (0.4%) occurred, compared with seven FIP deaths in the placebo group (2.7%).³⁶ RT-PCR of blood from all of the vaccinated cats that developed FIP showed that virus was present in the cats before the vaccine was administered. Thus many of the cats in which Primucell appeared ineffective had been vaccinated when they were already incubating FIP.¹¹⁶ Because the vaccine works partly by stimulating local immunity, it is less effective if virus has already crossed the mucous membranes. Obviously, it follows that Primucell is more efficacious in cats that have not been exposed to FCoV (or are seronegative) than in seropositive cats. Clearly, an attempt must be made to prevent kittens from becoming infected with FCoV—by early weaning and isolation—before they are vaccinated.

The efficacy of Primucell, based on preventable fraction (see Vaccine Efficacy, [Chapter 100](#)) has been reported to be 50% to 75%.¹⁴³ In a survey of 138 cats from 15 cat breeders, in which virtually all of the cats were seropositive, no difference in FIP-associated deaths was found between the vaccinated group and the placebo group.³⁶ The manufacturers do not specify that FCoV antibody testing should precede vaccination. However, because Primucell does not work in a cat that is incubating the disease, FCoV antibody testing is beneficial. Because Primucell causes seroconversion and low antibody titers, testing before vaccination is advisable.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 11-6 Protocol for Minimizing Feline Coronavirus Introduction or Spread in a Cattery¹⁴⁴

PROTOCOL	DESCRIPTION
Reducing fecal contamination of the environment	Have adequate numbers of litter trays (one tray for every one or two cats). Declump litter trays at least daily. Remove all litter, and disinfect litter trays at least weekly. Keep litter trays away from the food area. Vacuum around litter trays regularly. Clip fur of hindquarters of longhaired cats.
Cat numbers	Ordinary households should have no more than 8–10 cats. Cats should be kept in stable groups of up to three or four. In rescue facilities, each cat should be kept in single quarters and not commingling with other cats. In a FCoV eradication program, cats should be kept in small groups according to their antibody or virus shedding status: seronegative or nonshedding cats together and seropositive or virus-shedding cats together.
Antibody or virus testing	Incumbent cats should be tested before introducing new cats or breeding. Only seronegative or virus-negative cats should be introduced into FCoV-free catteries. It is safer to introduce seropositive cats than seronegative cats into infected households, but the newcomer and the incumbent cats are still at risk for developing FIP.
Isolation and early weaning	Cat breeders and rescuers of pregnant cats should follow the protocol outlined in Table 11-5.
Vaccination with Primucell	If new cats must be introduced into a household with endemic infection, they should be vaccinated with Primucell (Pfizer Animal Health, New York, NY) before introduction.

¹² CHAPTER 12 Feline Enteric Viral Infections

Craig E. Greene

12.1 FELINE ASTROVIRAL INFECTIONS

12.1.1 Etiology and Epidemiology

Astroviruses were first described in feces from cases of human infantile gastroenteritis. These viruses have since been identified in several other species, including cats. When negatively stained and examined by transmission electron microscopy (EM), astroviruses appear as unenveloped, spherical particles approximately 28 to 30 nm in diameter, with a characteristic five- or six-point, star-shaped surface pattern, depending on the orientation (Fig. 12-1).

A limited serologic and virologic survey of diarrheic cats from the United Kingdom suggests that the infection is not very common; less than 10% of animals tested have antibody to the Bristol isolate. However, more than one serotype may exist, as in humans, in whom seven serotypes are known.¹²

12.1.2 Clinical Findings

Only two cases of a natural astrovirus infection in cats have been reported in detail. In both cases, the illness was characterized by persistent green, watery diarrhea; dehydration; and anorexia. No hematologic abnormalities were noted, and the only biochemical abnormalities were mild acidosis and hypokalemia in one of the cats. Other variable signs were gas-distended loops of the small intestine, pyrexia, depression, poor body condition, and vomiting. Vomiting and diarrhea have been reported in another infected cat, although no further clinical details were given.

In an outbreak of diarrhea in a breeding colony, EM revealed astrovirus in the feces of 25% of affected kittens. Initial signs in these kittens were inappetence, depression, and prolapse of the third eyelid. Other litters in the colony previously had developed a similar syndrome, with diarrhea that persisted 4 to 14 days. A significant number of adult cats were also affected. Sera from several of these animals had antibody to astrovirus.

Experimental oral administration of an astroviral isolate to specific pathogen-free (SPF) kittens resulted in mild diarrhea 11 to 12 days later. This condition coincided with a period of pyrexia and virus shedding with subsequent seroconversion. The kittens remained otherwise well.

12.1.3 Diagnosis

EM most conveniently diagnoses astrovirus infection of negatively stained preparations of diarrheic stools. Growing some isolates in cell culture is possible, although no cytopathic effect is produced, and virus-infected cells must be located by specific immunofluorescence. Other isolates cannot be grown in cell culture at the present time; therefore this method of diagnosis is not viable. Information on the sequence of the viral RNA is becoming available and should lead to improved methods of diagnosis based on molecular techniques, such as polymerase chain reaction (PCR).²

Infectious Diseases of the Dog and Cat, 3rd Edition

12.1.4 Therapy, Prevention, and Public Health Considerations

Treatment of affected animals is probably not necessary other than to replace lost fluids and electrolytes if the diarrhea is severe or prolonged. No vaccine is available.

Human serum can contain antibody to feline astrovirus, but whether this finding reflects zoonotic infection or a serologic relationship between human and feline astroviruses is unknown. Molecular evidence suggests that, in recent evolutionary history, feline and porcine rotaviruses have become established in the human population.¹

12.2 FELINE ROTAVIRAL INFECTIONS

12.2.1 Etiology and Epidemiology

Rotaviruses are classified as a genus within the family *Reoviridae* and are of worldwide distribution. They can be distinguished from reoviruses and orbiviruses, when viewed by negative-stain EM, by the characteristic morphology of the 70 nm–diameter intact virion. This virion appears as a wheel with the core in the center forming a hub, the inner layer of capsomeres radiating outward as spokes, and the outer layer giving a sharply defined rim.

Rotaviruses are classified into various serogroups (A through G) based on genetic and immunologic similarities. They have been isolated from many species of animals and are the major enteric viral pathogens in humans and the main species in domestic livestock, causing significant economic losses. By contrast, although infection of cats is common, with up to 100% of populations being seropositive, clinical disease is rare.

Analysis of the capsid encoding genes (VP4, VP6, and VP7) by restriction endonuclease assay allows the differentiation among the strains of different origin. The VP7 profiles differentiate strains of animal and human origin more efficiently.¹⁶

Nonstructural glycoprotein NSP4 of group A rotaviruses from mice has been identified as a viral enterotoxin. The amino acid sequence of this protein from rotaviruses isolated from diarrheal and asymptomatic kittens were similar; however, no consistent difference was found between these isolates from clinically healthy or ill cats.¹³ Group C rotaviruses, similar to those from pigs, have been isolated from dogs in Germany.¹⁴

12.2.2 Clinical Findings and Diagnosis

Feline rotavirus was first described in 1979 in kittens of 6 weeks and 8 months of age that passed semiformal to liquid stools. The virus isolated from the 6-week-old kitten induced anorexia and diarrhea when given to a 3-day-old, colostrum-deprived kitten. Subsequently, feline rotavirus has been recognized more frequently in the stools of normal cats, and a transmission study using a strain isolated from a diarrheic cat failed to produce disease in adult cats or kittens as young as 10 days.

103

104

Fig 12-1 Negatively stained astrovirus particles. Arrows indicate particles with five- and six-pointed, star-shaped surface patterns. (Courtesy Charles Ashley, Bristol Public Health Laboratory, Bristol, United Kingdom.)

Rotavirus may be readily demonstrated in feces by negative-stain EM or by polyacrylamide gel electrophoresis and silver staining of RNA extracted directly from feces. The latter method is more suitable for screening large numbers of specimens. A PCR method has been described that is considerably more sensitive than either of the other two methods.¹⁹ Other methods, such as enzyme-linked immunosorbent assay or latex agglutination, have been used, but they have been developed for group A viruses, whereas many feline isolates belong to other groups. Some, but not all, isolates can be grown in cell culture, but this is time consuming.

12.2.3 Pathologic Findings

Histologic findings include swollen intestinal villi with mild infiltration by macrophages and neutrophils. Viral antigen can be detected by fluorescent antibodies, and virions by EM, in epithelial cells.

Infectious Diseases of the Dog and Cat, 3rd Edition

12.2.4 Therapy, Prevention, and Public Health Considerations

Treatment is symptomatic for diarrhea. Signs are mild and transient, and mucosal integrity is not impaired. Fluid therapy can be given intravenously or subcutaneously, depending on the severity of dehydration. No vaccine is currently available for cats.

Genetic characterization of group G3 canine rotavirus strains in Italy, the United States, and Japan, and human and simian rotavirus isolates have shown highly conserved genetic sequences in the VP4 and VP7 genes, suggesting close genetic homogeneity.^{3,4} Rotaviruses of different hosts can infect other species when inoculated experimentally, but these cross infections generally are asymptomatic. Human rotavirus strain HCR3, which was isolated from a healthy infant in 1984, has close genetic homologies with feline rotavirus strain FRV64 and canine rotavirus strains CU-1 and K9, but not with other rotaviruses more commonly isolated from people.¹¹

Evidence from molecular studies^{6,10} suggests that feline rotaviruses may have infected people in Japan. Similarly, in Thailand, a human isolate from an infected infant with diarrhea showed close genetic and phenotypic homologies to other human and feline strains.¹⁵

12.3 OTHER VIRAL ENTERITIDES

12.3.1 Torovirus-Like Agent

During the course of a microbiologic survey of cats with the syndrome of protruding nictitating membranes and diarrhea, a novel virus was detected that hemagglutinated rat erythrocytes.⁸ Hemagglutination-inhibition (HI) testing and immune EM suggested that the virus was torovirus-like, but PCR and thin-section EM failed to confirm this finding. The virus could not be grown in cultured cells. Experimental inoculation of SPF kittens induced mild, intermittent diarrhea and pyrexia with hematologic changes (principally neutrophilia, but one kitten also developed lymphocytosis). The agent appears to be ubiquitous, because the majority of cats have antibody against it, but its significance as an enteric pathogen is unclear. In another study, torovirus particles were not detected in the feces of cats with protruding nictitating membranes.¹⁷

12.3.2 Feline Reovirus

All mammalian reoviruses belong to three serotypes, and all three of these have been isolated from cats. Feline reoviruses have generally been considered to be minor respiratory or ocular pathogens, although they can readily be isolated from both respiratory and enteric tracts. Experimental inoculation of kittens with serotype-2 isolates, however, has resulted in the development of mild diarrhea.^{7,9} Feline reoviruses are widespread in nature as judged by serosurveys.

12.3.3 Other Viruses

A large number of other viruses have been detected in the stools of normal and diarrheic cats, but their role as pathogens is unclear. These viruses include parvovirus-like particles (serologically unrelated to feline panleukopenia virus), picornavirus-like particles, coronavirus-like particles (morphologically distinct from feline infectious peritonitis viruses and feline enteric coronavirus), calicivirus, “togavirus-like particles,” and “thorn apple-like particles.”

13 CHAPTER 13 Feline Leukemia Virus Infection

Katrin Hartmann

Feline leukemia virus (FeLV) was first described in 1964 by William Jarrett and co-workers when virus particles were seen budding from the membrane of malignant lymphoblasts from a cat with naturally occurring lymphoma.^{156,157} The virus was shown to produce a similar malignancy when experimentally injected into healthy cats and thus was proven to be capable of transmitting lymphocytic neoplasia. Although household clusters of lymphoma cases had been observed among cats for many years, it was not until the discovery of FeLV that an infectious etiology was considered likely. However, following this discovery, it was assumed that all hematopoietic tumors in cats were caused by FeLV independent of whether the cats remained FeLV positive.⁹⁶ It is currently accepted that tumor-causing factors other than FeLV play more important roles, specifically in older cats.

FeLV infection occurs globally.³⁸ For many years after its discovery, FeLV was considered to (1) be the principal scourge in cats, (2) account for most disease-related deaths in pet cats, and (3) be responsible for more clinical syndromes than any other single agent.²⁶⁸ It had been estimated that approximately one third of all cancer deaths in cats were caused by FeLV, and an even greater number of infected cats died of anemia and infectious diseases caused by suppressive effects of the virus on bone marrow and the immune system.³⁸ However, today these assumptions are changing because the prevalence and importance of FeLV as a pathogen in cats are decreasing, primarily because of testing and eradication programs and routine use of FeLV vaccines.

13.1 ETIOLOGY

FeLV, a γ -retrovirus of domestic cats, is a member of the Oncornavirus subfamily of retroviruses and contains a protein core with single-stranded RNA protected by an envelope. FeLV is an exogenous agent that replicates within many tissues, including bone marrow, salivary glands, and respiratory epithelium. The virus is noncytopathic and escapes from the cell by budding from the cell membrane (Figs. 13-1 and 13-2). It can cause clinical illness related to the hematopoietic and immune systems and neoplasia. After initial infection, if the immune response does not intervene, FeLV spreads to the bone marrow and infects hematopoietic precursor cells. In infected cells, DNA copies of the viral RNA are transcribed, and it is these copies that are inserted randomly into the host DNA (Fig. 13-3). Once this provirus is integrated, cell division results in daughter cells that also contain the viral DNA. This ability of the virus to become part of the host's own DNA is the most important factor in the lifelong presence of the virus after bone marrow infection. Consequently, every infected cell has to be recognized and destroyed to “cure” an infection. Once the pool of hematologic and immune stem cells becomes infected, true elimination of the virus becomes unlikely.¹⁸⁴

13.1.1 Virus Origin

Both, exogenous (foreign, “pathogenic”) and endogenous (inherited, “nonpathogenic”) retroviruses are present in cats. Pathogenic exogenous viruses that can be transmitted horizontally from cat to cat include FeLV, feline immunodeficiency virus (FIV, see Chapter 14), and feline syncytium-forming virus (FeSFV, see Chapter 17), which is widespread but has a low pathogenicity.

On the basis of similarities in nucleotide sequences, it has been determined that FeLV evolved from a virus in an ancestor of the rat. It is likely that this event took place in the late Pleistocene up to 10 million years ago in the North African desert. Ancestral rats and cats roamed freely, and the virus was transmitted to cats through

Infectious Diseases of the Dog and Cat, 3rd Edition

ingestion or a rat bite. The initial spread of FeLV among cats might have been inhibited by the aridity of the North African desert.¹⁸

FeLV is divided into several subgroups (based on the genetic map), but only subgroup FeLV-A is infectious and transmitted from cat to cat. The other subgroups (e.g., FeLV-B, FeLV-C, FeLV-*myc*) are not transmitted from cat to cat under natural circumstances but can be generated *de novo* in an FeLV-A-infected cat by mutation and recombination of the FeLV-A genome with cellular genes or genes from endogenous retroviruses in the cat's genome. In addition, feline sarcoma virus (FeSV) is a recombination of the FeLV-A genome with cancer-associated cellular genes (proto-oncogenes) and is generated *de novo* in an FeLV-A-infected cat.

Certain endogenous, nonpathogenic retroviruses (e.g., RD-114 virus, enFeLV, MAC-1 virus) are normally present in the genome of the cat population and inherited by transmission from cat to kitten through germline. These endogenous fractions of proviral DNA (also called *proviral sin*) cannot be induced to produce infectious virus particles. They are present but not replicating in every feline cell. Their main importance is based on the fact that these DNA fractions can potentially recombine with FeLV-A DNA in case of FeLV-A infection and thus increase the pathogenicity of FeLV-A. RD-114 is the most studied endogenous feline retrovirus. Although no evidence shows pathogenicity of or any immune response to RD-114 virus in cats, it may play some role in normal fetal differentiation. RD114 is most closely related to an endogenous baboon retrovirus and only distantly related to FeLV.^{34,38,310}

13.1.2 FeLV Genome and Proteins

FeLV is a typical retrovirus, containing single-stranded RNA that is transcribed by the enzyme reverse transcriptase (RT) into DNA, the so-called *provirus* that is subsequently integrated into the cellular genome. The gene sequence contains long terminal repeats (LTRs), which are repeated sequences that have regulatory function and control expression of the other viral genes but generally do not code for a protein product. From the 5' to the 3' end the gene order is LTR-*gag-pol-env*-LTR (Table 13-1). Within the LTRs, recurrent/enhancer sequences (UREs) are frequently found in myeloid leukemias of cats and thought to be associated with oncogenesis.^{209,230} The *gag* (group-associated antigen) gene encodes the internal structural proteins, including p15c, p12, p27, and p10. The *gag* protein p27, which is used for clinical detection of FeLV, is produced in virus-infected cells in amounts exceeding what is necessary for assembly of new virus particles. Thus it is abundant in the cytoplasm of individual infected cells and also in the plasma of infected cats, which is why most available immunochromatographic tests such as the enzyme-linked immunofluorescent assay (ELISA) or fluorescent antibody (FA) assays are designed to detect this protein. Free p27 not only circulates in plasma but is also shed in tears and saliva, where it also can be detected. The *pol* (polymerase) gene specifies the viral enzyme RT, which is responsible for synthesis of DNA on the RNA template. The *env* (envelope) gene encodes the envelope components gp70 and p15e. The *env* protein gp70 defines the virus subgroup and appears to be important for inducing immunity. Antibodies to gp70 are subgroup specific and result in neutralization of the virus and immunity to reinfection. Thus gp70 is important in natural resistance and as a target for vaccine production. The transmembrane protein p15e is thought to interfere with host cell immune responses, thus facilitating viral persistence.

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 13-1 Production and release of virus from a feline malignant cell. Viral envelope antigens can have a spike or knob shape. Host histocompatibility antigens may appear on the virus as the virus buds from the cell membrane. Viral structural proteins may appear on the host cell. Virus replication can also occur in nonmalignant cells. FOCMA, Feline oncornavirus membrane antigen. (Courtesy University of Georgia, Athens, Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 13-2 FeLV Subgroups^a

VIRAL SUBGROUPS	FREQUENCY OF ISOLATION IN FeLV-POSITIVE CATS	ASSOCIATED DISEASE	COMPARISON BY SPECIES OF IN VITRO REPLICATION
A	100% viremic cats, mildly pathogenic but highly contagious, mildly cytopathogenic	Hematopoietic neoplasia, experimentally may cause hemolysis	Cat, rabbit, pig, mink, human
B	Occurs with subgroup A in 50% or more of cats with neoplastic disease (lymphoma)	Not pathogenic alone, virulent in recombination with subgroup A, noncontagious	Cat, dog, cow, hamster, pig, human
C	Rarely isolated, arises by mutation from FeLV subgroup A	Nonregenerative anemia and erythremic myelosis, nonreplicating and noncontagious	Cat, dog, guinea pig, human
T ^b	Highly cytopathic, T-cell tropic virus; affinity for two host cell proteins: Pit1 and FeLiX; evolved from FeLV subgroup A	Lymphopenia, neutropenia, fever, diarrhea	Cat

a Modified from Jarrett O. 1990. Feline leukemia virus subgroups, pp 473–479. In Hardy WD, Essex M, McClelland AJ (eds), *Feline leukemia virus*. Elsevier, New York, NY; Nakata R, Myiazawa T, Shin YS, et al. 2003. Reevaluation of host ranges of feline leukemia virus subgroups, *Microbes Infect* 5:947–950.

b Subgroup T is a variant of subgroup A. Changes in the envelope protein result in increased cytopathogenicity of T strains.

13.1.3 FeLV Subgroups

The three most important FeLV subgroups (FeLV-A, FeLV-B, FeLV-C) have been classified on the basis of interference testing, virus neutralization, and ability to replicate in nonfeline tissues (Table 13-2). Only FeLV-A is contagious and passed horizontally from cat to cat in nature. Subgroups B and C evolve de novo in an FeLV-A-infected cat by mutation and recombination between FeLV-A and cellular or endogenous retroviral sequences contained in normal feline DNA. Replication of FeLV-B and FeLV-C is only possible with the help of FeLV-A because important genomic sequences are replaced in these recombinant viruses. Proposed FeLV-A helper functions include enhanced replication efficiency, immune evasion, and replication rescue for defective FeLV-B and FeLV-C virions. However, in certain experiments, it was possible to induce replication without FeLV-A. In newborn specific-pathogen-free (SPF) kittens an experimental FeLV-B or FeLV-C infection has been established without FeLV-A.^{17,276} However, all naturally infected cats carry subgroup A either alone or in combination with subgroup B, subgroup C, or both. Thus if antibodies against subgroup A are produced, the cat is protected. Pathogenicity of subgroup B and C is higher than of subgroup A.²⁶⁷ Different properties of the envelope proteins in the different subgroups have been shown to be the major pathogenic determinant, but the mechanisms by which envelope differences influence pathogenesis are not well understood.²²⁴ Subgroup B is commonly associated with malignancies. Subgroup C is rare and is mainly associated with nonregenerative anemia. In experimental infections a subgroup B strain (Rickard strain) caused lymphoma in nearly 100% of kittens by 1 year of infection, whereas subgroup C isolates repeatedly produced fatal nonregenerative anemia.²⁴² Simultaneous inoculation of subgroup A in combination with subgroup B in cats was associated with an attenuated infection compared to infection with subgroup A alone.²⁴⁶ Thus subgroup B may be acting as an attenuated vaccine. A fourth FeLV subgroup, subgroup T, is highly cytolytic for T lymphocytes and causes severe immunosuppression.^{15,177,178}

Infectious Diseases of the Dog and Cat, 3rd Edition

13.2 EPIDEMIOLOGY

In nature, FeLV has been reported mainly to infect domestic cats. Case reports of FeLV in nondomestic felids are few, and FeLV does not appear to be enzootic in wild felids other than European wildcats (*Felis silvestris*) in France and Scotland.⁴⁵ Some evidence shows that other wild felids may be susceptible. A multicentric T-cell lymphoma associated with FeLV infection was found in a captive Namibian cheetah (*Acinonyx jubatus*).²⁰⁶ FeLV was also detected in an 11-month-old captive-bred male neutered bobcat (*Felis rufus*) showing signs of lethargy, anorexia, neutropenia, lymphopenia, and nonregenerative anemia.²⁸⁹ Introduction of FeLV into free-living and captive nondomestic felid populations could have serious consequences for their health and survival.

Some evidence shows that FeLV might replicate in nonfelid tissue (see [Table 13-2](#)). For example, FeLV-B replicates in cells of cats, dogs, cows, pigs, hamsters, monkeys, and humans; FeLV-C replicates in cells of cats, dogs, guinea pigs, and humans.^{152,155,275} Although malignant transformations do not occur in nonfelid cell cultures,¹⁹¹ experimental FeLV infection with development of lymphomas could be induced in young dogs and marmosets²⁶⁰; in experimental infections with FeSV, fibrosarcomas could be produced in nonfelids in vivo. It was thought that FeLV-A only replicates in cat cells in vitro, and that infection in vivo that always requires FeLV-A, cannot happen in nonfelids. However, it has been found that two independent FeLV-A isolates from United Kingdom and United States also have infected various nonfeline cell lines including cells from humans, rabbits, pigs, and minks.²²⁷ However, no reports have been made on natural transmission of FeLV to nonfelids.

13.2.1 Prevalence

FeLV infection exists in domestic cats worldwide. In contrast to FIV infection, in which the prevalence varies significantly, the FeLV infection rate of free-roaming cats is similar throughout the world, ranging from 1% to 8% in healthy cats. Infection rates of up to 21% have been reported from large studies of sick cats.¹⁸⁴ Originally, certain diseases such as lymphoma and leukemia were associated with very high rates (up to 75%) of FeLV infection or feline infectious peritonitis (FIP; up to 32%). In recent years, cats that test negative for FeLV but have these diseases have become more common because the overall prevalence of FeLV has decreased.³⁷

Clear evidence shows that the overall rate of FeLV infection is decreasing. For example, the Tufts Veterinary Diagnostic Laboratory annually evaluates 1500 to 2400 FeLV test results submitted by practitioners from healthy and ill cats. A gradual but significant decline from 8% in 1989 to 4% in 1995 occurred in the number of positive test results.³⁶⁻³⁸ An overall seroprevalence rate of infection in Japan was 2.9%, with higher rates of infection in southern and urban sites than in northern and suburban sites.²⁰⁷ Germany has had a clear decrease in prevalence over the last 20 years from 5% to 2.5%.¹¹⁴ The decreased infection rate is particularly true in catteries. The availability of testing in these closed facilities made it possible to remove all infected animals. Likewise, the current practice of testing cats in animal shelters and testing new pets entering a household has contributed to the decline in prevalence. Vaccination also contributes to the decrease, but epidemiologic studies suggest that the testing and removal practice is more effective than vaccination.²⁷² The first vaccine was introduced in 1985, but the observed decline in the overall infection rate began before this time.¹⁸⁴

The prevalence of FeLV is higher in cats that are allowed to go outside because direct contact is required for transmission. In a study in the United States, antibody prevalence (which predicts exposure) was clearly related

Infectious Diseases of the Dog and Cat, 3rd Edition

to the time spent outdoors and the degree of exposure to other cats. Cats in a study in Boston and Detroit, of which many were allowed to roam outside, had 63% and 47% positive antibodies rates, respectively, whereas only 5% of New York cats that were primarily confined to high-rise apartments had antibodies.²⁴²

Risk groups for FIV and FeLV infections are different. Whereas fighting, free-roaming, intact male cats are at highest risk for acquiring FIV infection, FeLV infection is the infection of “social cats” because it is mostly spread through social contacts. Thus in contrast to FIV infection, which is transmitted primarily through biting—behavior common among male cats because of their propensity for fighting—FeLV infection is found almost equally in male and female cats, with a slightly higher rate in male cats. This may be a result of the wandering behavior that is more common in male cats and the subsequent increased number of cat contacts. In one study, 733 unowned free-roaming cats in Raleigh, North Carolina, and 1143 unowned free-roaming cats in Gainesville, Florida, were tested for FIV and FeLV infection, and prevalence of FeLV infection was not significantly different between males (4.9%) and females (3.8%).¹⁷⁹

Although no breeds are predisposed to being infected with FeLV, infection is less commonly found in purebred cats today, mainly because they are usually kept indoors. In addition, awareness in the cat breeder community of FeLV infection leads to frequent testing and avoidance of bringing an infected cat into a closed cat population.

13.2.2 Transmission

FeLV is contagious and spreads through close contact between viral shedding cats and susceptible cats. Transmission of FeLV occurs primarily via saliva, where the concentration of virus is higher than in plasma. Viremic cats constantly shed millions of virus particles in the saliva. The concentration of virus in saliva and blood of healthy viremic cats is as high as it is in those with signs of illness. FeLV is passed effectively horizontally among communal cats that have prolonged close contact. Social behavior such as sharing food and water dishes, mutual grooming, and using common litter areas are the most effective means of transmission. Although the virus may enter many tissues, body fluids, and secretions, it is less likely to spread via urine and feces. Fleas have been considered a potential source of transmission because FeLV RNA has been detected in fleas and their feces.^{319,320} Iatrogenic transmission can occur via contaminated needles, instruments, fomites, or blood transfusions.

The viral envelope is lipid soluble and susceptible to disinfectants, soaps, heating, and drying. Virus is readily inactivated in the environment within a few seconds. Therefore close contact among cats is required for spread of infection, and indirect transmission (e.g., via human beings) is not possible. Single cats strictly kept indoors are not at risk for acquiring infection. It is only because of latency and potential reactivation that viremia is occasionally detected in middle-age cats that have lived alone indoors since they were adopted as kittens. Because of the viral lability, a waiting period is not needed before introducing a new cat into a household after removal of an infected cat. FeLV is not a hazard in a veterinary hospital or boarding kennel as long as cats are housed separately and routine cage disinfection and hand washing are performed between handling cats. FeLV is maintained in nature because infected cats may live and shed virus for several years.

Vertical transmission from mother to kittens occurs in FeLV-viremic cats. Neonatal kittens can be infected transplacentally or when the queen licks and nurses them. Transmission also can occur in queens that are latently infected (and therefore have a negative result on routine tests) because a latent infection may be reactivated during pregnancy. In addition, isolated FeLV infection of the mammary glands of FeLV-negative cats with transmission of FeLV via milk has been described. If in utero infection occurs, reproductive failure in the form of fetal resorption, abortion, and neonatal death is common, although up to 20% of vertically infected

Infectious Diseases of the Dog and Cat, 3rd Edition

kittens may survive the neonatal period to become persistently infected adults.¹⁸⁴ It is possible to observe that newborn kittens from infected queens have negative FeLV antigen test results at the time of birth but may become positive over the following weeks to months once the virus starts replicating. Thus if the queen or any kitten in her litter is infected, the entire family should be treated as if infected and isolated from uninfected cats.

Susceptibility to FeLV infection is highest in young kittens. Studies in a household with many FeLV-infected cats showed that 7 of 10 kittens placed there at 3 months of age became viremic within 5 months, whereas only 3 of 17 adults in the same household became viremic over 7 years.^{34,38} Experimental infection is difficult if not impossible in healthy adult cats. Depending on the FeLV strains used, experimental infection can even be difficult to achieve in kittens older than 16 weeks of age.¹³⁴ This age resistance is independent of immunity from previous contact or vaccination. An explanation for the age resistance is that the number of cellular receptors necessary for FeLV-A to enter target cells seems to decrease in older cats, thus establishment of infection becomes more difficult. The cellular receptors are not fully identified, and strain-dependent differences seem to exist. For example, T-cell-tropic FeLV cannot infect cells unless a classic multiple membrane-spanning receptor molecule and a second coreceptor or entry factor are present. This cellular protein can function either as a transmembrane protein or a soluble component to facilitate infection.⁷ Age resistance to FeLV also may be related to maturation of macrophage function.¹³¹ In addition, age resistance seems to exist in nature; the prevalence of anti-FeLV antibodies increases steadily over time, indicating an increased exposure to the virus throughout life. In a survey in Scotland, only 6% of kittens younger than 5 months had anti-FeLV antibodies. The percentage increased to 55% at 1 to 2 years of age and to 74% by 3 years.²⁴² Despite the evidence for increased exposure to FeLV throughout life, the cumulative rate of persistent viremia is opposite that of antibody production. Of 8642 cases of FeLV reported by North American veterinary teaching hospitals since 1973, the highest rate of viremia was reported in cats younger than 2 years of age.¹⁸⁴ Although FeLV infection was reported in cats of all ages, the rate declined steadily as cats aged. Considering these results in addition to the antibody surveys, this suggests that although exposure to FeLV accumulates with age, susceptibility to develop persistent viremia after infection simultaneously decreases. However, the age-related resistance is not absolute and depends on the infection pressure. Risk of developing persistent viremia increases also in adult cats when they are housed together with FeLV-shedding cats. This is shown by the increased rate of viremic cats in households with endemic FeLV infection and by natural exposure studies in which a certain percentage of cats becomes FeLV-positive over years when they are housed together with infected cats. However, the risk of an adult cat becoming persistently viremic after one short contact with a FeLV-shedding cat is certainly very low and probably lower than the risk of developing vaccine-associated sarcomas after FeLV vaccination. Therefore use of FeLV vaccination should be considered carefully in adult cats.

13.3 PATHOGENESIS

The outcome of FeLV infection is very different in each cat. Although it mainly depends on immune status and age of the cat, it is also affected by pathogenicity of the virus, infection pressure, and virus concentration.

13.3.1 Stages of FeLV Viremia

Different courses, outcomes, and classifications of FeLV infection are described in [Figs. 13-4](#) and [13-5](#) and [Table 13-3](#). After initial infection, which most commonly occurs via oronasal routes, virus replicates in the local lymphoid tissue in the oropharyngeal area. In many immunocompetent cats, viral replication is stopped by an effective cell-mediated immune (CMI) response, and virus is completely eliminated from the body. These cats usually have high levels of neutralizing antibody and are called *regressor cats*. In these cats, virus never

Infectious Diseases of the Dog and Cat, 3rd Edition

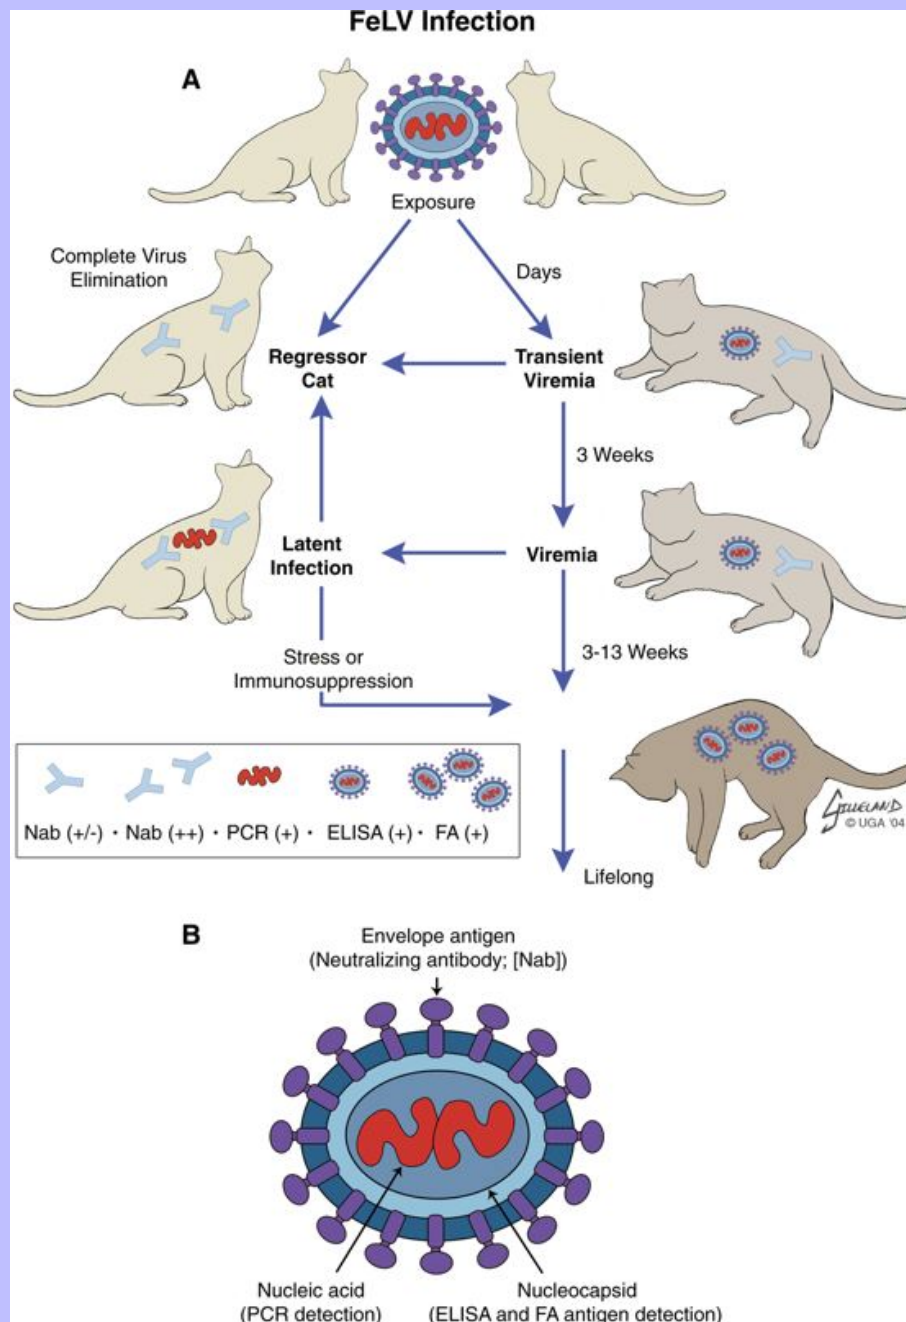

spreads systemically, and infection remains undetected because they never react positively with antigen testing methods. This explains why the majority of cats in a population show evidence of exposure by the presence of anti-FeLV antibodies after contact with FeLV, but only a small proportion actually become viremic. These regressor cats build a very effective immunity and are protected against new viral challenges, probably for several years. Protective immunity is partly humoral and partly cellular, and antibody production is not necessarily required for protection; about 2% are effectively protected without detectable antibodies.

If the immune response does not intervene adequately, replicating FeLV spreads systemically within mononuclear cells (lymphocytes and monocytes). During this first viremic episode, free FeLV-p27 antigen is detectable, and cats have positive results on tests that detect free antigen in plasma (e.g., ELISA). The initial viremia may be characterized by malaise, fever, or lymphadenomegaly resulting from lymphocytic hyperplasia. The virus spreads to target tissue including thymus, spleen, lymph nodes, and salivary glands. If the viremia can be terminated within weeks or months, it is called *transient viremia*. In most cats, transient viremia only lasts 3 to 6 weeks (with a maximum of 16 weeks). During this time, cats shed virus and are infectious. Many cats are able to clear viremia very early before bone marrow becomes infected. These cats not only terminate the viremia, they also completely eliminate the virus from the body. These cats also develop a very effective immunity and are protected against new exposures to virus. They have a low risk of developing FeLV-related illnesses.

After about 3 weeks of viremia, bone marrow cells become involved and affected hematopoietic precursor cells produce infected granulocytes and platelets that circulate in the body. At this time, a high level of viremia has developed, and lymphoid organs and salivary glands become infected with up to 1 million viruses per milliliter of saliva. From this time point on, viral antigen is also detectable in platelets and granulocytes by tests such as direct FA that detect intracellular antigen. In contrast to antigen tests (e.g., ELISA) that detect free p27 antigen and become positive during the first viremia, direct FA test results become positive later and only after infection is established in bone marrow. This explains discordant ELISA and direct FA results.

Infectious Diseases of the Dog and Cat, 3rd Edition

Even if bone marrow becomes infected, a certain percentage of cats can clear the viremia; the longer the viremia lasts, the less likely it is that these cats can clear it. However, once bone marrow cells are infected (after 3 weeks of viremia), cats cannot completely eliminate the virus from the body even if they terminate the viremia because the information to build the virus (its proviral DNA) is present in bone marrow stem cells—it is a *latent infection*. Although proviral DNA remains, no virus is actively produced, and cats with latent infection have negative results from routine tests that detect FeLV antigen. Latent infection can only be diagnosed by culturing bone marrow samples or with the polymerase chain reaction (PCR).

Latent infection can be reactivated spontaneously or in response to immune suppression, and cats can become viremic and show positive results again in antigen tests. Latent infections may reactivate in pregnancy, which also may explain the reemergence of FeLV infection in kittens. Mammary glands of latently infected queens may begin producing infectious viral particles during the induction of lactation.²³⁹

If the immune response of the cat is not strong enough and viremia persists longer than 16 weeks, chances are very high that the cat will remain persistently viremic and infectious to other cats for the remainder of its life—a condition called *persistent viremia*. Persistently viremic cats have low levels of neutralizing antibody, and virus persistently replicates in bone marrow, spleen, lymph nodes, and salivary glands. These cats develop FeLV-associated diseases, and most of them die within 3 years. The risk for the development of a fatal persistent viremia primarily depends on immune status and age of the cat but also on the infection pressure. Young and immunosuppressed cats are at higher risk for developing persistent viremia. In a cat with a first-time single contact with a FeLV-shedding cat, the risk of developing persistent viremia averages only 3%. However, if an FeLV-shedding cat is introduced to a naive group of cats and the cats are housed together for an extended period, the risk for a cat to develop persistent viremia increases to an average of 30%.¹³¹

Fig 13-5 Interactions of FeLV with host cells and immune system leading to various clinical problems in cats with ineffective immune responses.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 13-3 Classification of FeLV Infection Based on Viral and Immune Testing

FeLV STATUS	FeLV ANTIGENS TEST RESULTS			VIRUS-POSITIVE BONE MARROW CULTIVATION OR PCR ^a	ELEVATED SERUM NEUTRALIZING ANTIBODY	ELEVATED SERUM FOCMA ANTIBODY
	BLOOD ELISA	DIRECT FA	BONE MARROW DIRECT FA			
Never exposed	–	–	–	–	–	–
Recovered	–	–	–	–	±	±
Latent	–	–	–	+	+	±
Immune carrier	+	–	–	+	+	±
Persistently viremic	+	+	+	+	–	±

a PCR can be performed on bone marrow, blood, or tumors.

13.3.2 Latent Infection

Cats that are viremic for longer than 3 weeks develop persistent infection of the bone marrow. High levels of circulating FeLV-specific effector cytotoxic T lymphocytes (CTLs) appear before neutralizing antibodies in cats that recover from infection after primary exposure to FeLV.^{74,75} Neutralizing antibodies, which develop after infection but not vaccination, are markers for a protective immune response. In previously exposed immune cats, neutralizing antibody may be helpful in protecting against subsequent challenge exposure by preventing viral expression. Although latency is a sequel to FeLV infection, the majority of cats completely eliminate the viral genes from their cells by 9 to 16 months after infection, and all but 10% have done so after 30 months.²³⁹ Once the bone marrow has been infected, virus can remain integrated in a small number of cells for a long time, kept in check by a partial immune response. As antibody concentration increases, virus production decreases.

The molecular basis of latency is the integration of a copy of the viral genome (provirus) into cellular chromosomal DNA. During the replication cycle, the enzyme RT produces a DNA copy using the viral RNA as a template. The copy is integrated into the cellular chromosomal DNA and maintained as a provirus for the lifespan of the cell. During cell division, proviral DNA is replicated and the information given to the daughter cells. Thus complete cell lineages may contain FeLV proviral DNA. However, the proviral DNA is not translated into proteins, and no infectious virus particles are produced. Therefore latently infected cats do not shed FeLV and are not infectious to others; however, as an exception, latently infected queens stressed by pregnancy have reverted to overt viremia and transmitted FeLV to their kittens. No harmful virus is produced during latent infections, and clinical signs (with few exceptions such as neoplasia or myelodysplasia) do not occur. Because no virus replicates, no FeLV antigen is produced, and the cats have negative results by routine tests that detect viral antigen (such as ELISA, direct FA, or viral culture of blood cells). However, the presence of latent virus can be demonstrated by bone marrow PCR or when bone marrow cells are cultured in vitro, thereby bypassing the effects of the immune system. Growth can be facilitated by adding glucocorticoids to the culture.

Latent infection can be reactivated because the information for producing complete viral particles is present and can potentially be reused when antibody production decreases (e.g., after immune suppression). This usually

Infectious Diseases of the Dog and Cat, 3rd Edition

occurs after stress and can be experimentally induced in cats by administration of high doses of glucocorticoids.²⁶⁹ Reactivation is more likely the earlier the stress factor occurs after the viremic phase. In the first weeks after viremia, viral replication can be experimentally reactivated in most cats. As the time passes, latent infections become more difficult to reactivate, even with high doses of glucocorticoids. By 1 year after infection, reactivation is considered unlikely and is almost impossible after 2 years. This may be explained by genetic code-reading mistakes that may occur if the information is frequently reproduced in these fast-dividing cells. Thus information to produce infectious viral particles gets lost, and reactivation becomes more and more unlikely over time. It has been demonstrated experimentally that the proportion of experimentally infected cats that had latent FeLV infections in their bone marrow decreased with time following disappearance of viremia.²⁴⁴ In the first 3 months after recovery from viremia, integrated virus could be isolated from the bone marrow of approximately 50% of experimentally infected cats. A pronounced decrease in the incidence of latent infections occurred 190 days after the viremia.^{239,244} More than 1 year later, only 5 of 19 previously challenge-exposed cats that were FeLV negative according to ELISA still had FeLV detectable in several tissues (e.g., bone marrow, spleen, lymph node, small intestine).¹¹⁸ At 3 years postviremia, only about 8% of cats still harbored latent infections in bone marrow, myelomonocytic cells, and stromal fibroblast cells.^{129,203,239,244,269} Latency is probably a stage in the elimination process of the virus. Most latent infections are not clinically significant because viral reactivation is unusual under natural circumstances. As long as the infection remains latent, the cats are not contagious.

However, viral latency explains relapsing viremias, protracted incubation periods, and persistent high titers of antibodies. A question always arises regarding whether latent FeLV infection can be responsible for clinical signs. However, for the majority of pathogenic mechanisms by which FeLV causes clinical signs, active virus replication is necessary; this is not the case in latent FeLV infections, in which the virus is harbored in a “dormant” and nonproductive form. However, latent infections may explain how myelosuppression or hematopoietic malignancy could be FeLV related in FeLV-negative cats. FeLV provirus can be inserted at many different sites in the host's genome, carrying potent regulatory signals. In the development of myelosuppressive disorders or tumors, integrated FeLV provirus may interrupt or inactivate cellular genes in the infected cells, or regulatory features of viral DNA may alter expression of neighboring genes. In addition, because bone marrow microenvironment cells (e.g., myelomonocytic progenitor cells and stromal fibroblasts) provide a reservoir of latent FeLV infections, it seems possible that the integrated provirus may alter cellular functions and contribute to the pathogenesis of myelosuppressive disorders. Finally, FeLV not only contributes its genes to the host, it also has been shown to appropriate cellular genes; several such transduced genes that are also in latently infected cells have been implicated in viral oncogenesis.^{259,266,281}

13.3.3 Atypical Infection

Only a few cats (in experimental studies, up to 10%) have persistent atypical local viral replication (e.g., in mammary glands, bladder, and eyes).¹³¹ This can lead to intermittent or low-grade production of p24 antigen. Therefore these cats may have weakly positive or discordant results in antigen tests, or positive and negative results may alternate. Queens with atypical infection of their mammary glands may transmit the virus to their kittens via milk but not have positive test results.

A particular FeLV feline acquired immunodeficiency syndrome (FAIDS) is composed of subgroup A virus and highly immunopathogenic variants that infect CD4+ and CD8+ T lymphocytes and IgG+ B lymphocytes in blood, lymph nodes, and myeloid cells.²⁵² This widespread proliferation greatly impairs the immune response.

Infectious Diseases of the Dog and Cat, 3rd Edition

13.4 CLINICAL FINDINGS

FeLV can cause variable clinical signs. The prevalence of hematopoietic malignancy, myelosuppression, and infectious diseases is higher in FeLV-infected multicat households than in the general population. The death rate of persistently viremic cats in multicat households is approximately 50% in 2 years and 80% in 3 years.^{38,184} Survival rates for persistently viremic cats kept indoors in single-cat households are higher. In closed households with endemic feline coronavirus (FCoV), FeLV, FIV, or all of these infections, FeLV infection has the greatest impact on mortality.²

Although the virus was named after the contagious malignancy that first garnered its attention, most infected cats are brought to the veterinarian for anemia or immune suppression. Of 8642 FeLV-infected cats examined at North American veterinary teaching hospitals, various coinfections (including FIP, upper respiratory infection, FIV infection, hemotropic mycoplasmosis, and stomatitis) were the most frequent findings (15%), followed by anemias (11%), lymphoma (6%), leukopenia or thrombocytopenia (5%), or leukemia or myeloproliferative disease (4%).³⁵

The exact mechanisms for the varied clinical responses of persistently viremic cats are poorly understood. It is clear that the clinical course is determined by a combination of viral and host factors. Some of these differences can be traced to properties of the virus itself, such as the subgroup that determines differences in the clinical picture. (For example, FeLV-B is primarily associated with tumors, and FeLV-C is primarily associated with nonregenerative anemia.) A study tried to define dominant host immune effector mechanisms responsible for the outcome of infection by using longitudinal changes in FeLV-specific CTLs. As mentioned previously, high levels of circulating FeLV-specific effector CTLs appear before virus neutralizing antibodies in cats that have recovered from exposure to FeLV. In contrast, persistent viremia has been associated with a silencing of virus-specific humoral and CMI host effector mechanisms. These results suggest an important role for FeLV-specific CTLs in immunity to FeLV.⁷⁴ Probably the most important host factor that determines the clinical outcome of cats persistently infected with FeLV is the age of the cat at the time of infection.¹³⁴ Neonatal kittens develop marked thymic atrophy after infection (“fading kitten syndrome”), resulting in severe immunosuppression, wasting, and early death. As cats mature, they acquire a progressive resistance. When older cats become infected, they tend to have milder signs and a more protracted period of apparent good health.¹⁸⁴ Clinical signs that are associated with FeLV infection can be classified as tumors induced by FeLV, bone marrow suppression syndromes, immunosuppression, immune-mediated diseases, and other syndromes (including reproductive disorders, fading kitten syndrome, and neuropathy).

13.4.1 Tumors

FeLV is a major oncogene that causes different tumors in cats, most commonly malignant lymphoma and leukemia and less commonly other hematopoietic tumors. Lymphomas also occur in the absence of detectable FeLV.³²² In addition, other tumors including osteochondromas, olfactory neuroblastoma, and cutaneous horns have been described in FeLV-infected cats.

The mechanism by which FeLV causes malignancy may be explained by insertion of the FeLV genome into the cellular genome near a cellular oncogene (most commonly *myc*), resulting in activation and overexpression of that gene. This effect leads to uncontrolled proliferation of that cell (clone). A malignancy results in absence of an appropriate immune response. FeLV-A may also incorporate the oncogene to form a recombinant virus (e.g., FeLV-B, FeSV) containing cellular oncogene sequences that are then rearranged and activated. When they

Infectious Diseases of the Dog and Cat, 3rd Edition

enter a cell, these recombinant viruses are oncogenic. In a study of 119 cats with lymphomas, transduction or insertion of the *myc* locus had occurred in 38 cats (32%).³¹²

Feline oncornavirus cell membrane antigen (FOCMA), an antigen present on the surface of transformed cells, was detected in 1973 but remains a subject of discussion and confusion among researchers. Its value as clinical tool (either diagnostic or preventative) is certainly limited. FOCMA was first detected on the surface of cultured lymphoma cells incubated with serum of cats that did not develop tumors, although they were infected with FeSV—a recombinant of FeLV with an oncogenic potential.^{67,291} FOCMA can be found on the surface of feline lymphoma cells and FeSV-induced fibrosarcomas but not on the surface of normal feline lymphocytes.^{104,318} FOCMA was first considered to be a cellular antigen that is expressed after FeLV infection or tumor transformation.^{65,104,291} It has also been proposed that FOCMA is a viral antigen of FeLV-C.³¹⁸ However, in other studies, it was shown that FOCMA and FeLV-C-gp70 are similar but not completely homologous.²⁹² Some authors believed that development of large amounts of antibodies against FOCMA could protect against the development of FeLV-induced lymphomas by complement-dependent lysis of tumor cells.^{39,63,65,85} Evidence for this was provided when experimentally FeLV-infected kittens did not develop neoplasia if they produced or passively received sufficient amounts of antibodies against FOCMA.^{64,67} Many cats with FeLV in cluster households have antibody titers to FOCMA. Those with the highest titers are most likely to remain free of malignancies. However, in cluster households, some cats that were initially viremic with a high FOCMA antibody titer developed lymphoma or leukemia months or years later after the titer declined.³⁸ Opinions about identity and importance of FOCMA are still diverse. FOCMA can be considered a nonhomogenous group of viral antigens that may, although not always, be present on the surface of FeLV-infected cells. At the least, FOCMA antibodies indicate exposure to FeLV but may not mean more than this. Alternatively, FOCMA antibodies may provide a protective mechanism against tumor development.

13.4.2 Lymphoma and Lymphoid Leukemia

13.4.2.1 Association with FeLV

In the 1960s, studies found that the most common primary feline malignancies are hematopoietic tumors, of which about 90% are malignant lymphomas. Malignant lymphomas and leukemias account for about 30% of all feline tumors, which is the highest proportion recorded in any animal species.^{42,56,57,95,96} The estimated incidence of feline lymphoma and leukemia in the 1960s was 200 cases per 100,000 cats per year.³⁸ Feline lymphomas are most commonly high grade with an immunoblastic or a lymphoblastic morphology, but they may be mixed lymphoblastic and lymphocytic or occasionally low-grade lymphocytic.^{316,317}

The association between FeLV and lymphomas has been clearly established in several ways. First, these malignancies could be induced in kittens by experimental FeLV infection.^{100,153,261} Second, cats naturally infected with FeLV had a higher risk of developing malignant lymphoma than uninfected cats.^{63,100} Third, most cats with malignant lymphoma were FeLV-positive in tests that detected infectious virus or FeLV antigens. Previously, up to 80% of feline lymphomas and leukemias were reported to be FeLV related^{*}; however, this is no longer considered to be the case. Since the 1980s a dramatic reduction in the prevalence of viremia has been noted in cats with lymphoma.^{114,210,221} The decrease in prevalence of FeLV infection in cats with lymphoma or leukemia also indicates a shift in tumor causation in recent years. Whereas 59% of all cats with malignant lymphoma or leukemia were FeLV positive in one German study from 1980 to 1995,

Infectious Diseases of the Dog and Cat, 3rd Edition

only 20% of the cats were FeLV positive in the years 1996 to 1999 in the same institution.¹¹⁴ In 1975 a survey of 74 Boston area cats with lymphoma or leukemia showed that 70% were FeLV positive, but only 3 cats had the alimentary form.³⁴ Between 1988 and 1994, 72% of all feline lymphomas treated at the Animal Medical Center in New York were of the alimentary form, and only 8% of affected cats were FeLV positive.³⁸ In a recent study in the Netherlands, only 4 of 71 cats with lymphoma were FeLV positive, although 22 of these cats had mediastinal lymphoma, which was previously highly associated with FeLV infection.³⁰⁶ A greater prevalence of lymphoma in older-age cats has been observed. One major reason seems to be the decreased prevalence of FeLV infection in the overall cat population as a result of FeLV vaccination, as well as testing and elimination programs. Of the purebred cat breeds, Siamese cats may be predisposed to lymphosarcoma.⁴⁰

113

114

Overall, the proportion of cats with lymphomas that test negative for the FeLV antigen (versus cats with lymphomas that test positive) has increased significantly during the last 20 years, and the prevalence of FeLV infection is decreasing. However, prevalence of lymphomas caused by FeLV may be higher than indicated by conventional antigen testing of blood specimens. Cats from FeLV cluster households had a fortyfold higher rate of development of FeLV-negative lymphomas than did those from the general population. FeLV-negative lymphomas have also occurred in laboratory cats known to have been infected previously with FeLV.²⁶⁶ FeLV proviral DNA was detected in malignant lymphomas of older cats that tested negative for FeLV antigen, also suggesting that the virus may be associated with a larger proportion of lymphomas than previously thought. PCR detected proviral DNA in formalin-fixed, paraffin-embedded tumor tissue in 7 of 11 FeLV-negative cats with lymphoma.¹⁴² However, other groups found evidence of provirus in only 1 of 22²⁸¹ and in 0 of 50 FeLV-negative lymphomas.¹¹⁴ FeLV-negative lymphomas that are induced by FeLV can be explained by different ways. First, latent FeLV infection may be responsible for the tumor development. Second, FeLV could be responsible for the development of the tumor, inducing a malignant cell clone, but not be persistently integrated into the genome of the neoplastic cell and therefore be eliminated while the tumor grows to a detectable size. Third, FeLV infection could be present in other cells (and not been detected) and induce oncogenesis via mechanisms such as cytokine release or chronic immune stimulation.

The FeLV status of cats with lymphomas varies depending on the type and locations of tumors. FeLV-positive lymphomas are mainly of a T-cell origin; FeLV-negative lymphomas are mainly of a B-cell origin.^{77,96,104,228} FeLV transforms mature T cells and immature or prothymocytes, null cells, and possibly monocytes. Transformation of mature B cells does not occur, because feline lymphoma cell lines and primary tumors lack surface immunoglobulin expression.²⁷¹

* References 39, 77, 78, 102, 107, 255, 282.

13.4.2.2 Classification

Lymphomas can be classified according to their location—in mediastinal (thymic), alimentary (intestinal), and multicentric lymphomas. *Mediastinal lymphoma*, frequently associated with FeLV infection and seen mainly in cats younger than 3 years, was previously the most prevalent site in cats but is now seen less frequently. Of cats with mediastinal lymphoma, 80% to 90% have been reported as FeLV positive,³⁷ but this rate has also seemed to decrease according to the study of Teske and coworkers.³⁰⁶ The tumor arises in the area of the thymus and eventually causes a malignant pleural effusion (Figs. 13-6 and 13-7). The fluid-nucleated cell count is usually greater than 8000/ μ l; the majority are large, immature lymphocytes. The most common presenting sign is dyspnea, but occasionally regurgitation from pressure on the esophagus or Horner syndrome from pressure on sympathetic nerves at the thoracic inlet is present.³⁸

Alimentary lymphoma occurs primarily in older cats that are usually FeLV negative. Clinical signs of alimentary lymphoma include vomiting or diarrhea, but many cats have anorexia and weight loss only.²⁰⁴ Tumors of the stomach and intestines may be focal or diffuse, and mesenteric lymph nodes are usually involved. Estimates of the prevalence of FeLV antigenemia in cats with alimentary lymphomas range from 25% to 30%.³⁸ However, in another study, only 6% of the cats with intestinal lymphomas were FeLV

Infectious Diseases of the Dog and Cat, 3rd Edition

positive, which is about twice the prevalence of gastrointestinal (GI) lymphoma in the general population.¹¹⁴ These data suggest that other stimuli (such as food components or inflammatory bowel disease) in the GI tract of older cats may be more important predisposing factors for tumor development.

Multicentric lymphoma is described with major involvement of several sites. About half of the cats with multicentric lymphoma are FeLV positive. Any organ may be involved, such as the retrobulbar area, nasal cavity, gingiva, skin, liver, kidneys, urinary bladder, brain, and lungs. Renal lymphoma is usually bilateral and does not cause signs of illness until the kidneys are so extensively infiltrated that renal failure occurs.

Kidneys are enlarged and usually irregular. Epidural lymphoma may cause sudden or gradual onset of posterior paralysis (Fig. 13-8). The bone marrow is involved in about 70% of these cats even though

complete blood cell count (CBC) may be normal.^{175,294}

Infectious Diseases of the Dog and Cat, 3rd Edition

13.4.3 Hematopoietic Neoplasia (Myeloproliferative Disorders)

13.4.3.1 Leukemias

More than half of the cats with nonlymphoid leukemia are FeLV positive. All hematopoietic cell lines are susceptible to transformation by FeLV, resulting in myeloproliferative disease or myelodysplastic syndrome (MDS; [Figs. 13-9](#) and [13-10](#)). Thus lymphoid and myeloid (including granulocytic, erythroid, and megakaryocytic) types occur. In erythremic myelosis, proliferation of erythrocyte precursors is usually associated with FeLV subgroup C, and most have positive test results for FeLV. Cats with this disorder have low hematocrit (HCT) levels (12% to 15%) with normal leukocytes and variable thrombocytopenia. The anemia is usually nonregenerative or poorly regenerative, and with time the HCT level does not increase. Despite the lack of regeneration, the mean corpuscular volume (MCV) and numbers of nucleated erythrocytes are usually higher. Abnormal erythrocyte stages are found in bone marrow and often in peripheral blood. MDS may result as a clonal proliferation of hematopoietic cells that is a preleukemic state of acute myeloid leukemia.^{125,286} In acute leukemia or MDS of any type, the bone marrow is filled with blast cells, and normal hematopoiesis is suppressed.¹²⁶ Clinical signs with acute leukemia are related to the loss of normal hematopoietic cells and include lethargy from anemia, signs of sepsis with granulocytopenia, and bleeding with thrombocytopenia. Hepatomegaly with icterus and splenomegaly are frequently present because of malignant infiltration or extramedullary hematopoiesis. Diagnosis of acute leukemia is made by CBC and bone marrow examinations. Bone marrow cytologic studies show increased cellularity, megaloblastic maturation, increased myelofibrosis, and immature blast cells.²⁸³ In cats with large numbers of circulating blast cells, the CBC may in itself be diagnostic. Although classifications have been proposed for the acute leukemias, the predominant cell type may be difficult to identify even with histochemical stains. Transformation, especially for the nonlymphoid leukemias, usually occurs at or very close to the stem cell level, so more than one cell line may be affected. Chronic leukemias are rare in cats and rarely associated with FeLV. They include well-differentiated chronic lymphocytic leukemia (CLL), chronic myelogenous leukemia (CML), polycythemia vera, and thrombocythemia. Eosinophilic leukemia may be a subtype of CML and has been described in association with FeLV. The differentiation between severe reactive eosinophilia (hypereosinophilic syndrome [HES]) and malignancy is difficult because both have been associated with large numbers of morphologically normal eosinophils in the marrow, peripheral blood, and other organs.³⁸ The prognosis for cats with myeloproliferative diseases is poor.

Fig 13-9 Peripheral blood film of a cat with erythroleukemia. Cat had severe anemia without reticulocytosis. More than 95% of circulating nucleated cells were erythroid precursors of varying degrees of maturity. Severe granulocytopenia was noted (Wright stain, $\times 1000$). (Courtesy Ken Latimer, Athens, Ga.)

13.4.3.2 Myelofibrosis

Abnormal proliferation of fibroblasts results from chronic stimulation of the bone marrow, such as chronic bone marrow activity from hyperplastic or neoplastic regeneration caused by FeLV. In severe cases the entire endosteum within the medullary cavity can be obliterated. Bone marrow involvement may require a core biopsy instead of needle aspiration to confirm the diagnosis.

13.4.3.3 Fibrosarcoma

Fibrosarcomas that are associated with FeLV are caused by FeSV, a recombinant virus that develops de novo in FeLV-A-infected cats by recombination of the FeLV-A genome with cellular oncogenes. Through a process of genetic recombination, FeSV acquires one of several oncogenes such as *fes*, *fms*, or *fgr*. As a result, FeSV is an acutely transforming (tumor-causing) virus, causing a polyclonal malignancy with multifocal tumors arising simultaneously after a short incubation period. With the decrease in FeLV prevalence, FeSV also becomes less common. FeSV-induced fibrosarcomas are multicentric and usually occur in young cats. Several strains of FeSV that have been identified from naturally occurring tumors are defective. They are unable to replicate without the presence of FeLV as a helper virus that supplies proteins (such as those coded by the *env* gene) to FeSV. The host range for FeSV depends on the helper FeLV-A. By manipulation of the helper virus in the laboratory, FeSV can enter cells of species not naturally infected.

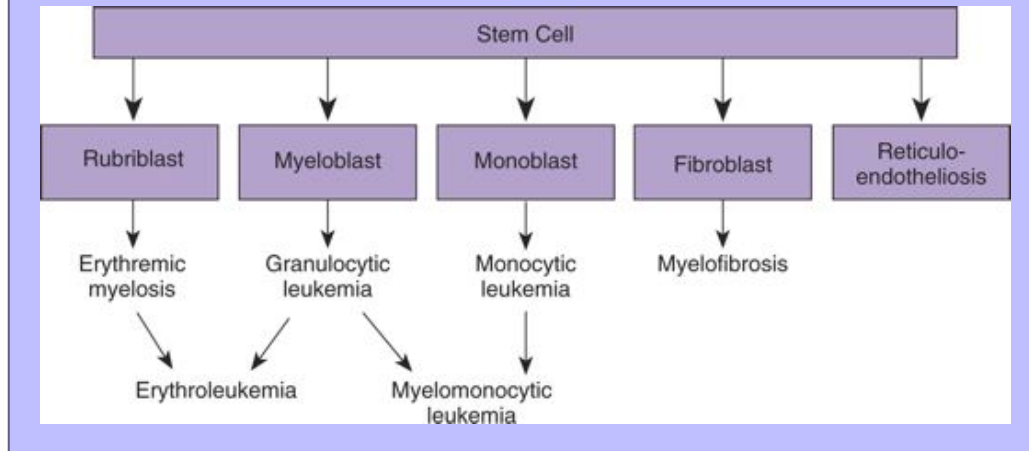

115

116

Infectious Diseases of the Dog and Cat, 3rd Edition

Experimental inoculation of FeSV has produced tumors in cats, rabbits, dogs, sheep, rats, and nonhuman primates.³⁰⁷ Many of these tumors regress spontaneously, even after reaching a large size.³⁸

Fig 13-10 Origin of cell lines in myeloproliferative disease. (Modified from Morrison JA. 2001. Erythemic myelosis. *Compend Cont Educ Pract Vet* 23: 880-885; with permission.) [Table 13-1](#) Summary of Genetic Map and Function of FeLV Proteins^a

Fibrosarcomas caused by various strains of FeSV tend to grow rapidly, often with multiple cutaneous or subcutaneous nodules that are locally invasive and metastasize to the lung and other sites. Solitary fibrosarcomas in old cats are not caused by FeSV. These tumors are slower growing, locally invasive, slower metastasizing, and occasionally curable by excision. The tumors are caused by the granulomatous inflammatory reaction at the injection site after inoculation of adjuvant-containing vaccines. It has been demonstrated that neither FeSV nor FeLV play any role in vaccine-induced sarcomas.⁶⁰

In addition to fibrosarcomas, FeSV has experimentally caused melanomas, showing that FeSV can transform cells of ectodermal as well as of mesodermal origin.³⁴ Intradermal or intraocular inoculation of FeSV into kittens produced melanomas in the skin or anterior chamber of the eye.³⁸ However, FeSV has not yet been associated with naturally occurring melanomas of cats.

Fibrosarcoma cells express FOCMA just as lymphoma cells do. Experimental infection with FeSV causes tumors that progress in some cats and regress in others. Those in which the tumors regress have high FOCMA antibody titers.

13.4.3.4

Other Tumors

Multiple *osteochondromas* (cartilaginous exostoses on flat bones) have been described with increased prevalence in FeLV-infected cats. Although histologically benign, they may cause significant morbidity if they occur in an area such as a vertebra and put pressure on the spinal cord or nerve roots. The pathogenesis of these tumors is unknown.^{195,250}

Infectious Diseases of the Dog and Cat, 3rd Edition

Spontaneous feline *olfactory neuroblastomas* are aggressive, histologically inhomogenous tumors of the tasting and smelling epithelium of nose and pharynx, and have high metastasis rates. Budding FeLV particles were found in the tumors and lymph node metastases, and FeLV PCR was positive in tumor tissue.²⁷⁸ Two of the three cats described had positive antigen test results. The exact role of FeLV in the genesis of these tumors is uncertain.

Cutaneous horns are a benign hyperplasia of keratinocytes that have been described in FeLV-infected cats.²⁴³ The exact role of FeLV in the pathogenesis is unclear.

Iris melanomas are *not* associated with retroviral infections as once believed. In one study, 3 of 18 eyes had positive test results for FeLV-FeSV proviral DNA.²⁹⁷ In another study, immunohistochemical staining and PCR did not reveal FeLV or FeSV in the ocular tissues of any cats with this disorder.⁴³

13.4.4 Nonneoplastic Hematologic Dysfunction

Hematopoietic disorders, particularly cytopenias caused by bone marrow suppression, are a common finding in cats infected with FeLV. According to past literature, anemia is a major nonneoplastic complication that occurs in a majority of symptomatic FeLV-infected cats. In turn, it has been cited that more than two thirds of all nonregenerative anemias in cats are the result of FeLV infection. Currently, as is the case with all FeLV-associated syndromes, this is clearly an overestimation because of the decrease in FeLV prevalence. Bone marrow suppression syndromes described in association with FeLV have included anemia (nonregenerative or regenerative), persistent, transient, or cyclic neutropenias, panleukopenia-like syndrome, platelet abnormalities (thrombocytopenia and platelet function abnormalities), and aplastic anemia (pancytopenia). For the majority of pathogenic mechanisms in which FeLV causes bone marrow suppression, active virus replication is necessary. However, it has been demonstrated that in some FeLV-negative cats, latent FeLV infection may be responsible for bone marrow suppression. Provirus may interrupt or inactivate cellular genes in the infected cells, or regulatory features of viral DNA may alter expression of neighboring genes. Additionally, cell function of latently infected myelomonocytic progenitor and stromal fibroblasts that provide bone marrow microenvironment may be altered. Alternatively, FeLV provirus may cause bone marrow disorders by inducing the expression of antigens on the cell surface, resulting in an immune-mediated destruction of the cell.

13.4.4.1 Anemia

Various causes of anemia associated with feline leukemia infection are summarized in [Table 13-4](#) and the following sections.

13.4.4.1.1 Hemolytic Anemia

Approximately 10% of FeLV-associated anemias are regenerative, indicated by a high reticulocyte count, high MCV, and presence of anisocytosis, nucleated erythrocytes, and polychromasia.²⁸³ They are caused by FeLV-induced immune-mediated hemolysis, secondary *Mycoplasma haemofelis* infection (hemobartonellosis; see [Chapter 31](#)), or hemorrhage from FeLV-induced thrombocytopenia. Clinical signs are lethargy, anorexia, depression, pale mucous membranes, icterus, dehydration, and splenomegaly associated with anemia. It is suspected that FeLV can induce an immune-mediated response leading to secondary autoimmune hemolytic anemia with positive Coombs' test, autoagglutination, and

116

118

Infectious Diseases of the Dog and Cat, 3rd Edition

spherocytosis. Hemotropic *Mycoplasma* organisms are not always observed on peripheral blood smears; however, diagnosis is possible with PCR techniques. Clinical manifestation of *M. haemofelis* infection is commonly found secondary to FeLV-induced immunosuppression (see [Chapter 31](#)).^{82,107} Regardless of the cause, regenerative FeLV anemias usually have a favorable response to treatment (see Therapy in this chapter).

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 13-4 Comparison of Hematologic Disorders Related to FeLV Infection

CAUSES	MECHANISM	HEMATOLOGIC FINDINGS AND TREATMENT
Regenerative Anemia		
Immune-mediated hemolysis	Virus-induced expression of foreign antigens on erythrocyte surface	<i>Findings:</i> Regenerative anemia (macrocytosis and reticulocytosis), variable icterus and hemoglobinemia, plasma proteins within reference ranges <i>Treatment:</i> Immunosuppression, which is generally effective
Hemotropic <i>Mycoplasma</i> infection (hemobartonellosis)	Virus-induced immunosuppression that allows hemopathogen proliferation	<i>Findings:</i> Regenerative anemia, variable icterus and hemoglobinemia, plasma proteins within reference ranges, organisms observed or PCR positive for <i>Mycoplasma hemofelis</i>
Blood loss from thrombocytopenia	Virus-induced suppression of platelet production by bone marrow	<i>Findings:</i> Regenerative anemia, thrombocytopenia (<50,000 platelets), low serum protein level <i>Treatment:</i> Transfusion and treatment of cause of thrombocytopenia
Nonregenerative Anemia		
Myelosuppression: pancytopenia	Virus-induced alteration of hematopoietic gene expression that affects early marrow precursor; affects multiple cell lines	<i>Findings:</i> Nonregenerative anemia, thrombocytopenia, leukopenia, often FeLV positive; may note more advanced myeloid effect of subgroup C infection <i>Treatment:</i> Poor response to bone marrow stimulants or immunosuppressive therapy
Myelodestruction: panleukopenia-like syndrome	Virus-induced replication and destruction of myeloid and lymphoid precursors and intestinal epithelium	<i>Findings:</i> Pancytopenia, leukopenia, vomiting, diarrhea <i>Treatment:</i> Poor response to bone marrow stimulation or treatment of overwhelming sepsis
Myelosuppression: pure erythrocyte aplasia	Virus-induced alteration of hematopoietic gene expression that is selective for red blood cell precursors	<i>Findings:</i> Nonregenerative anemia, other cell lines within reference ranges; if viral-induced, often subgroup C infection <i>Treatment:</i> Responsive to immunosuppression
Anemia of chronic inflammatory disease	Virus or secondary bacterial stimulation of inflammatory cytokines that sequester iron	<i>Findings:</i> Nonregenerative anemia, usually with normocytosis <i>Treatment:</i> Removal or treatment of coexisting inflammatory disease if present; no response to erythropoietin
Anemia of chronic disease	Virus-induced neoplastic disease or immunosuppression-induced secondary debilitating illness	<i>Findings:</i> Nonregenerative normochromic, normocytic anemia <i>Treatment:</i> Treatment of secondary disease
Myeloproliferative disease: erythroleukemia (erythremic myelosis), reticuloendotheliosis, various leukemias	Virus-induced neoplastic transformation of erythrocyte precursors, leukocyte precursors or stem cells, or all of these	<i>Findings:</i> Nonregenerative anemia with macrocytosis and variable numbers and types of nucleated erythrocytes; often FeLV positive <i>Treatment:</i> Poor response to cytotoxic chemotherapy

Infectious Diseases of the Dog and Cat, 3rd Edition

Myelophthisis: lymphoma, lymphocytic or granulocytic leukemia, or other bone marrow proliferative syndrome	Virus-induced neoplastic process that crowds bone marrow, causing suppression of erythropoiesis	<i>Findings:</i> Nonregenerative anemia and may affect other cell lines; may detect abnormal nucleated cells in peripheral blood <i>Treatment:</i> Cytotoxic chemotherapy
Pure Leukocyte and Platelet Abnormalities		
Leukemia	Virus-induced neoplastic process involving leukocytes of myeloid or lymphoid cell lines	<i>Findings:</i> Nonregenerative anemia with large increase in leukocyte or precursors in peripheral blood; often FeLV positive <i>Treatment:</i> Poor response to chemotherapy
Neutropenia	Virus-induced immune-mediated or idiopathic neutropenia, often follows stressful episode	<i>Findings:</i> Pure neutropenia, usually without a left shift; normal findings with all other cell lines <i>Treatment:</i> Glucocorticoid therapy
Thrombocytopenia	Virus-induced immune-mediated thrombocytopenia	<i>Findings:</i> Pure thrombocytopenia <i>Treatment:</i> Glucocorticoid therapy
Thrombocytosis	Virus-induced neoplastic proliferation of megakaryocytes	<i>Findings:</i> Marked thrombocytosis (>600,000 platelets) <i>Treatment:</i> Poor response to cytotoxic chemotherapy

13.4.4.1.2

Anemia from Inflammatory Cytokines

Most FeLV-associated anemias are nonregenerative and caused by the bone marrow suppressive effect of the virus, resulting from primary infection of hematopoietic stem cells and infection of stroma cells that constitute the supporting environment for hematopoietic cells. In vitro exposure of normal feline bone marrow to some strains of FeLV causes suppression of erythropoiesis.³⁸ The exact mechanisms of the way FeLV causes this bone marrow suppression is not completely known; however, these cats have normocytosis or macrocytosis without evidence of reticulocyte response. Whenever macrocytic anemia (MCV > 60 fl) occurs in a cat in absence of reticulocytosis, FeLV infection should be suspected. These cats do not have folate or vitamin B₁₂ deficiencies. Iron is present in macrophages but not erythrocyte precursors; however, iron kinetics are normal. This anemia contrasts with anemia of chronic inflammatory disease caused by bacterial infection in which iron sequestration causes microcytosis. As in many FeLV-associated nonregenerative anemias, suppression of erythropoiesis results in markedly increased serum erythropoietin levels.

Macrocytosis in chronic FeLV infection is believed to represent an FeLV-induced defect by skipped mitoses in cell division during erythropoiesis. It is usually associated with normocellular bone marrow; hypocellularity may be found with an increased myeloid-erythroid ratio.^{38,184}

13.4.4.1.3

Pure Erythrocyte Aplasia

Severe isolated anemia (HCT <15%) without regeneration (pure erythrocyte aplasia) suggests infection with FeLV-C.²⁸³ FeLV-C causes pure erythrocyte aplasia that likely occurs through interactions of the cell surface receptor.^{254,302} The cell-surface receptor interactions block the differentiation of erythroid progenitors between burst-forming units and colony-forming units by interfering with signal transduction

Infectious Diseases of the Dog and Cat, 3rd Edition

pathways essential for erythropoiesis.^{253,283,329} Bone marrow examination shows an almost complete lack of erythroid precursors with normal myeloid and megakaryocytic precursors. In this case, serum erythropoietin levels are also markedly increased, indicating that anemia is not caused by an erythropoietin deficiency.¹⁸⁴ It is not a neoplastic or immune-mediated process because it is resistant to therapy. Treatment with immunosuppressive drugs (glucocorticoids and cyclophosphamide or cyclosporin) resulted in resolution of anemia within 3 to 5 weeks; however, relapse occurred when treatment was discontinued.²⁹⁹

13.4.4.1.4

Pancytopenia

Severe pancytopenia or aplastic anemia may be present in FeLV-infected cats and involves all cell lines. Bone marrow cytology is usually hypocellular or may show necrosis.²⁸⁷ Cats with pancytopenia often test positive for FeLV. The virus probably affects precursors near the stem cell level. In some cats, cyclic hematopoiesis with periodic fluctuation in reticulocytes, granulocytes, and platelets may be noted. Alteration of accessory cells within the bone marrow microenvironment providing the structural framework, cytoadhesive molecules, and growth-regulatory cytokines necessary for normal hematopoiesis may be the cause. FeLV can affect bone marrow accessory cell viability, growth, production, or all of these of hematopoietic progenitor growth-regulating substances by altering cytokine messenger RNA levels in general and strain-specific patterns.¹⁸⁶⁻¹⁸⁸ During a bone marrow evaluation, few if any precursors may be found with cytologic methods, and core biopsy specimens may be needed. The aplastic marrow may represent a more advanced stage of myelosuppression than pure erythrocyte aplasia. Bone marrow transplantation or immunosuppression has been used to treat people; however, it has not been successful in cats.

118

13.4.4.1.5

Anemia of Chronic Disease

In addition to the direct effect of the virus on erythropoiesis, other factors can cause nonregenerative anemia in FeLV-infected cats. Lymphoma or leukemia, as well as secondary infectious diseases such as systemic mycosis or mycobacteriosis, may cause severe anemia by “crowding out” bone marrow cells. Some FeLV-infected cats develop a mild anemia (HCT of 20% to 30%) referred to as *anemia of chronic disease* caused by systemic infection or stress. The HCT often increases spontaneously if the underlying problem is treated successfully, even if the cat continues to test positive for FeLV.

119

13.4.4.2

Platelet Abnormalities

Thrombocytopenia may occur secondary to decreased platelet production from FeLV-induced bone marrow suppression or leukemic infiltration. Platelet abnormalities in FeLV-infected cats may involve changes in quantity, size, shape, and function. The lifespan of platelets is shortened in some FeLV-infected cats. Platelets harbor FeLV proteins as a result of infection, and giant platelets and thrombocytosis have been observed in some persistently viremic cats.²⁸³ In addition, megakaryocytes, the marrow precursors of blood platelets, are frequent targets of productive FeLV infection. Immune-mediated thrombocytopenia, which rarely occurs as a single disease entity in cats, often accompanies immune-mediated hemolytic anemia in cats with underlying FeLV infection. Platelet abnormalities may result in bleeding tendencies.

Infectious Diseases of the Dog and Cat, 3rd Edition

13.4.4.3 Leukocyte Abnormalities

FeLV-infected cats may have reductions in granulocyte or lymphocyte counts. Lymphopenia is primarily a result of direct replication of the virus in lymphocytes. Neutropenia is also common²³ and generally occurs alone or in conjunction with other cytopenias. In some cases, myeloid hypoplasia of all granulocytic stages is observed, suggesting direct cytopathic infection of neutrophil precursors by FeLV. In some neutropenic FeLV-infected cats, an arrest in bone marrow maturation may occur at the myelocyte and metamyelocyte stages.

13.4.4.4 Glucocorticoid-Responsive Neutropenia

It has been hypothesized that an immune-mediated mechanism is responsible for cases in which neutrophil counts recover with glucocorticoid treatment. Cyclic neutropenia also has been reported in cats with FeLV infection and usually is effectively treated with glucocorticoids, suggesting that immune-mediated mechanisms are likely to be involved in this syndrome. The cycles are usually regular, ranging from 8 to 14 days. Bone marrow cytology during the neutropenic phase may indicate either granulocytic hyperplasia or hypoplasia, with a disproportionate number of cells in the promyelocytic stage. Similar bone marrow findings could result from inflammatory or immune-mediated diseases, myelodysplasia, or granulocytic leukemia. Cats with neutropenia usually have recurrent fever or persistent bacterial infections. Some cats show persistent gingivitis, occasionally without the usual signs of inflammation such as hyperemia and purulent exudate because granulocytes are necessary for the inflammatory response.³⁸

13.4.4.5 Feline Panleukopenia-Like Syndrome

Feline panleukopenia-like syndrome (FPLS), also known as *myeloblastopenia*, consists of severe leukopenia (<3000 cells/ μ l) with enteritis and destruction of intestinal crypt epithelium that mimics feline panleukopenia (FPV) infection (see [Chapter 10](#)). Unlike panleukopenia, anemia is also usually present in FeLV-infected cats. Recently, FPV antigen has been demonstrated by direct FA in intestinal sections of cats that died with this syndrome after being experimentally infected with FeLV.¹⁹⁶ FPV was also demonstrated by electron microscopy (EM) despite negative ELISA test results for FPV. It appears that this syndrome is actually not caused by FeLV itself as previously thought but by coinfection with FPV. FPLS has many clinical similarities to FeLV-associated enteritis (FAE) and FeLV-FAIDS, which results in replication in many lymphoid, myeloid, and intestinal cells.

13.4.5 Immune Suppression

Diseases associated with immune suppression account for a large portion of the morbidity and mortality of FeLV-infected cats.^{53,235,241} FeLV-infected cats are predisposed to secondary infections primarily because of immune suppression similar to that in human patients infected with the human immunodeficiency virus (HIV), but it is more severe than the immune suppression caused by HIV infection. Evaluation of the immune status of FeLV-infected cats is hampered by the lack of well-characterized tests. Thus clinicians primarily depend on CBC and clinical presentation for diagnosing immune dysfunction. Some commercial laboratories offer selective counts of CD4+ and CD8+ cells, but the value of these parameters rarely has been evaluated in naturally infected cats (see [Appendix 5](#)).¹²⁷

Infectious Diseases of the Dog and Cat, 3rd Edition

The exact mechanisms of the way the virus damages the immune system is poorly understood, as is why different animals have such varying degrees of immune suppression in response to the same virus. Immune suppression is occasionally associated with unintegrated viral DNA from replication-defective viral variants.²³⁸ These pathogenic immunosuppressive variants, such as FeLV subgroup T, require a membrane-spanning receptor molecule (Pit1) and a second coreceptor protein (FeLIX) to infect T lymphocytes.¹⁷⁸ The latter protein is an endogenously expressed protein encoded by an endogenous provirus arising from FeLV subgroup A, which is similar to the FeLV receptor-binding protein of FeLV subgroup B.¹⁵ Affected cats may develop thymic atrophy and depletion of lymph node paracortical zones following infection. Lymphopenia and neutropenia are common. In addition, neutrophils of viremic cats have decreased chemotactic and phagocytic function compared with those of normal cats. This abnormality persists for an unknown period, even if viremia is transient. In some cats, lymphopenia may be characterized by preferential loss of CD4+ helper T cells, resulting in an inverted CD4+-CD8+ ratio (which is more typical of FIV infection).²⁵³ More commonly, substantial losses of helper cells and cytotoxic suppressor cells (CD8+ cells) occurs.¹²⁷ Many immune function tests of naturally FeLV-infected cats have been reported to be abnormal, including poor response to T-cell mitogens, prolonged allograft reaction, reduced immunoglobulin production, depressed neutrophil function, and complement depletion. Interleukin-2 (IL-2) and interleukin-4 (IL-4) are decreased in some cats.^{184,187} However, studies disagree on whether interferon- γ (IFN- γ) is deficient or increased. FeLV does not appear to suppress interleukin-1 (IL-1) production from infected macrophages. Increased tumor necrosis factor- α (TNF- α) has been observed in serum of infected cats and infected cells in culture. Although each cytokine plays a vital role in the generation of a healthy immune response, the excess production of certain cytokines such as TNF- α can also cause illness.

Primary and secondary humoral antibody responses to specific antigens are delayed and decreased in FeLV-infected cats. In vaccination studies, FeLV-infected cats have not been consistently able to mount an adequate immune response to vaccines such as rabies. Therefore protection in an FeLV-infected cat after vaccination is not comparable to that in a healthy cat, and more frequent vaccinations have to be considered. T cells of FeLV-infected cats produce significantly lower levels of B-cell stimulatory factors than do those of normal cats.⁵³ This defect becomes progressively more severe over time. However, when B cells of FeLV-infected cats are stimulated *in vitro* by uninfected T cells, their function in FeLV-infected cats is normal. Although humoral immunity to specific stimulation decreases, nonspecific increases of IgG and IgM have been noted.

Many reports have been made of FeLV-infected cats having concurrent bacterial, viral, protozoal, and fungal infections, but few studies exist proving these cats have a higher rate of infection than do FeLV-negative cats or that they have a less favorable response to therapy. Thus although FeLV is well known to suppress immune function, it should not be assumed that all concurrent infections are a result of FeLV infection. Secondary infections most commonly associated with FeLV include FIP, hemobartonellosis, coccidiosis, and upper respiratory infections.^{184,256,257} From a clinical standpoint, it is important to realize that many of these secondary diseases are treatable.

13.4.6 Skin Disease

Infections associated with dermatologic conditions are usually caused by immunodeficiency.²⁴⁷ Retrovirus-infected cats have a greater diversity of cutaneous and mucosal microflora compared with uninfected cats.²⁸⁸ Traumatic injuries are complicated by secondary bacterial infections or abscesses. Otitis

Infectious Diseases of the Dog and Cat, 3rd Edition

externa and miliar dermatitis may develop from ectoparasites or allergies but persist because of secondary bacterial infections.

13.4.7 Immune-Mediated Diseases

In addition to immune suppression, FeLV-infected cats are subject to various immune-mediated diseases caused by an overactive or dysregulated immune response to the virus. FeLV-associated immune-mediated diseases including autoimmune hemolytic anemia, glomerulonephritis,⁶ uveitis with immune complex deposition in iris and ciliary body,²¹ and polyarthritis. Chronic progressive polyarthritis can be triggered by FeLV; in about 20% of cats with polyarthritis, FeLV seems to be an associated agent.²⁴³

The loss of T-suppressor cell activity and the formation of antigen-antibody complexes contribute to these immune-mediated diseases.²⁴² Measurement of FeLV antigens has shown that cats with glomerulonephritis have more circulating viral proteins than do other FeLV-infected cats. Proteins that can lead to antigen-antibody complex formation include not only whole virus particles but also free gp70, p27, or p15E.^{48,313} Circulating immune complexes have also been observed after experimental treatment of persistent viremia with monoclonal antibodies to gp70 and in studies of inoculation of complement-depleting factors.

13.4.8 Other Syndromes

13.4.8.1 FeLV-Associated Enteritis (FAE)

FAE has been observed in cats with chronic FeLV viremia.^{167,168} Clinical GI signs most frequently observed were hemorrhagic diarrhea, vomiting, oral ulceration or gingivitis, anorexia, and weight loss. Other systemic signs were nonspecific or included rhinitis, dyspnea, or apathy. Cats often die or are euthanized for an illness other than the one affecting the GI tract. FAE is associated with degeneration of intestinal epithelial cells and crypt necrosis, symptoms that are similar to those caused by FPV infection. Unlike cats with FPV infection, cats with FAE have normal or hyperplastic intestinal lymphoid tissue and no lymphoid depletion. FAE differs in a similar way from the panleukopenia-like syndrome reported with coinfection of FPV and FeLV.¹⁹⁶ In contrast to FeLV-infected cats without enteritis, those with FAE have large quantities of FeLV gp70 and p15E proteins in their intestinal crypt epithelial cells.

13.4.8.2 FeLV-Feline Acquired Immunodeficiency Syndrome

Enteritis with proliferation of FeLV-antigen within the enterocytes is also seen when cats have been experimentally infected with FeLV-FAIDS variants of FeLV. FAIDS begins with a prodromal period of lymphoid hyperplasia associated with viral replication in lymphoid follicles, followed by lymphoid depletion associated with extinction of viral replication. When affected by FAIDS, cats develop enterocolitis with crypt necrosis and villous atrophy.¹³³ Intractable diarrhea and weight loss are associated with an immunodeficiency syndrome characterized by lymphopenia, suppressed lymphocyte stimulation, impaired cutaneous allograft rejection, hypogammaglobulinemia, and opportunistic infections such as respiratory disease or stomatitis. These observations suggest that the development of FAE may be FeLV-strain dependent.

Infectious Diseases of the Dog and Cat, 3rd Edition

13.4.8.3 Reproductive Disorders

FeLV-infected queens can transmit the virus transplacentally. Reproductive failure in the form of fetal resorption, abortion, and neonatal death is common if in utero infection occurs. The apparent infertility might actually be early resorption of fetuses. Abortions usually occur late in gestation, with expulsion of normal-appearing fetuses. Bacterial endometritis may accompany these abortions, particularly in cats with leukopenia.³⁸

13.4.8.4 Fading Kitten Syndrome

Kittens born to an infected queen may become exposed to FeLV transplacentally, but heavy exposure also occurs at birth and throughout the nursing period. Some kittens become immune, but most become viremic and die at an early age of the so-called fading kitten syndrome, characterized by failure to nurse, dehydration, hypothermia, and thymic atrophy within the first 2 weeks of life.¹⁸⁴

13.4.8.5 Neuronopathy

Neurologic dysfunction has been described in FeLV-infected cats. Although most neurologic signs seen in FeLV-infected cats are caused by lymphoma and lymphocytic infiltrations in brain or spinal cord leading to compression, in some cases no tumor is detectable with diagnostic imaging methods or by necropsy. Anisocoria, mydriasis, central blindness, or Horner's syndrome have been seen without morphologic changes. In some regions (such as the southeastern United States), urinary incontinence caused by neuropathies in FeLV-infected cats has been described.²⁷ Direct neurotoxic effects of FeLV have been discussed as pathogenetic mechanisms. The ability of the HIV envelope glycoprotein gp120 to produce increased intracellular free calcium leading to neuronal death has been observed in infected humans. Envelope glycoproteins of other retroviruses including FeLV may have similar calcium-increasing effects. A polypeptide of the FeLV envelope was found to cause dose-dependent neurotoxicity associated with alterations in intracellular calcium ion concentration, neuronal survival, and neurite outgrowth. The polypeptide from an FeLV-C strain was significantly more neurotoxic than the same peptide derived from an FeLV-A strain.^{69,217}

Clinical signs in 16 cats with chronic FeLV infection consisted of abnormal vocalization, hyperesthesia, and paresis progressing to paralysis. Some cats developed anisocoria or urinary incontinence during the course of their illness. Others had concurrent FeLV-related illnesses such as myelodysplastic disease. The clinical course of affected cats involved gradually progressive neurologic dysfunction. Microscopically, white-matter degeneration with dilation of myelin sheaths and swollen axons was identified in the spinal cord and brain stem of affected animals.²⁷ Immunohistochemical staining of affected tissues revealed consistent expression of FeLV p27 antigens in neurons, endothelial cells, and glial cells. Furthermore, proviral DNA was amplified from multiple sections of spinal cord.²⁷ These findings suggest that in some FeLV-infected cats, the virus may cytopathically affect cells in the CNS.

120

121

Infectious Diseases of the Dog and Cat, 3rd Edition

13.4.8.6 Hepatopathy

Feline leukemia was associated with icterus and various inflammatory and degenerative liver diseases.^{256,257} Hepatic lipidosis is a major complicating factor that can explain some of these cases; however, unexplained focal liver necrosis was also observed.

13.5 DIAGNOSIS

13.5.1 FeLV Testing

13.5.1.1 General Guidelines

Testing for FeLV and consequently preventing exposure of healthy cats to FeLV-infected cats is the most effective way to prevent the spread of infection. Testing to identify infected cats is the mainstay of preventing transmission, and FeLV vaccination should not be considered a substitute for testing. The American Association of Feline Practitioners (AAFP) in conjunction with the Academy of Feline Medicine (AFM) has established guidelines for testing cats for FeLV ([Table 13-5](#)).¹⁸² All sick cats (regardless of any prior test results), new cats being brought into a household, cats with unknown FeLV status, cats exposed to the virus, and cats at high risk of infection should be tested. Identifying infected cats before other cats are exposed provides the best opportunity to prevent spread of the disease. The AAFP also recommends retesting all cats that show clinical signs because symptoms might be associated with an underlying infection, and a positive FeLV test result significantly alters prognosis and influences the choice of treatment. In addition, all cats should be tested before receiving a vaccination. Cats can be tested at any age. Because the screening tests detect antigen and not antibodies, neither maternal antibodies nor antibodies from vaccination or previous viral exposure interfere with testing. To completely eliminate any risk to an established household when bringing in a new cat, a follow-up test should be performed at least 90 days after the initial test or after a possible exposure to FeLV because cats may be in the early stage of infection at the time of the first test; the test should be performed before bringing the cat into the home.¹⁸² General principles for FeLV testing are outlined in [Table 13-6](#).

13.5.1.2 Methodology

Routine screening for FeLV became available with the development of direct FA testing for virus in 1973.¹⁰⁰ When ELISA methods were developed a few years later, clinicians gained the ability to perform rapid and reliable in-house testing. In 1979 the first commercial ELISA came on the market. It was very sensitive in detecting low concentrations of antigen in serum of infected cats,¹⁹³ but it was not very specific. Lutz and others¹⁹⁸³ developed an ELISA containing monoclonal antibodies against three different epitopes of p27 antigen that do not cross-react with proteins of other retroviruses, so the resulting test was more specific. Today, several ELISA and other immunochromatographic assays (ICGAs) or rapid immunomigration (RIM) assays are in use. These newly developed, membrane-fixed ICGAs are based on a principle similar to ELISA in which color is generated as a result of an immunologic reaction, but the assays have a slightly different design than ELISA. These tests are available for use as rapid in-house tests.²⁶⁴

Infectious Diseases of the Dog and Cat, 3rd Edition

FA and ELISA/ICGA have remained the mainstay of clinical testing.¹⁰³ FA and ELISA/ICGA detect FeLV core protein p27, which is produced abundantly in most infected cats; however, ELISA/ICGA detects free soluble FeLV p27 in plasma or serum, whereas direct FA detects p27 antigen within the cytoplasm of infected blood cells.

Table 13-5 Recommendations for FeLV Testing^a

General Considerations

Indications for Testing

General health screening, at least once for all cats

Illness, regardless of prior negative test results or vaccination

Disorders associated with FeLV infection (hematologic, neoplastic, or immunosuppressive)

Adoption (regardless of age): prevents exposure, serves as baseline for future problems

Potential exposure: test at least 28 days from exposure or retest again

Test Selection

ELISA for screening: better on serum or plasma than whole blood

Saliva or tears testing: highly inaccurate and should not be used

Direct FA tests for cell-associated antigen: usually present with high viral loads

PCR: detects latent infection, only indicated if other tests results negative, has false-negative results, widely varied and nonstandardized methods, best on bone marrow

Direct Fluorescent Antibody Testing

Interpretation

Not 100% accurate test

Positive result: (1) only indicates viral infection and does not indicate current illness, (2) should be confirmed by another method or test system, (3) has no bearing on predicting morbidity or mortality

Discordant Results

Defined as conflicting results with various test methods

If two ELISA methods differ: perform direct FA

Positive ELISA and direct FA: suggest persistent viremia and true positive status

Positive ELISA and negative direct FA: suggest repeated assay in 6 to 8 weeks

Recommend annual retesting after any discordant test result until agreement

Negative FeLV results in young (younger than 12 weeks old) kittens: requires retesting in 4 to 6 weeks

Infectious Diseases of the Dog and Cat, 3rd Edition

- a Modified from American Association of Feline Practitioners and Academy of Feline Medicine: Advisory panel report on feline retrovirus testing and management, 2001.¹⁸³

Some ELISAs have been developed for tear and saliva samples in place of blood.¹¹⁶ In general, these tests are not as accurate as blood testing because viral shedding is intermittent and the tests are subject to more technical errors^{12,116}; they are not recommended because the consequences for false-negative and false-positive results can be disastrous for individual cats or multiple-cat populations.¹⁸⁴

13.5.1.2.1

ELISA/ICGA

ELISA/ICGA methods detect free soluble FeLV-p27 in plasma or serum and are the recommended screening tests. A positive whole blood, serum, or plasma ELISA/ICGA result means that the cat is viremic. These tests become positive in the first phase of viremia within the first weeks after infection, before the bone marrow is affected. Thus positive results may be reflective of transient or persistent viremia.¹⁶ In experimental settings, most cats have positive results within 28 days after exposure.¹⁵⁰

Table 13-6 Summary of General Principles for FeLV Testing¹⁸²

1. All cats should be tested for infection with FeLV.
2. FeLV-infected cats may live for many years. A decision for euthanasia should never be made solely on the basis of whether a cat is infected.
3. A confirmed positive test result should be considered only an indication of retrovirus infection, not clinical disease. Disease in FeLV-infected cats may not necessarily be a result of retrovirus infection.
4. No test is 100% accurate under all conditions, therefore all results should be interpreted in light of the patient's health and prior exposure to FeLV.

Even the new improved ELISA/ICGAs can have false-positive results for numerous reasons. They can be performed on serum, plasma, or whole blood. In some studies, higher rates of false-positive results were recorded when whole blood samples were used, particularly when the samples were hemolyzed. Thus ELISA should only be performed with plasma or serum. However, the newer ICGA contains a filtering membrane, so whole blood and serum and plasma do not produce different results.¹¹⁵ False-positive results were also a problem in some test systems that used murine-derived reagents in cats that had naturally occurring antimouse antibodies,¹⁹³ which are present in about 1% to 2% of all cats. Newer tests have solved that problem by including additional control steps. Technical and user errors contribute to false-positive results as well.^{103,198} These errors are most likely to occur during the washing steps of kits using microwell or plate formats. Membrane-based tests eliminate separate washing steps and include positive and negative controls for each test sample. Because many new ELISA/ICGA tests have come on the market, especially in Europe, comparative studies are necessary. In two studies, specificities of commercially available ELISA/ICGA were comparable, and positive predictive values (PPVs) of most tests were about 80%.^{88,115} False-positive results are more important today because the decreasing prevalence of FeLV is leading to lower predictive values of the available tests. The reliability of a test (its predictive value) depends on the rate of infection within a cat population. For example, FeLV is present in most cats with thymic lymphoma, so a positive test result is likely to be accurate in this situation. In a lower-risk population, such as a closed cattery known to be free of FeLV, a positive test should be viewed

Infectious Diseases of the Dog and Cat, 3rd Edition

with more suspicion, and confirmatory tests should be performed.¹⁸⁴ False-negative results are rare in all tests and PPVs are very high (close to 99%).^{88,115} Therefore positive results have to be interpreted carefully, and confirmatory tests have to be considered after a positive result. If confirmatory tests (e.g., virus isolation, PCR) are not available or too expensive to perform, at the very least a second in-house test should be performed to rule out a false-positive result. If the second test is positive, it significantly increases the predictive value. Retesting should be performed immediately and has nothing to do with the different stages of viremia; it is only used to compensate for the weaknesses of the test systems. Confirmation tests should at least be performed in low-risk cats before any decisions are made that have major consequences for cat and owner.

13.5.1.2.2

Direct Fluorescent Antibody Testing

Direct FA was the first method developed for routine testing for FeLV infection.¹⁰⁰ Direct FA detects cell-associated p27 antigen primarily in neutrophils and platelets in the peripheral blood and only becomes positive after infection of the bone marrow (after at least 3 weeks of viremia). Positive results are likely to reflect persistent viremia,^{97,99,184} therefore direct FA is not recommended as a screening test because cats that are in the first weeks of viremia and still infectious to others are not detected. Direct FA can be used for prognostic reasons or to confirm positive and suspicious samples. Because direct FA requires special processing and fluorescent microscopy, it must be performed by a qualified reference laboratory (see [Appendix 5](#)). Generally, two or more quality blood smears should be air dried and mailed, unfixed, to the laboratory. Because the antigen is present at highest concentrations in neutrophils and platelets, false-negative results may occur when these two cell lines are deficient. False-positive results occur when smears are too thick, background fluorescence is high, and the test is prepared and interpreted by inexperienced personnel. Using anticoagulated blood rather than fresh blood for making smears can also cause errors.^{147,324} Variations in quality control among facilities has been reported, and careful attention should be paid to the selection of the reference laboratory.¹⁸⁴

13.5.1.2.3

Sequential Testing

ELISA/ICGA and direct FA are useful clinically. Cats that only have positive ELISA/ICGA results are more likely to convert and have negative results than are cats with positive results on ELISA/ICGA and direct FA. To distinguish between transient and persistent viremia, cats should be retested with ELISA 6 weeks after the first positive test result. If a cat still has a positive result, it should be retested after another 10 weeks. If at this time the cat still has a positive result, it is most likely persistently viremic and will have positive results for the rest of its life. Another rapid method without the retesting delay is to immediately test a cat with a positive ELISA/ICGA result with direct FA. If the direct FA result is positive, the likelihood of a transient viremia is small. Only 3% to 9% of cats with positive direct FA results have a transient viremia.^{96,103,150,154,197} A small number of cats with discordant test results that develop persistently ELISA-positive and direct FA-negative results may have focal infections that are kept localized by their immune systems.¹⁵⁴ A negative ELISA result but positive direct FA result is always a false result—either a false-negative ELISA result (which is very unlikely) or a false-positive direct FA result.

Infectious Diseases of the Dog and Cat, 3rd Edition

13.5.1.3 Virus Isolation

The virus isolation test is the test that was originally developed to identify FeLV-infected cats.^{51,151} It is not practicable for routine diagnosis because it is difficult and time consuming to perform and requires special facilities. It can be used for the confirmation of positive test results and suspicious samples.

13.5.1.4 Nucleic Acid Detection

PCR has been adapted to clinical use for the diagnosis of FeLV infection. However, current reagents and testing protocols are neither standardized nor validated.³³⁴ This test differs from direct FA and ELISA/ICGA methods in that it does not detect viral antigen (protein) but rather detects viral nucleic acid sequences (RNA or proviral DNA). It is sensitive because the process involves amplification of FeLV sequences to enhance detection. PCR must be performed by well-equipped and well-trained laboratories because minor alterations in sample handling can destroy the delicate nucleic acid material or introduce minute amounts of cross-contamination, leading to either false-negative or false-positive results, respectively (see [Appendix 5](#)).¹⁸⁴ In addition, PCR is highly strain specific. As a retrovirus, mutations in FeLV occur naturally. Minor strain variations may prevent binding of the primers, a step necessary to amplify the viral genome. Cats infected with mutated FeLV react negatively with a specific PCR. A negative result does not necessarily mean they are uninfected. PCR is only diagnostic if it has a positive result and is performed by a reputable laboratory so that contamination can be excluded. With this in mind, PCR has greatly enhanced the possibilities to detect FeLV infection in blood, cultures, solid tissue, and fixed specimens. Most FeLV-PCR tests detect proviral DNA, the viral genome sequence that is integrated into the host genome. The main indications for PCR are the suspicion of a latent infection in cats with lymphomas, chronically inflamed oral gingival lesions, and bone marrow suppressive syndromes.^{118,142,314} In latent infection, no or minimal replication virus is present, thus tests such as ELISA that detect viral antigen are negative. Using quantitative PCR, viral loads in experimentally infected cats with negative ELISA test results (i.e., that were latently infected) that mount an effective immune response were much lower (300-fold less) than in cats with positive ELISA test results (i.e., that were transiently or persistently viremic).¹²⁹ Furthermore viral antigen (as detected by ELISA) is often not produced because of host immunity. However, proviral DNA may be integrated in the cellular genome and can be detected by PCR. PCR of peripheral blood may not yield more accurate results than ELISA testing,^{144,219} probably because of the low levels of viral genome present in latently infected cats and the difficulty associated with extracting nucleic acid from whole blood. However, using nested and real-time quantitative PCR, proviral genome could be detected in 10% of experimentally and naturally exposed cats with negative ELISA test results.¹²⁹ PCR of bone marrow samples in cats with myelosuppression and of tumor tissue samples from cats with lymphoma have demonstrated in latent FeLV infection in FeLV-antigen-negative cats.¹⁴² PCR was also better than immunohistochemical methods in detecting virus in lymphomas.^{142,144} Positive PCR results on peripheral blood from cats with lymphosarcoma were low (2%), whereas those from cats with corresponding lymphogenous tumors were much higher (26%).⁸¹ Rates of detection are similarly greater on bone marrow versus blood from latently infected cats that test negative by other methods. PCR may also be useful in determining the true status of cats with discordant results from other testing techniques. Ideally, samples should be taken from bone marrow, lymph node aspirates, or neoplasms rather than peripheral blood. The combination of routine screening testing combined with confirmatory tests accurately determines the FeLV infection status of most cats. However, some animals have repeatedly discordant results. Presently, approximately 10% of cats

Infectious Diseases of the Dog and Cat, 3rd Edition

suspected to be FeLV infected that have antigen-negative blood results have been found by PCR on blood or bone marrow to latently harbor FeLV. Improvements in PCR extraction, methods, and primer selection may improve its level of detection in the future.

13.6 THERAPY

Despite the fact that persistent FeLV viremia is associated with a decreased life expectancy, many owners elect to provide treatment for the myriad clinical syndromes that accompany infection. Although some older studies suggested that FeLV-infected cats only live a maximum of 3 years after diagnosis, the studies involved group-housed cats in multiple-cat, FeLV-endemic environments. With proper care, FeLV-infected cats may live many more than 3 years and in fact may die at an older age from causes completely unrelated to their retroviral infection. As mentioned, decisions about treatment or euthanasia should never be based solely on the presence of FeLV infection. It is important to realize that FeLV-infected cats are subject to the same diseases that befall uninfected cats, and the mere presence of an FeLV-related disease may or may not be caused by FeLV.

13.6.1 Management of FeLV-Infected Cats

13.6.1.1 FeLV-Infected Households

Shedding of virus generally occurs through salivary glands, and cat to cat transmission can occur by allogrooming and sharing of food and water bowls and litter boxes. In a household with an FeLV-infected cat, all cats should be tested so that their status is known. If one or more FeLV-positive cats are identified in an otherwise negative household, the owner must be informed of the potential danger to other cats in the house. They should be told that the best method of preventing the spread of infection is to isolate the infected individuals in other rooms to keep the infected cats from interacting with other housemates. The risk of transmission is not very high because the cats that have lived together with the FeLV-shedding cats have already been infected and are more likely to be immune to new infection. However, studies in cluster households have shown that virus neutralization is not lifelong, therefore a previously immune cat can become viremic. In a household with few cats, an owner may elect to keep all the cats. The risk of infection in adult FeLV-negative cats is approximately 10% to 15% if they have lived with a viremic cat for more than several months.³⁵ If owners refuse to separate housemates, the uninfected cats should receive an FeLV vaccination in an attempt to enhance their natural level of immunity in this environment of high viral exposure. However, vaccination does not provide high levels of protection under these circumstances. If the household is closed to new cats, the FeLV-negative cats will tend to outlive the infected cats, so after months or years all remaining cats will be immune.

13.6.1.2 Individual Cats

FeLV-infected cats should be confined indoors not only to prevent spread to other cats in the neighborhood but also to protect the vulnerable immunosuppressed cats from other infectious agents carried by other animals. Good nutrition and husbandry are essential to maintaining good health. FeLV-infected cats should be fed a high-quality, commercial feline diet. Raw meat, eggs, and unpasteurized milk should be avoided because the risk of acquiring foodborne bacterial or parasitic infections is greater in immunosuppressed individuals.¹⁸²

Wellness visits to the veterinary clinic should occur at least semiannually to promptly detect changes in health status. A detailed history should be obtained to assist the veterinarian in identifying possible problems

Infectious Diseases of the Dog and Cat, 3rd Edition

requiring more intensive investigation. A thorough physical examination should be performed at each visit. Special attention should be paid to the oral cavity to detect the frequently occurring dental and gum diseases. Lymph nodes should be palpated and carefully evaluated for changes in size or shape. The anterior and posterior segments of both eyes should be thoroughly examined. The skin should be examined closely for evidence of external parasite infestation or fungal disease. The body weight should be accurately measured and recorded because weight loss is often the first sign of deterioration in the cat's condition. A CBC should be performed at each visit. Biochemistry profiles and urinalyses should be performed yearly. Urine should be collected by cystocentesis so cultures can be performed if necessary. Fecal examinations should be considered for cats with a possible exposure to internal parasites or a history of GI disease. A routine program should be used for control of GI parasites, ectoparasites, and heartworms if applicable. Intact males and females should be neutered to reduce stress associated with estrus, mating behaviors, or both. Neutered animals are also less likely to roam outside the house. Surgery is generally well tolerated by asymptomatic FeLV-infected cats. Perioperative antibiotic administration should be used during dental procedures and invasive surgeries.¹⁸²

Vaccination programs to prevent common serious infectious diseases should be maintained. Although no scientific evidence proves that FeLV-infected cats are at increased risk from modified live virus (MLV) vaccines, attenuated viral vaccines to prevent other infections should not be given to FeLV-infected cats because MLV vaccines may regain their pathogenicity. Although FeLV vaccines are nonliving, they are not recommended because they have no effect on the viremia, carrier state or elimination, or clinical FeLV disease in already infected cats. If an owner cannot be convinced to keep an FeLV-positive cat inside, a rabies vaccination should be given in accordance with state and local regulations. In vaccination studies, it was demonstrated that FeLV-infected cats may not be able to mount an adequate immune response to vaccines. This has been proven for rabies but is likely to be true for other vaccines as well. Therefore protection in an FeLV-infected cat after vaccination is not comparable with that in a healthy cat, so more frequent vaccinations have to be considered in these cats, especially in areas with high rabies prevalence.

13.6.2 Treatment of FeLV-Associated Diseases and Drug Precautions

For the most part, secondary diseases in FeLV-infected cats are treated in the same way they are treated in uninfected cats. However, more intensive diagnostic testing should proceed as soon as possible in the course of illness for FeLV-infected patients. Secondary infectious conditions in infected cats may require more intensive and prolonged therapy than in uninfected cats. The owner should be forewarned, and the clinician should not be discouraged if the response to treatment takes longer than expected.

Cats with FeLV infection may have a fever. FeLV itself does not cause fever, so a search for a concurrent infection must be made in febrile cats. Fevers of unknown origin that are unresponsive to antibiotics may be caused by a coinfecting virus, protozoa, or fungus.

Glucocorticoids and other immune suppressive drugs should be avoided whenever possible unless clearly indicated for a specific problem. They interfere with granulocyte chemotaxis, phagocytosis, and the killing of bacteria, thus compounding the risk of infection.³⁸ In FeLV-negative cats living in a household with FeLV-positive cats, glucocorticoid treatment should be avoided because it increases the risk of reactivation of a latent infection. All myelosuppressive drugs should be avoided in FeLV-infected cats because they potentiate the myelosuppressive syndromes caused by FeLV.

Infectious Diseases of the Dog and Cat, 3rd Edition

13.6.2.1 Bone Marrow Suppression Syndromes

In FeLV-infected cats with anemia, blood transfusion is a very important part of the treatment, especially if the anemia is nonregenerative. Most cats respond after the first transfusion. Of 29 anemic (HCT < 20%) FeLV-infected cats treated with blood transfusions for more than 2 weeks, the HCT returned to normal ranges in eight cats. This may be explained by the cyclic cytopenias that are occasionally seen in FeLV-infected cats. Prednisone may increase the life span of erythrocytes if any component of the anemia is immune mediated, but it should be used only if there is proof of an immune-mediated reaction. Occasionally secondary infections (e.g., erythrocytic mycoplasmal infections) are responsible for the anemia. Because this type of anemia (which is regenerative) has the best prognosis of the FeLV-induced anemias, the possibility of an animal having such infectious diseases should always be examined. Deficiencies of iron, folate, or vitamin B₁₂ are rare, therefore replacement therapy is not likely to be helpful.³⁸ Even though erythropoietin concentrations are often elevated in cats with FeLV-related anemia, treatment with human recombinant erythropoietin (rHuEPO) may be helpful. rHuEPO treatment not only increases erythrocyte counts but also increases platelet and megakaryocyte numbers in animals and humans with clinical disease.²³³ In one study, rHuEPO also increased leukocyte counts in cats.⁹ No study has been performed involving FeLV-infected cats but in a study in FIV-infected cats, all treated cats had a gradual increase in erythrocyte counts, hemoglobin concentrations, and HCT levels, as well as increased leukocyte counts consisting of either increased numbers of neutrophils, lymphocytes, or a combination of these.⁹ The recommended dosage is 100 IU/kg given subcutaneously (SC) every 48 hours until the desired HCT (usually 30%) is reached and then as needed to maintain the HCT. A response may not be seen for 3 to 4 weeks and if it does not occur, iron supplementation may be required. Iron should not be given to cats that have received transfusions because whole blood contains 0.5 mg/ml of iron, and hemosiderosis may occur in the liver. Antierythropoietin antibodies may develop in 25% to 30% of treated animals after 6 to 12 months. Binding of these antibodies to the rHuEPO and the native erythropoietin nullifies their physiologic actions on erythroid progenitor cells, causing bone marrow failure and refractory anemia. However, antierythropoietin antibodies dissipate after discontinuation of treatment.

Some FeLV-infected cats do not respond to rHuEPO treatment. Reasons for resistance to erythropoietin, other than development of antierythropoietin antibodies and iron deficiency, include concurrent infection with FeLV and other infectious agents of bone marrow stromal cells. In some nonresponsive cats, repeated blood transfusions may be the only treatment possible.

In some FeLV-infected cats with neutropenia, an immune-mediated mechanism is suspected of leading to a maturation arrest in the bone marrow at myelocyte and metamyelocyte stages. Neutrophil counts can be corrected in many of these cats by immune suppressive doses of glucocorticoids.

In animals with myeloid hypoplasia and in the absence of myeloid precursors, direct effects of FeLV are suspected and glucocorticoids should not be used. Treatment with filgrastim, a granulocyte colony-stimulating factor (G-CSF) that is marketed as recombinant human product (rHuG-CSF) for treatment of neutropenia in humans, has caused transient responses. Filgrastim is used in cats at 5 µg/kg SC every 24 hours for up to 21 days. Potential side effects include bone discomfort, splenomegaly, allergic reactions, and fever.^{9,86} Short-term increases in neutrophil counts may be followed by neutropenia with continued use of filgrastim because of development of dose-dependent neutralizing antibodies to this heterologous product after 10 days to 7 weeks; treatment should not be used for more than 3 weeks.^{9,86} Another potential risk is the development of persistent antibodies against endogenous feline G-CSF after 10

Infectious Diseases of the Dog and Cat, 3rd Edition

days (at higher dosages) to 7 weeks, resulting in rebound neutropenia. One study suggests that filgrastim is contraindicated in FIV-infected cats because it led to an increased viral load,⁹ but data on the use of filgrastim in FeLV infection are limited. In one study, a small number of naturally FeLV-infected cats were treated with filgrastim; however, treatment did not result in significant changes in neutrophil counts.¹⁷² Other authors reported that it has been used in FeLV-infected cats with cyclic neutropenia with some success.¹⁸⁴

13.6.2.2

Lymphoma and Leukemia

Although untreated lymphoma is usually fatal within 1 to 2 months, many cats can be helped with chemotherapy, and a few will have remissions that may last several years. Although the prognosis is worse when lymphomas are associated with FeLV,^{68,173,306,315} some cats greatly benefit from a treatment. Before treatment is considered, a diagnosis of lymphoma must be confirmed by cytologic or histologic studies and the condition of the cat evaluated to determine its prognosis (Table 13-7). Staging of lymphoma in cats is more difficult than in dogs because cats are more likely to have visceral involvement. For example, cats with alimentary lymphoma generally have a poorer prognosis than cats with lymphoma at other sites because anorexia and debilitation are often present. However, cats with a resectable intestinal mass or well-differentiated histologic features have extended survival times after treatment with chemotherapy. Cats with mediastinal lymphoma have a generally favorable response to chemotherapy.^{205,306} Nasal lymphoma seems to remain localized longer than lymphomas in other sites, and radiation alone has significantly prolonged survival. A staging system recommended by Mooney and co-workers is of value in cats with less advanced disease because these cats have a better rate of remission and longer survival.²²⁰

Combinations of chemotherapeutic drugs offer the best chance for complete remission (Tables 13-8 and 13-9). Single-agent glucocorticoids are minimally effective and should be considered for palliation only after clients have rejected the option of combination chemotherapy. The drugs most frequently administered in combination include cyclophosphamide, vincristine, and prednisone, a combination called *COP*. This combination has been effective in achieving remission rates of up to 75%.³⁰⁶ The drugs are occasionally combined with doxorubicin, a combination called *COPA*. Less commonly, l-asparaginase, cytosine arabinoside, and methotrexate are included in feline protocols. In a report of 38 cats treated with *COP*, approximately 75% achieved complete remission, with a median remission duration of 150 days and a 1-year remission rate of 20%.^{33,34} Most cats in this group were FeLV infected, and the most frequent tumor site was the mediastinum. Years later, the same number of cats that were from the same geographic area and treated with the same protocol had a complete remission rate of only 47%, with a median remission duration of 86 days. In the latter group, few cats were FeLV infected, and the alimentary form was the most frequent.²²¹ Therefore FeLV infection should not be a reason not to treat lymphoma in a cat. At this time, *COP* is still a reasonable protocol for induction of remission. For maintenance of remission, adding doxorubicin (a combination called *COPA*) has been more successful than continued *COP*, with a median complete remission of 243 days.²²¹ In contrast, doxorubicin alone was not effective for induction of remission.^{36,38} Therefore if doxorubicin is used for treatment of feline lymphoma, it should be combined with other effective chemotherapeutic drugs in a combination protocol.¹⁷³

All these drugs are immunosuppressive and some are myelosuppressive, so they could lead to production of other FeLV-associated diseases. Owners must be advised to watch for signs of illness. Infections must be treated quickly and aggressively, especially if they occur at the time of the granulocyte nadir. The point at which therapy may safely be discontinued is controversial, but the trend is toward shorter treatment times for

Infectious Diseases of the Dog and Cat, 3rd Edition

cats in continuous complete remission. Previously, most protocols continued for a year or more; now many stop after 6 months of continuous complete remission. Some cats can be expected to relapse when treatment ends, so owner awareness and periodic checkups are important.

Table 13-7 Prognostic Indicators in Feline Lymphoma

PROGNOSTIC INDICATORS	DESCRIPTION
Good	Small tumor burden Peripheral lymph nodes, nasal cavity, or mediastinum as primary site Normal major organ function Good appetite, minimal weight loss
Adverse	Anemia, neutropenia, or thrombocytopenia Bone marrow involvement Prolonged paralysis with spinal lymphoma Fever, sepsis, or focal infection (e.g., gingivitis, chronic rhinitis) Skin or alimentary involvement Emaciation or anorexia
Factors with minimal ramifications	FelV status Age, gender Histopathologic findings (lymphoblastic vs. immunoblastic): not known to affect cat prognosis, but immunoblastic more favorable in dogs

Table 13-8 COPA Therapy Protocol for Treatment of Feline Lymphoma

	WEEK NUMBER															
	1	2	3	4	5	6	7	8	9	10	11	12	13	16	19	22

Infectious Diseases of the Dog and Cat, 3rd Edition

- a Outline of the multiagent protocol: *cyclophosphamide*–10 mg/kg PO; *vincristine*–week 1, 0.025 mg/kg IV; weeks 5, 9, 11, 13, and 17, 0.03 mg/kg IV; *l-asparaginase*–450IU/kg SC; *prednisolone*–week 1, 4 mg/kg PO daily; week 3, 3 mg/kg PO daily; weeks 4 and 5, 2 mg/kg PO daily; weeks 6 and 7, 1 mg/kg PO daily; *doxorubicin*–week 3, 20 mg/m² (1 mg/kg) IV; weeks 7 and 15, 25 mg/m² (1.1 mg/kg) IV; *methotrexate*–0.8 mg/kg PO. Give treatment once a week as indicated, but give prednisolone daily for the first week and weeks 3 through 8.

Cats with acute leukemia are difficult to treat because the bone marrow becomes filled with neoplastic blast cells, which must be cleared before the normal hematopoietic precursors can repopulate. This process may take 3 to 4 weeks, therefore neutropenia and anemia may not be immediately reversible. Although prophylactic antibiotics are not given routinely in the treatment of feline leukemia or lymphoma, broad-spectrum bactericidal antibiotics should be given to FeLV-infected cats, especially if fever or other signs of infection occur. The remission rate for cats with acute lymphatic leukemia treated initially with vincristine and prednisone is approximately 25%, whereas the rate for cats with acute myelocytic leukemia (treated with doxorubicin or cytosine arabinoside) is close to zero. The reason for the extremely poor response may be that a very early stem cell is involved, and nearly total ablation of the bone marrow is necessary to clear the malignant clone.³⁸

13.6.3 Antiviral Chemotherapy

In numerous studies, naturally or experimentally FeLV-infected cats have been treated with various substances. More antiviral or immunomodulatory treatment trials are published for FeLV infection than any other infectious disease. Unfortunately, many results are difficult to interpret, and evaluation of these data is hampered by the lack of well-controlled clinical trials in which new treatments are compared against a standard care or placebo. Currently, no treatment has been proved effective in clearing FeLV infection. To be effective in treatment of FeLV infection, an agent must inhibit viral replication effectively and allow for recovery of the immune system. Lifelong treatment may be required, thus the agent should be effective when given orally and should be relatively nontoxic and inexpensive. So far, no such agent has been found to treat cats with FeLV infection (see [Chapter 2](#) and [Appendix 8](#) for additional information on the drugs in the following section).

13.6.3.1 Zidovudine

Zidovudine (AZT) has been used in experimental and clinical trials in FeLV-infected cats. It is effective against FeLV in vitro.³⁰⁵ It has been shown to be somewhat effective in treating cats experimentally infected with FeLV when treatment is initiated less than 3 weeks after infection. When treated less than 1 week after challenge, cats were protected from bone marrow infection and persistent viremia.⁸⁷ However, in a study involving naturally FeLV-infected cats that were treated with AZT and high-dose SC human IFN- α for 6 weeks, treatment with AZT, human IFN- α or both did not lead to a statistically significant improvement of clinical, laboratory, immunologic, or virologic parameters.¹¹² In general, therapeutic efficacy of AZT in FeLV-infected cats seems to be less promising than in FIV-infected cats. AZT should only be used at a low dosage of 5 mg/kg every 12 hours orally (PO) or SC in FeLV-infected cats. For SC injection, the lyophilized product (marketed for intravenous [IV] injection in humans) should be diluted in isotonic sodium chloride solution (5 ml) to prevent local irritation. For PO administration, syrup (raspberry flavor) or gelatin capsules (compounded individually for every cat) can be given. AZT is rapidly and completely absorbed from the GI tract, and absorption is unaffected by the presence of food. During treatment, routine CBCs are necessary because nonregenerative anemia is a common side effect, especially if FeLV-associated bone marrow

Infectious Diseases of the Dog and Cat, 3rd Edition

suppression is already present. CBCs should be performed weekly for the first month. If values are stable after the first 4 weeks, it is recommended that a CBC be done monthly for monitoring. Cats with severe bone marrow suppression should not be treated because of the risk of a life-threatening anemia. In cats with concurrent chronic renal failure, the dosage should be reduced to avoid toxicity. HCT declines within 3 weeks of initiating treatment to about 60% of baseline but rebounds afterward in most cases, even without discontinuation of treatment. If HCT drops below 20%, discontinuation is recommended and anemia usually resolves within a few days.^{108,109,113} Neutropenia occurs less frequently than anemia and may be prevented or treated with filgrastim. Other side effects in cats, including vomiting or anorexia, rarely develop. One side effect occasionally noted by owners is the development of a fuller and shinier hair coat. AZT should not be combined with other myelosuppressive drugs. Concurrent use of nonsteroidal antiphlogistics has to be monitored carefully because it can delay AZT metabolism, result in kidney toxicity, or lead to neutropenia.

13.6.3.2 Didanosine

Didanosine (ddI) is also used to treat HIV infection in human beings (see [Chapter 2](#)). The drug treats FeLV 126
in vitro³⁰⁵; however, controlled in vivo studies confirming the efficacy of ddI in cats with FeLV infection are 127
not available.

13.6.3.3 Zalcitabine

Like AZT, zalcitabine (ddC) is currently used to treat HIV infection in humans. It is effective against FeLV in vitro^{136,248,305} and has been used in experimental studies to treat FeLV-infected cats. It has a very short half-life (see [Chapter 2](#)) and therefore has been administered via IV bolus dose or controlled-release SC implants. Controlled-release administration of ddC inhibited de novo FeLV replication and delayed onset of viremia. However, when therapy was discontinued after 3 weeks, an equivalent incidence and level of viremia were established rapidly.¹³⁶ In a study evaluating the prophylactic antiviral activity against FeLV, dosages were toxic, although in some cats onset of viremia was delayed for several weeks.²⁴⁸ In humans, the drug is used orally; however, no data exist on PO administration in cats.

13.6.3.4 Ribavirin

Use of ribavirin (RTCA) is limited because of the development of dose-dependant hemolytic anemia in humans. RTCA is also a nucleoside analog but in contrast to other anti-HIV compounds that act primarily to inhibit RT activity, RTCA allows DNA synthesis to occur but prevents the formation of viral proteins, probably by interfering with capping of viral mRNA. RTCA is active against FeLV in vitro.⁸⁷ However, in vivo therapeutic concentrations are difficult to achieve because of toxicity, and cats are extremely sensitive to the side effects (see [Chapter 2](#) and Drug Formulary, [Appendix 8](#)). Therefore it cannot be recommended for use in feline patients.

13.6.3.5 Foscarnet

Foscarnet (PFA) is a pyrophosphate that has a wide spectrum of activity against DNA and RNA viruses including retroviruses (see [Chapter 2](#)). It has in vitro activity against FeLV,³⁰¹ but no reliable data exist on its efficacy in cats in vivo. Toxicity limits its use, and renal dysfunction is evident in most people after 2 weeks of therapy. As it does in humans, it causes nephrotoxicity and myelosuppression in cats.

Infectious Diseases of the Dog and Cat, 3rd Edition

13.6.3.6 Suramin

Although suramin has been used for the treatment of patients with HIV infection, it has only minor clinical value. Suramin was used to treat FeLV-infected cats, although a limited number of cats was used (see [Chapter 2](#) and [Appendix 8](#)).

13.6.4 Antibody Therapy

Antibody therapy has been used in an attempt to treat FeLV. Antibodies were derived from immune cats or were obtained as murine monoclonal antibodies (mabs) to epitopes of gp70. Antibodies have successfully treated experimentally infected cats only when given within 3 weeks of infection. Naturally infected cats showed no response, even though the mabs persisted longer in viremic cats than in normal control animals. FeLV-infected cats also developed residual circulating immune complexes that could cause adverse reactions.³⁸

13.6.5 Immune Modulatory Therapy

Immune modulators or cytokine inducers have been used in the treatment of FeLV-infected cats. Attempts to stimulate the immune response have been used more extensively in FeLV infection than in any other infectious disease in veterinary medicine. However, controlled studies including large numbers of naturally infected cats do not exist for most of these agents.

13.6.5.1 Interferon- α

IFN- α has immunomodulatory and antiviral activity. Two common treatment regimens have been created for use of recombinant human IFN- α in cats: high-dosage SC injection (10^4 to 10^6 IU/kg every 24 hours) or low-dosage PO administration (1 to 50 IU/kg every 24 hours; see [Chapter 2](#) and [Appendix 8](#)). Parenteral administration of IFN- α leads to the development of neutralizing antibodies that limit its activity. Several studies have been performed on the use of human IFN- α in FeLV-infected cats. In vitro, FeLV replication is inhibited by human IFN- α . Treatment with high-dose IFN- α , either alone or in combination with AZT, resulted in significant decreases in circulating FeLV p27 antigen; however, because of anti-IFN- α antibody development, cats became refractory to therapy.³³³ In another study in naturally FeLV-infected cats using high-dose parenteral treatment, IFN- α with or without AZT did not lead to a statistically significant improvement of clinical, laboratory, immunologic, or virologic parameters.¹¹² Low-dose oral IFN- α was used in a placebo-controlled study in cats with experimentally induced FeLV infection.⁴⁴ Cats were given IFN- α orally either 0.5 IU or 5 IU once daily following experimental challenge on 7 consecutive days on alternate weeks for 1 month. No difference was noted in the development of viremia; however, treated cats had significantly fewer clinical signs of illness and longer survival times when compared with the placebo group. The cats given 0.5 IU had a better response. Several uncontrolled studies have reported a beneficial response in cats when treated with low-dose oral IFN,^{295,311,326} but they only included a limited number of cats and have been difficult to interpret without control groups. In a larger study, prognostic outcomes of 69 FeLV-infected cats with clinical signs that had been treated with low-dose oral IFN (30 IU/kg for 7 consecutive days on a 1-week-on, 1-week-off schedule) were compared with historical controls. Significantly longer survival times were reported in the treated cats.³²⁶ Alternate-week treatment is continued until the cat is considered clinically healthy, and treatment may be reinstituted if clinical signs recur.³²⁶ In another

Infectious Diseases of the Dog and Cat, 3rd Edition

placebo-controlled study, treatment of client-owned, ill FeLV-infected cats given oral low doses of IFN- α (30 IU per cat for 7 consecutive days on a 1-week-on, 1-week-off schedule) either alone or in combination with *Staphylococcus* protein A did not result in any statistically significant difference in FeLV status, survival time, clinical or hematologic parameters, or subjective improvement in the owners' impressions when compared with a placebo group.²¹⁴

13.6.5.2 Interferon- ω

Feline IFN- ω has been licensed for use in veterinary medicine in some European countries and Japan (see [Chapter 2](#) and [Appendix 8](#)). Cats will not develop antibodies to IFN- ω because of its homologous origin. Feline IFN- ω inhibits FeLV replication in vitro.²⁶⁵ In a placebo-controlled field study, 48 cats with FeLV infection were treated with IFN- ω in a dosage of 10^6 IU/kg every 24 hours SC on 5 consecutive days. The survival times of treated versus untreated cats in a 2-month follow-up period showed a statistically significant difference.²¹¹ The same investigators studied a similar regimen of three 5-day series of IFN- ω beginning on days 0, 14, and 60 in FeLV-FIV coinfecting cats.^{49a} Cats (39 were treated and 42 received placebo) were monitored for up to 1 year, and supportive therapies were used in both groups. There was greater clinical illness during the initial 4 months and higher mortality at the 9-month (1.7 times the risk) and 12-month (1.4 times the risk) periods in the control group compared with the treated group. However, no virologic parameters were measured throughout these studies to support the hypothesis that the IFN actually had an anti-FeLV effect rather than an inhibitory effect on secondary infections. Additional studies are needed. A treatment protocol of 10^6 IU/kg IFN- ω every 24 hours SC on 5 consecutive days is suggested but may be modified in the future. No side effects have been reported in cats.

127

13.6.5.3 Parapox Virus Avis and Parapox Virus Ovis

Parapox virus avis (PIND-AVI) and parapox virus ovis (PIND-ORF) are attenuated poxviruses that induce IFN and colony-stimulating factors and activate natural killer cells. Initial reports suggested that these compounds were able to cure 80% to 100% of FeLV-infected cats.¹³⁷ However, two placebo-controlled double-blind trials using the same treatment protocol were not able to repeat these striking results.^{110,111} More than 20 immunologic, clinical, laboratory, and virologic parameters were examined (including FeLV p27 antigen concentration, clinical signs, lymphocyte subsets, and survival time), but no statistically significant differences could be demonstrated between paramunity inducer and placebo administration.

128

13.6.5.4 Acemannan

Acemannan, is a water-soluble, long-chain complex carbohydrate (mannan) polymer derived from the aloe vera plant (see [Chapter 2](#) and [Appendix 8](#)). In one noncontrolled open-label trial, 50 cats with natural FeLV infection were treated with acemannan (2 mg/kg intraperitoneally [IP] every 7 days for 6 weeks). At the end of the 12-week study, 71% of the cats were known to be alive.²⁸⁰ All cats remained FeLV-antigen positive, and no significant change was detected in clinical signs or hematologic parameters. The fact that the study did not include a control group and clinical and laboratory evaluations failed to document improvement from pretreatment evaluations makes it difficult to determine whether the use of acemannan improved the outcome of infection.

Infectious Diseases of the Dog and Cat, 3rd Edition

13.6.5.5 Staphylococcus Protein A

Staphylococcus protein A (SPA) is a bacterial polypeptide that has been used in various modalities to treat FeLV-infected cats (see [Chapter 2](#)). In a study, kittens with experimental FeLV infection were treated with SPA (7.3 µg/kg IP twice per week for 8 weeks); however, neither anemia nor humoral immune function improved.²¹⁴ In a placebo-controlled study, treatment of client-owned ill FeLV-infected cats with SPA (10 µg/kg twice per week for up to 10 weeks) did not cause a statistically significant difference in the FeLV status, survival time, or clinical and hematologic parameters when compared with a placebo group, but it caused a significant improvement in the owners' subjective impressions of the health of their pets. Interestingly, a combination of SPA with low-dose oral IFN-α was less effective than SPA alone.²¹⁴

13.6.5.6 Propionibacterium acnes

P. acnes, formerly *Corynebacterium parvum*, is available for veterinary use and has been used in treating FeLV-infected cats, but no prospective studies have been performed. Veterinarians have described their clinical experience in round-table discussions and anecdotal reports (see [Chapter 2](#)).^{184,185}

13.6.5.7 Bacille Calmette-Guérin

Bacille Calmette-Guérin (BCG) is a cell wall extract of a nonpathogenic strain of *Mycobacterium bovis* that has been used to treat kittens experimentally infected with FeSV (see [Chapter 2](#)). However, BCG was not able to prevent tumor development or increase the survival rate in any setting.¹³

13.6.5.8 Serratia marcescens

A commercially available biologic extract of *Serratia marcescens* (BESM) stimulates normal feline macrophages derived from bone marrow to release maximum concentrations of IL-6, TNF-α, and IL-1, leading to elevations in rectal temperature and neutrophil counts (see [Chapter 2](#)). In a study with FeLV-infected cats, weekly treatment with BESM preparations failed to prevent or reverse viremia in cats when initiated before or 6 weeks after inoculation with FeLV.⁶⁰

13.6.5.9 Levamisole

Levamisole (see [Chapter 2](#)) is a broad-spectrum anthelmintic that has been given to FeLV-infected cats,³⁵ but its effect has never been substantiated by controlled studies. Levamisole remains an investigational therapy.

13.6.5.10 Diethylcarbamazine

Diethylcarbamazine (DEC) may mitigate the course of FeLV infection in cats. Uncontrolled studies have suggested that continuous oral DEC treatment given shortly after evidence of FeLV infection prevents or delays FeLV-associated lymphopenia and prolongs survival.^{169,170} In one controlled study, its therapeutic effect against FeLV infection was investigated in 24 SPF kittens experimentally infected with a lymphoma-causing strain of FeLV. The kittens were divided into four groups and received either a high

Infectious Diseases of the Dog and Cat, 3rd Edition

dosage of DEC (12 mg/kg every 24 hours), a low dosage of DEC (3 mg/kg every 24 hours), AZT (15 mg/kg every 12 hours), or a placebo orally for 10 weeks. Although AZT was effective in preventing persistent viremia, neither dosage of DEC was effective. However, AZT and both dosage levels of DEC prevented lymphoma development.²²⁹ DEC has severe side effects including hepatic injury.²⁴

13.6.5.11 Treatment of Viral-Induced Feline Sarcomas

Treatment of FeSV-induced fibrosarcoma is early, wide, and deep surgical excision. If no metastases are present and microscopic tumors remain after surgery, radiation can be successful in delaying recurrence. Experimentally FeSV-induced fibrosarcomas in kittens occasionally regress after treatment with anti-FOCMA serum, but this is unlikely to translate into clinical efficacy.³⁸

13.7 PREVENTION

13.7.1 General Considerations

Because FeLV is prevalent in body excretions such as saliva, cats with viremic infections pose an immediate risk to other cats in their environment. Because of the environmental lability of retroviruses such as FeLV, direct contact among cats and immediate fomite transfer are the major risk factors. Viremic cats should be physically separated from other cats in the environment. In a veterinary clinic, FeLV-infected cats can be housed in the same ward as other hospitalized patients as long as certain precautionary measures are taken. FeLV is very fragile, surviving only seconds at most outside the host animal. The virus is susceptible to all disinfectants including common soap, so simple precautions and routine cleaning procedures can prevent transmission in the hospital setting. FeLV-infected patients should be housed in individual cages and confined to them throughout their hospitalization. They should *never* be placed in a “contagious ward” with cats that have other infections such as viral respiratory disease. Animal caretakers and other hospital staff members should be advised to wash their hands between direct contacts with patients and after cleaning cages. (These measures are taken primarily to protect FeLV-infected, immune suppressed cats.) Dental and surgical instruments, endotracheal tubes, and other items potentially contaminated with body fluids of a FeLV-infected cat should be thoroughly cleaned and sterilized between uses. Fluid lines, multidose medication containers, and food can become contaminated with body fluids (especially blood or saliva) and should not be shared among patients. FeLV can be transmitted hematogenously, therefore all feline blood donors should be screened and confirmed to be free of infection before donating blood.¹⁸² Because FeLV was detected in the corneal tissues of cats by PCR and immunohistochemistry,¹²² screening potential corneal donors for FeLV infection is also generally warranted.

128
129

Preventative methods, including testing and removal strategies and vaccination, have been very successful in significantly decreasing the prevalence of FeLV infection in the last 20 years.

13.7.2 Test and Removal Strategy

When FeLV was first described in the mid 1960s, the highest rate of infection was found in large multiple-cat households and catteries. In contrast, free-roaming cats had lower rates of infection, and those housed in single-cat households were only rarely infected. Convenient and reliable testing became available in the mid-1970s. Very quickly, cat breeders implemented test and removal programs, which proved to be extremely effective for eliminating the virus from catteries. The most dramatic example was a mandatory test and removal

Infectious Diseases of the Dog and Cat, 3rd Edition

program in the Netherlands in 1974 that was imposed on all cat breeders.³²³ When testing was first implemented, the prevalence of FeLV in purebred catteries was 11%. Within 4 years, the rate was reduced to less than 2%, and no infected cat has been reported since 1984. FeLV should be considered an abnormality in a well-run cattery. Many stray-cat shelters also implement testing in their conditioning protocols, thus further reducing the rate of FeLV infection.¹⁸⁴ Epidemiologic studies suggest that the testing and removal strategies have more influence on the decrease in prevalence than vaccination.²⁷²

13.7.3 Vaccination

13.7.3.1 History and Efficacy

Because most naturally exposed cats produce antibodies to virus and become immune, it is theoretically possible to produce an effective vaccine. However, accomplishing the task proved to be more difficult than anticipated. The mechanism of protection against FeLV, and especially the role of CMI, is not completely understood. Neutralizing antibody to subgroup A virus is probably most important because it is the only subgroup that is transmitted naturally. The other subgroups arise by recombinant events only after a cat is infected.

Development of a safe and effective vaccine against FeLV presented a special challenge that other infections did not. Early vaccines carried a higher risk of anaphylaxis than did other feline vaccines. Original prototypes of inactivated-virus vaccines were not only ineffective but also increased the severity of the immunosuppression. Live-virus vaccines produced immunity, but some vaccinated kittens developed clinical disease from “attenuated” virus. Researchers were also concerned that the vaccine virus could integrate into the host genome and later cause FeLV-negative lymphomas, thus most vaccine research focused on the use of whole killed-virus preparations or subunit vaccines.

The first anti-FeLV vaccine was licensed in 1985. Since that time, the original vaccine has undergone modifications, and several other products have appeared on the market. Licensed vaccines use whole killed virus, and most contain adjuvant or genetically engineered recombinant parts of the virus. Vaccination does not interfere with testing for FeLV. Currently, recommendations for most vaccines are for two SC doses for initial protection followed by annual boosters; some are licensed for a 3-year booster. It is not necessary to administer vaccine from the same manufacturer for boosters (see [Chapter 100](#) and [Appendixes 2 and 3](#) for additional information on FeLV vaccination recommendations).

The relative efficacy of the vaccines is the subject of much controversy. Many of the published vaccine efficacy trials were performed or funded by the manufacturers, without having simultaneous evaluation of more than one vaccine. Furthermore, testing protocols vary widely among studies, making meaningful comparison rather difficult. Because of the natural resistance of cats (especially older cats) to FeLV infection, investigators often use artificial immune suppression (e.g., glucocorticoids) and administration of large viral doses to increase the challenge virulence in FeLV vaccine studies. Some have immunosuppressed vaccinated and control cats before intranasal (IN) challenge with virulent virus, and others have performed parenteral challenge with large doses of virus without immune suppression. The relationship of these challenges to natural exposure has been questioned,^{31,124,131,180,181} making it difficult to know what the vaccine's actual effect in a natural exposure environment would be. Some studies have involved natural challenges when vaccinated and control cats lived together with FeLV-shedding cats.^{89,174} This type of challenge is preferable, but no standard challenge protocol has been accepted by vaccine manufacturers. This type of natural exposure challenge experiment, in which naive cats are housed together with an

Infectious Diseases of the Dog and Cat, 3rd Edition

FeLV-shedding cat and that are most comparable to multiple-cat household situations, provide an environment with a very high infection pressure. In this high-pressure situation, none of the licensed vaccines proved to be 100% effective. Therefore it is not safe to bring an FeLV-shedding cat into a household with FeLV-negative cats, even if these cats are vaccinated.

No accurate postvaccination measure exists that can determine whether cats are protected after vaccination. Neutralizing antibody titers develop in few vaccinated cats despite their being protected against challenge infection.¹⁴⁸ The immune mechanism protecting cats from persistent viremia is CMI through the effects of CTLs.^{75,93} Neutralizing antibody titers do not predict postvaccinal protection; however, they can indicate which cats are protected after recovery from natural infection. Although ELISA and other antibody assays against envelope antigens exist, only neutralizing antibody titers are predictive of protection. Unfortunately, commercially available testing for neutralizing antibody is not available.

13.7.3.2

Vaccine-Associated Sarcomas

A clear epidemiologic association exists between rabies and FeLV vaccinations and later development of soft tissue sarcomas at the injection site (sarcomas referred to as *injection site sarcomas*, *vaccine-associated sarcomas*, and *vaccine site-associated sarcomas*).^{119,120,162,163,199} The most frequently occurring type of these soft tissue sarcomas are fibrosarcomas, but undifferentiated sarcomas, rhabdomyosarcomas, chondrosarcomas, osteosarcomas, and malignant fibrous histiocytomas are also found. The estimated incidence ranges from 1 tumor per 1,000 vaccines to 1 tumor per 10,000 vaccines.¹⁹⁹ Reported rates of reactions were 0.32 vaccine-associated sarcomas per 10,000 vaccines and 11.8 postvaccinal inflammation reactions per 10,000 vaccines in cats.⁸⁴ If inflammatory reactions are a necessary prelude to sarcoma, then these rates suggest that 1 in 35 to 40 reportable inflammatory reactions transition to sarcomas. These tumors may occur as soon as 4 months or as long as 2 years after vaccination, with a median of approximately 1 year.¹⁶² They are derived from the granulomatous inflammation at the injection site. In addition to FeLV vaccination, every SC, intradermal (ID), or IM injection can cause these tumors in cats, and certain long-acting injectable medications may also be associated with sarcoma formation.¹⁶³ However, an apparent association exists between inflammation or injury at an injection site and the risk of tumor development. Cats seem to have a unique response to adjuvants in vaccines.²⁸ Usually in attenuated vaccines, adjuvant is added to enhance the inflammation that is necessary in a killed product to provide necessary immunity. However, this inflammation promotes malignant transformation. Traces of adjuvants can be seen in the inflammatory reaction and later in histologic sections of tumors in the transformed fibroblast.¹¹⁹ Intracellular crystalline particulate material was found in an ultrastructural study in 5 of 20 investigated tumors and in one case was identified as aluminum based.²⁰² Although no specific vaccine or adjuvant has been incriminated,¹⁶³ local irritation from adjuvants might stimulate fibroblasts to the point that malignant transformation occurs.¹⁸⁰ FeLV and FeSV themselves are not involved in the tumor development.⁶⁰ Also, replication or expression of endogenous retroviruses is obviously not involved.¹⁶⁶

129

130

The recognition of the malignancies associated with widespread annual vaccination has led the AAFP to revise vaccination recommendation for cats⁴ and create new guidelines for testing of feline retrovirus infections.¹⁸² Until the safety of vaccines improves, care should be taken to weigh the risk of FeLV infection against the risk of receiving the vaccine. The AAFP questions the automatic annual revaccination in cats and recommends tailoring vaccine protocols for each feline patient. Only cats at risk of contracting the disease should be vaccinated. Cats living in closed households that have no risk should not be vaccinated. New cats

Infectious Diseases of the Dog and Cat, 3rd Edition

in multicat households or in shelters should be tested before being introduced. Testing is recommended before every FeLV vaccination so that only FeLV-negative cats undergo vaccination. FeLV vaccination of FeLV-positive cats is not beneficial, although it is probably not harmful either. Vaccination of a latently infected cat does not prevent reactivation and is not beneficial, although again, it is probably not harmful either. Adult cats have an age resistance, and in an older cat the risk of developing a vaccine-associated sarcoma is most likely higher than the risk of developing a persistent FeLV viremia. Unfortunately, no studies provide data on the age at which vaccination should be stopped.

The AAFP recommends administering any vaccine with an FeLV component SC in the left rear leg, whereas the rabies vaccination is given in the right rear leg (“left for leukemia, right for rabies”) as far distally as possible. The vaccination locations aid in the treatment of subsequent sarcomas (by amputation of the leg) because these tumors are very difficult to completely excise and often recur after resection.¹⁹⁹

Administration of the vaccine between the scapulae is contraindicated because tumor resection is almost impossible in this location. IM injection is also contraindicated because the tumors develop with the same frequency but are more difficult to detect early. Any nodule that is present longer than 3 months at an injection site should be removed and examined histologically. FeLV vaccines that are licensed for 3-year boosters should be used if available. Vaccines that do not contain adjuvant should be used instead of adjuvant-containing vaccines. In Europe a licensed recombinant vaccine containing all three genes of FeLV was cloned in a canarypox vector. The advantage of this new technology is that it does not need inflammation at the injection site because it is distributed in the body by the canarypox and exposed to the immune system by other mechanisms. Genetic information of certain FeLV proteins is integrated into the canarypox genome with which it enters the cell. It is here that the FeLV proteins are produced leading to antibody production and reaction of the cellular immunity. Safety of this type of vaccine has been proven.

Very good, immediate, and long-term efficacy in this vaccine has been established.^{251,304} In a natural challenge experiment, vaccinated cats were housed together with FeLV-shedding cats for 27 weeks; the canarypox vaccine was equally as effective as commercially available vaccines.⁸⁹ This vaccine is commercially available for use in cats and is administered by a needle-less air injection system (see [Chapter 100](#) and [Appendix 3](#)). In one study in rats, inflammation at the injection site was less with recombinant canarypox vaccines compared with conventional vaccines.^{200,201} In a limited experiment in cats, the typical granulomatous inflammation did not develop at the injection site when using this vaccine.⁵² A DNA vaccine has also been developed for FeLV that contains all FeLV genes and the feline IL-18 gene as an adjuvant. It has been highly protective in challenge experiments with kittens by producing FeLV-specific CTLs and protection against challenge infection.^{75,93,149}

13.8 PUBLIC HEALTH CONSIDERATIONS

Because FeLV is known to be contagious, concern arose about the possible danger of FeLV to people. Numerous facts suggest that human infection is not impossible. The virus does grow in human bone marrow cells in culture.²²² Lymphoma has been experimentally induced by injection of large doses of virus into neonatal pups and marmosets.²⁶⁰ One epidemiologic study linked prior contact with sick cats to subsequent development of childhood leukemia. The contact between FeLV-infected cats and children with leukemia was double that of contact between healthy children and healthy cats.^{22,245} Cell-bound antibody believed to be directed toward FeLV-RT has been found on malignant cells of people with chronic myelocytic leukemia in blast cell crisis. Veterinarians were shown to have a higher death rate from leukemia than a control population of physicians and dentists.^{19,31,34,71,91} However, the increased death rate could also be explained by their higher exposure rate to radiation.

Infectious Diseases of the Dog and Cat, 3rd Edition

Epidemiologic studies searching for FeLV or antibody to any of its components in people have been confusing and inconclusive. Some investigators have found antibodies to FeLV in humans with leukemia and owners of viremic cats,^{25,72,146,236} whereas others using more specific radioimmune assays have obtained negative results. No person has ever been found to be viremic with FeLV. PCR was used unsuccessfully to find FeLV sequences in blood and bone marrow of young and adult humans with leukemia but with no success.²³¹ One explanation for the discrepancy between culture of the virus in human cells and the absence of proof of human infection may be related to the lytic action of human complement on the virus. No case of human leukemia has ever been traced to FeLV. Although it is almost impossible to prove a negative hypothesis, it appears that FeLV is not a human health hazard. A potential risk to immunosuppressed people that live in close contact with FeLV-infected cats cannot be completely excluded and should be discussed with such owners. However, the risk involved is mainly from secondary zoonotic infections that an immunosuppressed cat might acquire and potentially transmit to an immune suppressed person.

14 CHAPTER 14 Feline Immunodeficiency Virus Infection

Rance K. Sellon

Katrin Hartmann

14.1 ETIOLOGY

Feline immunodeficiency virus (FIV) is a lentivirus that shares many properties characteristic of other lentiviruses, such as human immunodeficiency virus (HIV). FIV has remained the object of intense investigation as a model of lentiviral pathogenesis and prevention. The amount of knowledge generated with regard to FIV continues to increase in many arenas. Acquainting the reader with all of the information that exists is beyond the scope of this chapter; rather, the object is to familiarize the reader with current concepts of FIV that are clinically relevant. Readers interested in a review of the basic genetic organization and life cycle of FIV, function of FIV genes and gene products, and its comparisons to other lentiviruses are referred to other sources.*

Although discussion of the FIV genome and its products is not the focus of this chapter, several FIV genes have clinically important aspects. For example, regions in the viral integrase enzyme determine the site of binding and integration of FIV provirus into the host cell DNA, which can influence host cell function.^{568,569}

Of the FIV genes, the envelope (*env*) gene and its proteins⁴⁷¹ provide the best examples of the clinical importance of FIV gene structure and function. Field isolates of FIV are divided into several subtypes based on sequence differences in a hypervariable region of the *env* gene.^{469,640} Worldwide, five different subtypes (or clades) have been recognized, subtypes A, B, C, D, and E.^{443,477} Extensive analysis of field subtypes in the United States and Canada has yet to be conducted. However, some studies suggest that subtypes A and B predominate in the United States, with occasional cats infected with subtype C.^{21,667} These studies also suggest regional differences in subtype distribution, with subtype A common in the western United States and subtype B predominant in the eastern United States. In Australia and Africa, subtype A has been described, and in South America, subtypes B and E have been found. European cats are infected with subtypes A, B, C, and D, with subtype A being the major subtype in the northern countries (e.g., Germany, The Netherlands), and subtype B being more important in southern countries (e.g., Italy).^{155,488,597} Subtypes B, C, and D predominate in Japan and other Asian countries, although subtypes A, B, C, and E have also been observed.* Analysis of European FIV subtypes has suggested that subgroupings within a given subtype are also possible, reflecting the genetic plasticity of FIV.⁵⁹⁷

As demonstrated by seroprevalence studies, naturally infected cats can harbor multiple subtypes,^{332,456} and superinfection indicates a lack of cross-protection among some subtypes, a finding that has bearing on FIV vaccine success (see Prevention).^{101,332,456} Evidence suggests that exchange of gene segments encoding the *env* protein from different subtypes can occur between isolates in superinfected cats.¹⁰¹

Env properties are clinically relevant because they determine cell tropism[†] and influence pathogenicity.[‡] Interactions of FIV *env* proteins with host cell ligands are critical initial steps during host cell infection.^{263,657} *Env* proteins are targets of immune responses,[§] and differences in, or conservation of, *env* sequences may reflect selection pressures exerted by the immune response of the infected cat.[¶]

Infectious Diseases of the Dog and Cat, 3rd Edition

Differences in *env* antigenic determinants still represent potential obstacles in the development of FIV vaccines protective against widely prevalent, and different, isolates of FIV^{250,573,576} (see Prevention).

14.2 EPIDEMIOLOGY

14.2.1 Prevalence

FIV is common worldwide, and its prevalence varies among geographic locations. Across the United States, the seroprevalence of FIV in cats at high risk of exposure and in clinically ill cats ranges from approximately 4% to 24%, with few apparent regional differences.^{108,346,451} Seroprevalence outside the United States varies. Some countries report few infected cats, and others, such as Italy and Japan, with large populations of free-roaming cats have prevalence rates that can approach 30%.^{*} Pockets of high prevalence, such as 47% reported in one group of feral cats in the United Kingdom, can also be seen.¹⁰¹ The prevalence of FIV in healthy cats is usually lower than in sick cats,^{391,435,679} with rates commonly at 2% to 5%,^{46,590} and foci of higher prevalence reflecting local cat population dynamics.¹⁸ Seroprevalence in nearly all surveys is higher in male cats than it is in female cats, which is considered the result of higher rates of virus transmission among biting and fighting cats.[†] Adult cats are found infected more often than adolescent cats and kittens are,⁴³⁵ which again likely reflects aggressive behavior between cats as the predominant means of natural transmission. In serologic surveys, it is uncommon for enzyme-linked immunosorbent assay (ELISA)-positive results to be confirmed by Western blotting; thus true infection prevalence may be overestimated, especially in the healthy cat population, because of false positive results.

Evidence from retrospective serosurveys suggests that FIV has been present in the domestic feline population since at least 1966.⁵⁶⁴ Infection with lentiviruses related to FIV has been reported in Florida panthers and many other nondomestic feline species in United States zoos, as well as in free-roaming nondomestic felids in the United States, Europe, Africa, Saudi Arabia, and Asia.[‡] The greater diversity of viral nucleic acid sequences and the decreased pathogenicity of the nondomestic felid isolates, compared with those that affect domestic cats, suggest that nondomestic felids have been living with the virus for a longer time and that the domestic cat strains may have emerged more recently from nondomestic strains.⁴⁵⁷ Domestic cats are susceptible to persistent infection with isolates from nondomestic felids, but the clinical and immunologic abnormalities that develop in FIV-infected domestic cats are typically not observed when domestic cats are infected with nondomestic feline lentiviruses.⁶³⁸ Furthermore, cross-infection studies suggest that infection with a nondomestic feline lentivirus (lion or puma lentivirus) may blunt the immunologic and virologic responses to

Infectious Diseases of the Dog and Cat, 3rd Edition

subsequent FIV infection.^{635,636} Probable transmission of an FIV isolate from domestic cats to an exotic cat species has also been documented.⁴⁴⁴

‡ References 34, 49, 74, 83, 173, 198, 457, 466, 500.

14.2.2 Transmission

In natural settings, FIV is transmitted primarily by parenteral inoculation of virus present in saliva or blood, presumably by bite and fight wounds, accounting for the higher prevalence in male cats. Experimentally induced bites are effective at transmitting virus from infected to naïve cats. Additional evidence supporting the importance of this route of transmission is the observation that FIV can be found in salivary gland epithelium^{402,474} during acute infection, as well as in saliva, blood lymphocytes, and plasma or serum.⁴⁰² Experimentally, FIV is easily transmitted by all parenteral routes (intravenous [IV], subcutaneous [SC], intramuscular [IM], intraperitoneal [IP]) using cell-free or cell-associated virus.

In experimental settings, high rates of transmission (over 50%), both in utero and postparturition via milk, have been documented in queens with acute and chronic FIV infections^{*}. The presence of greater viral loads in milk than milk secreting cells or plasma suggests that virus can be concentrated in milk.⁶ Available evidence suggests that, in a given litter, some kittens can acquire infection in utero, and others will not.⁵³⁹ Transmission has also been reported after oral,^{425,560} intrarectal, and intravaginal inoculation with cell-free or cell-associated virus.^{81,322,448-450} The feline female reproductive tract has CD4 and CD8 T cells, B cells, macrophages, and dendritic cells, all known targets of FIV infection. Systemic spread following mucosal routes of inoculation can occur within days.^{91,450}

Despite the experimental evidence of transmission via the mucosal routes, no evidence suggests that these routes have an important role in maintaining natural infections. Available epidemiologic and serologic surveys do not, however, exclude the possibility of occasional transmission by these routes. High kitten mortality in FIV-positive neonates or rapidly progressive infections, as observed in some experimental studies,[†] may lead to underestimates of in utero and neonatal transmission in natural settings. Additionally, the observation that kittens born to FIV-infected mothers can have FIV provirus detected in tissues, but not necessarily blood, in the absence of detectable antibodies further complicates the understanding of congenital transmission rates under natural conditions.⁵

Infectious virus has been documented in both cell-free and cell-associated fractions of semen from acutely and chronically infected male cats.^{300,304} Infection can be established following laparoscopic insemination of queens with semen from infected male cats.^{301,303} Although contribution of seminal transmission to maintenance of natural infections is unknown, it is likely low.

Horizontal transmission of FIV in multiple-cat households is an arguably infrequent event, with some studies suggesting it rarely occurs and others suggesting that horizontal transmission may be common.^{3,478} FIV DNA-positive but antibody-negative cats have been detected in situations in which the DNA-positive cats had been housed in experimental colonies for long periods (months to years) with FIV-infected cats. Despite being DNA-positive, the cats were asymptomatic and did not develop typical immunologic abnormalities observed in

Infectious Diseases of the Dog and Cat, 3rd Edition

antibody-positive cats.¹²⁵ Similar cases of DNA-positive but antibody-negative cats have been observed in other studies.^{5,449} The clinical consequences, if any, of this latent type of infection remain unknown at present.

Experimentally, miscellaneous modes of transmission, such as using suture contaminated with blood from an FIV-positive cat, have been documented.¹⁵⁴ Inoculation of proviral DNA has also produced infection.^{486,533,591} Although infection has been established with these modes, natural infections are unlikely to occur through these routes.

† References 5, 6, 448, 449, 458, 459.

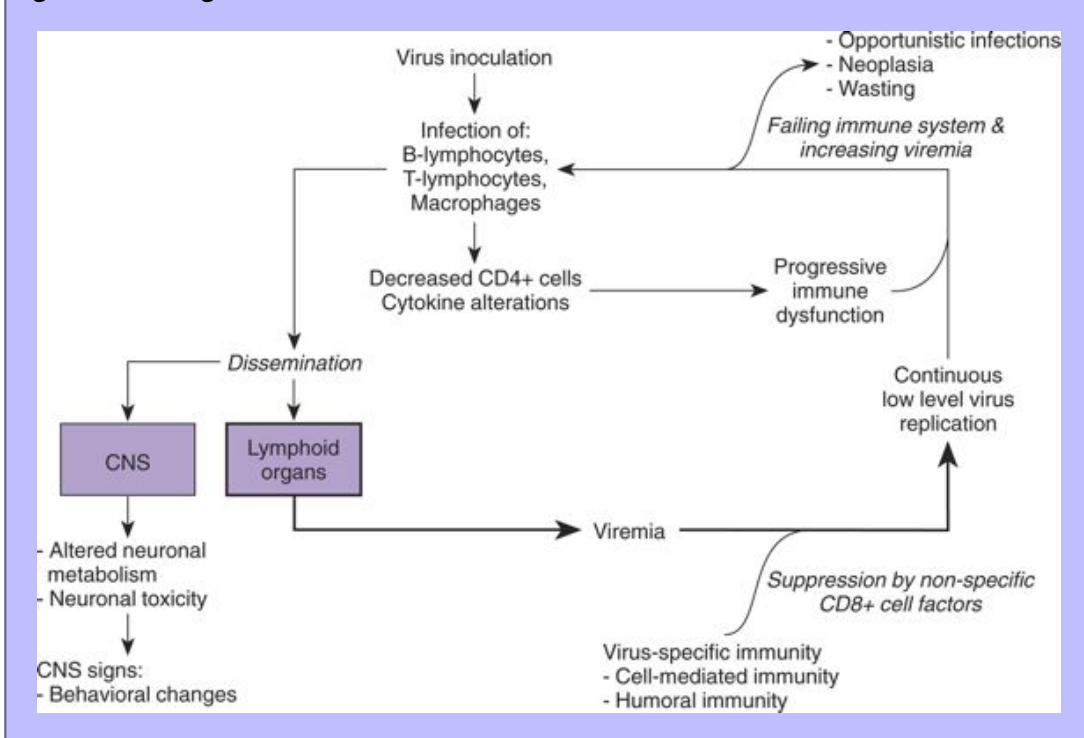

14.3 PATHOGENESIS

The picture emerging from recent studies of FIV pathogenesis suggests that the events that follow infection, such as differences in viral kinetics, clinical features and progression of FIV infection, and the character of immune responses to FIV following infection, are likely the result of an interplay of a large number of factors. Such factors include the age of the animal at the time of infection (young animals developing clinical signs faster), properties of the FIV isolate, the amount of virus used for infection, the route of infection (parenteral versus mucosal or other route), and whether the inoculum is in the form of cell-free or cell-associated (i.e., infected cells) virus.*

132

133

Fig 14-1 Pathogenesis of FIV infection.

After experimental inoculation, viral particles are cleared by tissues rich in macrophages, and viral replication then occurs in target cells of lymphoid organs (thymus, spleen, lymph nodes), and other tissues rich in macrophages

Infectious Diseases of the Dog and Cat, 3rd Edition

and lymphoid cells.[†] Viremia peaks within several weeks postinoculation (PI).^{42,130} Using polymerase chain reaction (PCR) or viral culture, the virus is easily detected in plasma or peripheral blood lymphocytes by 2 weeks PI or earlier.⁴⁰² FIV also spreads to mononuclear cells (lymphocytes, monocytes, and macrophages) in organs such as the bone marrow, lung, intestinal tract, brain, and kidney.^{42,540,547} Virus-infected follicular dendritic cells in lymph nodes may infect na-ve T cells migrating through the lymph node.^{20,624}

After peak viremia, circulating virus decreases to low levels as the host mounts an immune response to FIV. A vigorous, but ultimately ineffective, humoral immune response is mounted against the virus (Fig. 14-1). Generally, anti-FIV antibodies first become detectable in experimentally infected cats 2 to 4 weeks PI, although exposure to lesser amounts of virus may delay the appearance of detectable responses.⁴⁶ Antibodies are produced against many FIV proteins,^{162,176,268,534} especially those of the viral envelope, capsid, and transmembrane proteins.³⁹⁹ Virus-neutralizing antibodies can be detected with in vitro assays,^{23,464,625} but the role that neutralizing antibodies play in suppression of FIV viremia in vivo is not clear.[‡] Some studies suggest that the humoral immune response in infected cats is responsible for driving the emergence of FIV variants that are resistant to in vitro neutralization.²¹¹ As noted previously, occasional cats will be provirus (DNA) positive, but remain antibody negative.

Although a robust humoral immune response is mounted, current evidence suggests that CD8+T-cell-mediated immunity (CMI) is responsible for suppressing early virus production after initial infection.^{81,82,114,203} Suppression of virus production has been demonstrated in vitro through mechanisms involving both cell-cell interactions and secretion of soluble factors, perhaps interleukin(IL)-16 or others.³⁵⁶ One interesting feature of the antiviral activity of the soluble factor is that it is not restricted to a specific FIV isolate.^{*} The mechanism behind this nonspecific, noncytolytic, T-cell-mediated, viral-suppressive activity may be inhibition of viral mRNA transcription.^{253,258} Inhibitory activity can be detected in some cats approximately 1 week PI and before detection of a humoral immune response, with virus-specific cytolytic T-cell activity detected later.¹⁹⁰ T-cell-suppressive activity can be maintained through the asymptomatic period, but as infection progresses into the chronic phase, suppressor activity may wane in infected cats.^{189,259} Virus-specific cytotoxic T-cell activity emerges in the weeks after infection and also plays a role in virus control.⁸⁶

Following acute infection and suppression of viremia, cats enter a clinically asymptomatic period of variable duration. This period is not one of true viral latency because FIV production continues in infected cells in tissues, and virus can still be recovered from blood lymphocytes, serum or plasma, cerebral spinal fluid (CSF), semen, and lymphoid tissues.[†] Plasma levels of virus and viral RNA can increase again during the terminal phases of infection (see Fig. 14-1).^{145,216,325}

FIV infects a wide range of cell types in vitro and in vivo (Table 14-1), but cell tropism is isolate dependent.^{131,152}

Unlike HIV, FIV does not use the feline CD4 molecule as a cellular receptor to infect target cells.^{272,445} A 133

molecule with receptor function for FIV has been identified as a chemokine receptor designated CXCR4.^{*} 134

Expression of CXCR4 mRNA or antigen can be demonstrated in a large number of cell types known to be susceptible to FIV infection, including lymphocytes and astrocytes, and intraepithelial mononuclear cells and epithelial cells of the rectum, colon, and female reproductive tract, perhaps accounting for some degree of transmucosal transmission observed in experimental studies.[†] However, not all cell types susceptible to infection express CXCR4. Some cells that express CXCR4 are not susceptible to infection with all FIV isolates, especially primary field isolates, and not all viral isolates display evidence of using CXCR4 as a pathway to cell

Infectious Diseases of the Dog and Cat, 3rd Edition

infection.^{197,263,351} Thus other, or additional, receptor molecules or modes of cell entry may likely be important in establishing productive infections in target cells.^{263,296} Potential candidates include heparan,¹³⁹ immunoglobulin-mediated entry into cells bearing the immunoglobulin Fc receptor (macrophages, B cells), or intercellular infection through contact of infected and uninfected cells. The hypothesis holds that for some FIV isolates and cell targets, CXCR4 acts as primary receptor for FIV and the CCR5 receptor, another type of chemokine receptor, influences FIV infection by modulating the expression of CXCR4, or serves as another FIV receptor.^{328,656}

Table 14-1 In Vivo and in Vitro Cell Tropism of FIV

Megakaryocytes ⁴⁴	
Salivary gland epithelium ⁴⁷⁴	

The hallmark of FIV pathogenesis is progressive disruption of normal immune function, some of the mechanisms of which have been elucidated. Early and persistent immunologic abnormalities that occur after experimental^{2,26,621} and natural^{248,447} infection in both domestic and nondomestic felids are decreases in both the number and relative proportions of CD4+ cells (see Fig. 14-1) in the peripheral blood, as well as in most primary lymphoid tissues examined.⁸⁴ Causes of CD4+-cell loss may include decreased production secondary to bone marrow or thymic infection, lysis of infected cells induced by FIV itself (cytopathic effects), destruction of virally infected cells by the immune system, or death by apoptosis.[‡] Apoptosis is a form of cell death that follows receipt of a membrane signal initiating a series of programmed intracellular events that ultimately lead to cell death. Apoptosis of CD4+, CD8+, and B cells has been documented in lymph nodes, spleen, and thymus of FIV infected cats^{261,548,620}; the degree of apoptosis has correlated inversely with CD4+ numbers and the CD4+/CD8+ ratio.²⁶¹ Ultimately, loss of CD4+ cells impairs immune responses because CD4+ cells have critical roles in promoting and maintaining both humoral and CMI.

As is seen with HIV infection in people, loss of CD4+ cells leads to inversion of the CD4+/CD8+ ratio (see Fig. 14-1). The inversion may occur weeks to months after infection, depending on the viral isolate studied.^{2,621} Contributing to the inverted ratio in some cases is an increase in the proportion of CD8+ cells (cytotoxic or T lymphocytes),^{2,248,658} in particular a population referred to as CD8+ alpha-hi, beta-low cells,^{570,571} a subset of CD8+ cells that arguably may contribute to suppression of viremia in FIV-infected cats. Although inversion of the CD4+/CD8+ ratio is a consistent feature of both natural and experimental infections, its use as a prognostic tool for cats is questionable, as has been demonstrated with HIV-infected people.^{59,644} FIV-infected cats may show severe inversion for prolonged periods without developing clinical signs, and available work demonstrates no correlation of the ratio with clinical stage of infection or plasma viremia.^{217,248} Despite being a target of viral infection, no reported changes have been found in numbers or proportions of B cells after FIV infection.

Infectious Diseases of the Dog and Cat, 3rd Edition

Other immunologic abnormalities occur with FIV infection. Over time, lymphocytes from infected cats lose the ability to proliferate in response to stimulation with B- and T-cell mitogens, and have impaired priming of T cells by T-cell-dependent immunogens in vitro.^{*} Lymphocyte function may also be impaired by reduced or altered expression of cell surface molecules, such as CD4, major histocompatibility complex II antigens or other co-stimulatory molecules, and cytokine receptors,[†] each of which has a critical role in antigen presentation, or amplification and control of immune responses.

FIV infection is associated with disrupted production of cytokines, molecules essential to normal immune function. Cytokine patterns detected from cultures of FIV-infected lymphocytes are dependent to some extent on the FIV isolate and tissue compartment studied.^{132,373} Reported changes in cytokine production in FIV-infected cats, as compared with noninfected cats, have included increased production of interferon (IFN)- γ , tumor necrosis factor (TNF)- α , IL-4, IL-6, IL-10, and IL-12.^{352,366,462,536} Increased IL-10/IL-12 ratios have been observed in FIV-infected cats also infected with *Toxoplasma gondii*,³⁶³ a pattern that would impair the development of CMI responses to *T. gondii*. Similarly, increased IL-10 has been documented in FIV-infected cats infected with *Listeria monocytogenes*, with FIV-infected cats exhibiting delayed clearance and more severe clinical signs of infection as compared with FIV-negative cats.¹³⁰

Alterations in function of nonspecific defenses such as neutrophils have also been described in FIV-infected cats.^{225,330} Natural killer cell activity has been reported as diminished⁶⁸¹ or increased⁶⁸⁷ in FIV-infected cats, depending on whether the cats were acutely or asymptotically infected, respectively.

Another manifestation of the immunologic dysregulation observed in many FIV-infected cats is hypergammaglobulinemia, primarily from increases in IgG.^{2,186} Hypergammaglobulinemia reflects polyclonal B-cell stimulation because the IgG produced is not FIV specific. It is a direct consequence of FIV infection because healthy FIV-positive, specific pathogen-free (SPF) cats are also hypergammaglobulinemic.¹⁸⁶ In addition to increased IgG, increased circulating immune complexes have been detected in FIV-infected cats.⁴⁰⁰ FIV has also been incriminated as causing a delay in the class shift of antibody isotypes from IgM to IgG based on work in cats infected with both FIV and *T. gondii*.³⁴¹

134
135

Abnormal neurologic function has been described in FIV-infected cats with varying degrees of central nervous system (CNS) inflammation. Although occasional studies have linked neurologic dysfunction and neuronal injury with the amount of virus present in the brain of infected cats,²⁹⁷ many studies support the hypothesis that neurologic dysfunction and histologic changes in the CNS are indirect events and not an immediate consequence of CNS-cell infection or viral replication within the CNS.^{410,475,506,542} Experimental infections in vivo have caused brain lesions in the absence of massive CNS infection.⁵⁴² Neurotoxins such as glutamate have been implicated as one cause of neuronal loss.^{*} Other work has incriminated a role for matrix metalloproteinases, which can break down collagen and alter properties of the blood-brain barrier, or altered neuronal cytoskeletal properties in the pathogenesis of neurologic dysfunction in FIV-infected cats.^{287,294,298} In vitro and, occasionally, in vivo studies suggest that infection of cells in the CNS, in particular the astrocyte and macrophage, may impair normal CNS-cell metabolism.^{*} Documented abnormalities of astrocyte and macrophage functions include altered intercellular communication, abnormal glutathione reductase activity that may render cells more susceptible to oxidative injury, alterations in mitochondrial membrane potential that disrupt energy-producing capacities of the cell, and impaired maintenance of intracellular calcium concentrations.⁶⁵ Some studies suggest that sequences in

Infectious Diseases of the Dog and Cat, 3rd Edition

the viral envelope protein are important in neurovirulence properties,[‡] and others indicate that neurologic cell dysfunction does not necessarily correlate with envelope-mediated replicative capacity.^{53,294} Interestingly, purified FIV gp120, an envelope protein, caused neurologic abnormalities when administered to rats.^{515,545}

The pathogenesis of some clinical features of FIV remains unexplained but, similar to neurologic disease, may result from abnormal function of, or inflammation in, affected organs. Wasting disease has been observed in the absence of obvious causes such as diarrhea or neoplasia. Abnormal renal function and nephritis have also been reported in FIV-infected cats.³⁶² Some aspects of clinical FIV will reflect the pathogenesis of the secondary diseases such as infections and neoplasms to which FIV-infected cats are considered susceptible.

14.4 CLINICAL FINDINGS

FIV infection progresses through several stages, similar to HIV-1 infection in people. Recognized clinical stages in cats include an acute phase, a clinically asymptomatic phase of variable duration, and a terminal phase of infection often referred to as feline acquired immunodeficiency syndrome (AIDS).^{169,217} Some investigators note two other phases in keeping with the terminology for HIV infection: progressive generalized lymphadenomegaly, which follows the asymptomatic phase, followed by AIDS-related complex (ARC).^{217,285,286,478} Still other researchers describe a sixth category to encompass miscellaneous diseases such as neoplastic, ocular, and immune-mediated diseases that are observed in some infected cats.⁴⁷⁸

Although division of FIV infection into these clinical stages may prove useful from the standpoint of gauging prognosis, no sharp distinction exists between them, and not all stages will be apparent in some infected cats. Furthermore, no readily available predictor has been found of the transition from the asymptomatic phase to the ARC or AIDS phase, although one study found that higher levels of viremia during the acute stage of infection were associated with more rapid progression to the terminal phases of the disease.¹⁴⁶ In a study of naturally infected cats, a trend was noted for increasing viremia with progression of clinical signs, with cats in the AIDS category of infection exhibiting higher viral loads than cats in the ARC or asymptomatic phase of infection.²¹⁷

Infectious Diseases of the Dog and Cat, 3rd Edition

Clinical signs of FIV infection are nonspecific (Table 14-2). Clinical signs attributed directly to FIV infection likely go unobserved in many naturally infected cats. During acute experimental infection, clinical signs may be transient and so mild as to go unnoticed. Some cats exhibit fever and malaise. Signs of acute enteritis, stomatitis, dermatitis, conjunctivitis, and respiratory tract disease can be seen. Generalized lymph node enlargement is common during acute experimental infection.⁴⁴⁹ The acute phase may last several days to a few weeks, after which cats will enter a period in which they appear clinically healthy. The duration of the asymptomatic phase varies and likely depends on factors such as the pathogenic potential of the infecting isolate and the exposure of the infected cats to other pathogens but can last for years. One experimentally infected cat, kept isolated from other cats, had FIV-infection for over 8 years without developing clinical signs.³²⁵ The age of the cat at the time of infection may also influence the length of the asymptomatic stage and the severity of clinical disease, depending on the isolate studied.^{479,493} During the later stages of infection, clinical signs are often a reflection of opportunistic infections, neoplasia, myelosuppression, and neurologic disease.

Infections with a significant number of opportunistic pathogens of viral, bacterial (Fig. 14-2), protozoal, and fungal origin have been reported in FIV-infected cats (Table 14-3). Few studies, however, have compared the prevalence of most of these infections in FIV-infected and noninfected cats. No correlation was found between FIV infection and infection with *Cryptococcus* or *Cryptosporidium*.^{434,646} Another study reported a higher number of fungal genera isolated from the skin, oropharynx, and rectum of FIV-infected cats compared with noninfected cats, but FIV-infected cats had no symptoms of fungal infections at the time of examination,³⁹² and no correlation was found between FIV infection and the presence of *Cryptococcus neoformans* or dermatophytes.⁵⁷⁸ In one study, seroprevalence of *T. gondii* was similar in both FIV-infected and noninfected cats, and FIV-infected cats did not have detectable oocyst shedding.⁶⁰¹ In another study, the prevalence of FIV was higher in *T. gondii* antibody-positive cats.¹⁵⁰ The prevalence of *Bartonella henselae*, the agent of cat scratch disease, or *B. clarridgeiae* has not been positively associated with FIV infection.^{213,245,396,397} An increased prevalence of FIV infection has also been reported in cats that were antibody-positive for Bornavirus,²⁷⁴ a virus detected in cats in eastern and northern European countries, and cats with orthopoxvirus.⁶²⁶ No significant association between FIV infection in cats with *Mycoplasma haemofelis*/*M. haemominutum* (*Haemobartonella felis*) has been found.²²⁷

Stomatitis is a common condition of FIV-infected cats and can occur during any stage of infection. The cause of stomatitis is uncertain, although the histologic findings of lymphocytes, plasma cells, and variable degrees of neutrophilic and eosinophilic infiltrates suggest either an immune response to chronic antigenic stimulation or immune dysregulation. Stomatitis is not often seen in SPF cats, suggesting that exposure to infectious agents may also play a role.³⁶² Experimental and naturally occurring co-infection of FIV-infected cats with calicivirus resulted in more severe disease.^{524,609} Odontoclastic resorptive lesions have been reported with higher prevalence in experimentally infected cats as compared with noninfected cats; such lesions have been speculated to be a consequence of gingivitis or stomatitis present in the cats.²⁴⁹

Diarrhea has been seen in experimentally infected cats in the absence of detectable enteric pathogens. Bacterial overgrowth and inflammatory lesions have been proposed as a cause in such cases but are not always evident.⁴⁷³

FIV-positive cats can develop ocular disease,^{170,340,461,664} and abnormalities may be found in both anterior and posterior segments. Anterior uveitis may result from secondary infections such as toxoplasmosis or may be directly related to FIV infection.^{170,461,664} Glaucoma, with and without uveitis, has also been described.^{170,461,664} Posterior segment changes that may be seen include pars planitis (an infiltration of leukocytes, mainly plasma cells, into the vitreous behind the lens), focal retinal degeneration, and inner retinal hemorrhages.^{170,664}

Respiratory disease may be observed in FIV-positive cats and can result from bacterial, fungal, protozoal, or parasitic infections.³⁵ Experimentally, FIV infection worsened the respiratory disease observed in an experimental model of acute toxoplasmosis.¹²⁷

Infectious Diseases of the Dog and Cat, 3rd Edition

Neoplasia is a common reason that FIV-infected cats are brought to a veterinary clinic. Lymphomas, leukemias, and a variety of other tumor types (see [Table 14-3](#)) have been reported in association with FIV infection.^{*} Statistically, FIV-infected cats are much more likely to develop lymphoma or leukemia compared with noninfected cats.^{96,499} Most lymphomas in FIV-infected cats are B-cell tumors.^{96,201,499,610} FIV provirus is only occasionally detected in tumor cells,^{39,38,37,649} suggesting an indirect role for FIV in lymphoma formation, such as decreased CMI surveillance or chronic B-cell hyperplasia.^{39,166} However, clonally integrated FIV DNA was recently found in lymphoma cells from one cat that had been experimentally infected 6 years earlier,^{37,38} raising the possibility of an occasional direct oncogenic role of FIV in some animals. The prevalence of FIV infection in one cohort of cats with lymphosarcoma was 50%,²⁰¹ much higher than the FIV prevalence in the population of cats without lymphosarcoma, which is supportive of a cause and effect relationship between FIV and feline lymphosarcoma.

Neurologic signs have been described in both natural and experimental, and acute and terminal, FIV infections.[†] Neurologic impairment following FIV infection appears to be isolate dependent.⁵¹⁰ The most common neurologic sign observed is behavioral change. Other deficits that have been described include seizures, paresis, multifocal motor abnormalities, impaired learning, and disrupted sleep patterns.^{224,514,594} Neurologic signs may improve if they occur during the acute stage of infection, although residual deficits are possible. Abnormal forebrain electrical activity and abnormal visual and auditory-evoked potentials have also been documented in cats that appeared otherwise normal.^{32,486,493,495} Less commonly, secondary infections such as feline infectious peritonitis, toxoplasmosis, or cryptococcosis cause neurologic deficits.

In the terminal phase of infection, a wasting syndrome may occur. If experimentally infected with some particularly pathogenic FIV isolates, SPF cats have developed a terminal wasting syndrome within 6 to 8 weeks PI.^{144,146}

14.5 DIAGNOSIS

14.5.1 Clinical Laboratory Findings

A large number of clinicopathologic abnormalities have been described in FIV-infected cats, but none are specific or pathognomonic for infection. During the acute phase of infection, cats may exhibit neutropenia and lymphopenia, which resolve as the cat progresses to the asymptomatic phase of infection.^{371,393} During the asymptomatic phase of infection, results of complete blood count (CBC) and biochemical analyses are often normal,^{371,374,393,567} but leukopenia may be encountered.^{18,567} Clinically ill FIV-infected cats may have a variety of cytopenias. Lymphopenia, caused mainly by decreases in CD4⁺ cells, is most common. Anemia and neutropenia may also be seen,^{75,565,566,592} although these abnormalities may be as much a reflection of concurrent disease as direct effects of FIV infection itself. Anemia, leukopenia, and less commonly thrombocytopenia²²⁹ have been observed in FIV-infected cats in the absence of other identifiable causes.^{18,479} Soluble factors have been shown to inhibit bone marrow function in FIV-infected cats, and bone marrow infection has been associated with decreased ability to support hematopoietic potential in vitro.⁶⁰³

Infectious Diseases of the Dog and Cat, 3rd Edition

Abnormalities of the biochemical profile of FIV-infected cats typically are few. Some cats have an increase in total protein caused by hyperglobulinemia. Azotemia has been reported in FIV-infected cats in the absence of other detectable causes of renal disease,^{362,503,611} but FIV as a definitive cause of renal disease awaits clarification. Other biochemical abnormalities, when found, will usually reflect concurrent disease. When compared with control cats, after 9 months of FIV infection, experimentally infected cats had increased serum globulin, glucose, triglyceride, urea, and creatinine concentrations and reduced serum cholesterol levels.²⁵⁰ The mechanism of such changes may include altered energy metabolism, subclinical hypercortisolemia, and release of cytokines in infected cats. Prolongations of the activated partial thromboplastin time have been reported in FIV-infected cats in the absence of other obvious causes of coagulopathy, although the prolongations were mild and not clinically apparent.²²⁹

Few descriptions of CSF changes have been provided in FIV-infected cats with neurologic disease. Cellular pleocytosis and increases in concentrations of IgG in the CSF have been reported,¹⁵³ expecting increases in cell number and total protein in CSF is not unreasonable. Viral RNA can be found in the CSF of some cats and suggests parenchymal infection.⁵⁴²

14.5.2 Serologic Testing

A definitive diagnosis of FIV infection is made most commonly by detection of FIV-specific antibodies in blood by either ELISA or rapid immunomigration-type assays, which are widely available and easy to use (see [Appendix 6](#)).⁵⁰⁵ These assays are reasonably sensitive and specific, although reported sensitivity and specificity can be quite variable, and both false-positive and false-negative results can be obtained with any of these “in-house” assays.^{201,238,537} Technical error in a specific test kit, and use of whole blood rather than serum, have been incriminated as causes of false-positive test results performed with in-house assays.²³⁸ Variability in sensitivity and specificity, in conjunction with differences in infection prevalence, affects the predictive values of these assays. One comparison of six in-house assays found positive predictive values that ranged from 83% on the high end to only 51% on the low end, while negative predictive values ranged from 96% to 99%.²³⁸ Such results emphasize the importance of confirmatory testing. Cats that have positive results by an in-house test should be retested, ideally by Western blot (see [Chapter 1](#)), to confirm the diagnosis.

Because FIV produces a persistent infection from which cats do not recover and infected cats usually develop high amounts of FIV-specific antibodies, detection of antibody has historically been synonymous with infection. However, the introduction of a commercial vaccine in the United States has the potential to complicate interpretation of antibody tests. Currently available assays, including Western blots, are incapable of distinguishing antibody responses induced by infection from vaccinal antibodies. In patients that are known with certainty to not have been vaccinated, antibody tests are still reliable to diagnose FIV infection. Misdiagnosis of FIV in uninfected cats (e.g., positive results in vaccinated cats) may lead to the inappropriate euthanasia of vaccinated cats or of kittens born to vaccinated queens. This issue is especially problematic in shelter medicine, given that confirmatory testing is frequently impractical. Experimental evidence also suggests that superinfection with different subtypes is possible (i.e., inconsistent cross-protection), and thus a cat vaccinated with a dual subtype vaccine may be susceptible to infection with a subtype not included in the vaccine. Serologic assays would not be helpful in determining the infection status of such cats.

Antibody tests also have to be interpreted carefully in kittens less than 6 months of age. Kittens up to 12 weeks of age can have passively acquired anti-FIV antibodies from mothers that are infected or have been

Infectious Diseases of the Dog and Cat, 3rd Edition

vaccinated.^{386a} Rarely do kittens become infected from their mothers under natural circumstances; therefore most kittens that initially test positive will eventually turn negative when maternal antibodies wane. Retesting these kittens after 6 months of age is advised. If the second test is negative, the earlier positive result was likely the result of maternal antibody. If still positive, the kitten is likely infected. A kitten of unknown background that is initially antibody negative is likely to be truly negative, but a small chance exists that the kitten has not had time to develop a detectable antibody response. These kittens should be retested after 8 to 12 weeks. If still negative, the kitten is unlikely to be infected. If positive, the kitten is probably infected.

Cats in the acute phase of infection may be antibody negative, and retesting suspect cats in 6 to 8 weeks is warranted to establish a diagnosis in cats with a recent history that puts them at risk of exposure. Most cats develop a detectable antibody response within 8 weeks of initial infection; however, in some experimental studies, antibody development has not been observed until 10 weeks after inoculation and in occasional animals has required 6 months or longer.^{253,478} Antibody development may not occur in rapidly progressive infections.⁴⁶⁰ These observations from experimental infections suggest that a single negative test result may, in some instances, be insufficient to discriminate recently infected animals from true negative animals.

FIV-specific antibodies are readily detected in blood of most cats throughout the asymptomatic phase of infection. Asymptomatic kittens with regressive infections (i.e., infections associated with very low or no antibody titers) have been observed after experimental infection, and evidence of FIV infection can be only demonstrated by culture or PCR.^{449,460} Because of debilitation of the immune system, some cats entering the terminal phase of infection may lose detectable antibody.¹⁴⁵ For such cats, Western blots may show FIV-specific antibodies not detected by some ELISAs. Flow cytometric analysis of peripheral blood lymphocytes may demonstrate inverted CD4+/CD8+ ratios in antibody-negative cats and is available at many veterinary teaching hospitals. Inverted CD4+/CD8+ ratios are only consistent with, but not diagnostic of, FIV infection.

137

138

With the introduction of the FIV vaccine and the associated problems of interpreting serologic test results in vaccinated animals, attention has turned to other methods of confirming FIV infection in suspect cats. Detecting infection by virus isolation or PCR-based assays has been suggested as an alternative to serologic testing.⁶³⁰ Although classical virus detection by blood cell culture and virus isolation from plasma is possible over the whole infection period, it is time consuming, expensive, and requires expertise. Therefore this method is not practical for routine diagnosis. PCR is a very sensitive and specific method currently used in research cats. If appropriately inactivated, the current vaccine should not result in provirus production and thus would not interfere with PCR assays that detect viral DNA.⁶³⁰ However, potential conflicts may arise in the future with PCR tests, depending on the level of attenuation of a vaccine. PCR requires specialized equipment and thus is presently performed only by specialized laboratories. Current PCR tests are not standardized across laboratories, and little is known about sensitivity, specificity, and overall diagnostic performance in naturally infected cats.^{50a} False-positive results are possible with FIV PCR as with any other PCR assay (see [Chapter 1](#)). The marked variability of the viral genome has raised concerns about the ability of the PCR to detect all FIV variants. False-negative rates of up to 50% have been reported.⁵⁹⁷ PCR reagents, including primer and probe sequences, are often selected based on genetic sequences of a few well-characterized FIV strains and so may not detect all isolates. Additionally, some laboratory cats with documented FIV infection have insufficient circulating provirus copies for detection by conventional PCR.^{5,362} Failure to identify infected cats (e.g., PCR-negative results caused by strain variations) may lead to inadvertent exposure and transmission of FIV to uninfected cats.

Infectious Diseases of the Dog and Cat, 3rd Edition

The American Association of Feline Practitioners, in conjunction with the Academy of Feline Medicine, has established guidelines for testing cats for FIV ([Table 14-4](#)). Although these guidelines were developed before the introduction of the FIV vaccine, the guidelines are still appropriate.

14.6 PATHOLOGIC FINDINGS

Numerous pathologic changes may occur after FIV infection. The lymph nodes of FIV-infected cats may be hyperplastic during the acute phase of infection and, in the terminal phase of infection, may have disruption of normal architecture with loss of follicles and cellular depletion.^{168,449,675} Dysplastic changes have been reported in the bone marrow of FIV-infected cats, along with the appearance of granulocytic hyperplasia and the formation of marrow lymphoid aggregates.⁷⁰ Inflammation in the respiratory and gastrointestinal (GI) tracts has also been seen. Infected cats can develop lymphoid interstitial pneumonitis, characteristic of lentiviral infections in other species.⁹³ Recent studies have also documented the existence of an FIV-associated myopathy characterized by infiltrates of lymphocytes and plasma cells in perivascular and pericapillary areas, and myofiber infiltrates of skeletal muscles in conjunction with myofiber necrosis. Affected animals, however, did not exhibit clinical signs of myopathy.⁴⁹²

Experimentally infected cats that develop neurologic disease may have lymphocytic infiltration of perivascular areas ([Fig. 14-3](#)).¹ Loss and reorganization of neurons, axonal sprouting, and gliosis are described in FIV-infected cats; many of these changes can be found in cats without obvious evidence of clinical signs of infection.^{411,416,417,501} Giant cell formation has also been reported.²²⁴ Renal lesions found in FIV-infected cats include glomerulosclerosis and tubulointerstitial infiltrates.^{362,503} Some of the common pathologic abnormalities observed in FIV-infected cats are listed in [Table 14-5](#).

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 14-4 Guidelines for FIV Testing in Cats

Testing cats for FIV is recommended for the following circumstances

All cats that are sick.

All cats that are to be adopted.

All cats that are of unknown status.

All cats that have risk factors for recent exposure, or suspected or known to have been recently exposed (retesting of negative cats may be needed to allow time for seroconversion).

Bite or fight wounds

Unsupervised outdoor activity

Resides with a cat whose FIV status is unknown

Resides with an FIV positive cat (annual testing recommended)

All cats that have been vaccinated for FIV (negative test results advised before vaccination).

Infectious Diseases of the Dog and Cat, 3rd Edition

14.7 THERAPY

In many naturally infected cats, FIV does not directly cause a severe clinical disease. With proper care, FIV-infected cats can live many years with a high quality of life and, in fact, may die in older age from causes unrelated to FIV infection. Nonetheless, treatment of FIV has been an area of investigation not only for the potential of helping FIV-infected cats, but also for the potential benefits of HIV-infected people. Approaches to treatment fall broadly into antiviral chemotherapy, immune modulatory therapy, and husbandry and supportive care.

Table 14-5 Pathologic Abnormalities Described in FIV-Positive Cats^a

AREA	ABNORMALITY
Lymph node	Follicular involution Follicular hyperplasia Follicular plasmacytosis
Thymus	Cortical involution, atrophy Lymphoid follicular hyperplasia and germinal center formation
Intestinal tract	Villous blunting Pyogranulomatous colitis Lymphoplasmacytic stomatitis
Liver	Periportal hepatitis
Bone marrow	Myeloid hyperplasia, lymphoid aggregates
Kidney	Interstitial nephritis Glomerulosclerosis
Central nervous system	Perivascular cuffing Gliosis Myelitis Decreased neuron density, axonal sprouting, vacuolar myelinopathy
Lung	Interstitial pneumonitis, alveolitis
Skeletal muscle	Lymphocytic myositis Myofiber necrosis Perivascular cuffing

a From references 42, 44, 76, 98, 133, 144, 153, 174, 278, 401, 503, 504, 530, 70, 93, 292, 386, 411, 416, 417, 492, 501, 675.

14.7.1 Antiviral Chemotherapy

Most antivirals developed for lentivirus infections are specifically intended for treatment of HIV infection, but several can be used to treat FIV infection because many enzymes of FIV and HIV have similar sensitivities to various inhibitors. In cell culture, many compounds have activity against FIV. However, many FIV treatment studies screen new compounds in vitro or in vivo to document a potential benefit for HIV-infected people. Most of these compounds will not appear on the market and will not be accessible to veterinarians even if some had very good efficacy against FIV. Thus the drugs available for cats are limited, and few controlled studies have been performed to support their clinical use. Refer to [Appendix 8](#) and [Chapter 2](#) for more information on drugs discussed in this section.

Treatment with nucleoside analogues such as zidovudine (3'-azido-2',3'-dideoxythymidine [AZT]) alone or in combination with other drugs, and phosphonylmethoxyethyladenine (PMEA) has been investigated in vitro and in vivo. * AZT blocks lentivirus–reverse transcriptase (RT) activity and is the most thoroughly studied anti-FIV

Infectious Diseases of the Dog and Cat, 3rd Edition

drug. AZT is integrated into the developing DNA strand, thus inhibiting infection of new cells, but not replication of virus already present in infected cells. AZT reduces plasma virus load, improves the immunologic and clinical status of FIV-infected cats, increases quality of life, and prolongs life expectancy.^{231,232} Depending on the study, treatment with AZT or PMEA before inoculation with FIV does not prevent infection or accumulation of provirus in target tissues but delays the onset of detectable viremia and some of the immunologic changes. * AZT improves neurologic abnormalities in FIV-infected cats.³⁶² Regression of stomatitis and increased CD4+/CD8+ ratios have been observed in placebo-controlled studies of naturally infected cats treated with AZT, PMEA, or related compounds.^{159,235,237} As is the case with HIV, evidence from in vitro studies suggests that FIV can become resistant to nucleoside analogs.^{214,520,521} In fact, a single point mutation in the FIV gene can create resistance to one or more of the nucleoside analogs.^{408,583}

During treatment with AZT, regularly performed CBCs are necessary because nonregenerative anemia is a common side effect, especially if the higher dosage is used.^{159,584} CBCs should be performed weekly for the first month. Some cats may develop a mild decrease of hematocrit (HCT) initially in the first 3 weeks that resolves even if treatment is continued. If the HCT drops below 20%, discontinuation of treatment is recommended, and anemia usually resolves within a few days. If values are stable after the first month, a monthly CBC is sufficient. Cats with bone marrow suppression should not be treated because of the risk of life-threatening anemia. In cats with concurrent chronic renal failure, the dose should be reduced to avoid toxicity from accumulation of the compound. Studies in cats treated with AZT for 2 years showed that AZT is well tolerated in most FIV-infected cats. A dosage regimen for AZT is listed in [Table 14-6](#).

Type 1 IFNs have both immunomodulatory and direct antiviral effects. Human IFN- α has been used in cats with FIV infection.⁵³⁵ Parenteral administration of IFN- α is more likely to produce an antiviral effect than is oral administration.⁵⁵⁵ Human IFN- α can be given in high doses (10^5 to 10^6 IU/kg) parenterally for a maximum of 6 to 7 weeks, after which cats are likely to develop antibodies.⁶⁸² Human IFN- α given orally, as is used by many veterinarians to treat retrovirus infections, is likely not absorbed but rather destroyed in the GI tract so measurable serum levels do not develop. Oral IFN- α may have an effect by stimulation of local lymphoid tissue in the oral cavity. However, no placebo-controlled studies have been done that have shown a positive effect of low-dose oral human IFN- α in FIV-infected cats. Feline IFN- ω was licensed for use in veterinary medicine in some European countries and Japan. Feline IFN- ω effectively inhibits FIV replication in vitro⁶⁰² but has yet to show antiviral benefit in FIV-infected asymptomatic cats.¹⁰⁰ One study of symptomatic cats co-infected with FeLV and FIV has been reported.^{136a} (See Interferon- ω , [Chapter 13](#).) IFN- τ has shown some efficacy against FIV in vitro, but in vivo studies have not been reported.⁵⁰⁸

Additional compounds, including other nucleoside analogs, protease inhibitors, fluoroquinolone derivatives, cyclosporine A and tacrolimus, androgenic steroids, quassinoids, N-acetylcysteine, ascorbic acid, peptides derived from the FIV-*env* and transmembrane regions, and bacterial-derived protein peptides with natural antimicrobial activity, DNA-binding polyamides, and algal extracts, have been investigated with some promising results from in vitro or in vivo studies. However, their clinical efficacy has not been established.[†]

139

Infectious Diseases of the Dog and Cat, 3rd Edition

140

Table 14-6 Drug Therapy for FIV Infection

DRUG	DOSE ^a (MG/KG)	ROUTE	INTERVAL (HOURS)	DURATION (WEEKS)
Antiviral				
AZT ^b	5 mg/kg	PO, SC ^c	12	prn
Cytopenias				
Erythropoietin	100 IU/kg	SC	48	2 ^d
Granulocyte colony-stimulating factor	5 mg/kg	SC	12	1–2
Stomatitis				
Metronidazole	5 mg/kg	PO	8	2–4
Clindamycin	12.5 mg/kg	PO	8	2–4
Prednisone	5 mg/cat	PO	12	2–4
Bovine lactoferrin	40 mg/kg	Topically to oral cavity	24	prn

PO, By mouth; SC, subcutaneously; prn, as needed; AZT, zidovadine.

- a Dose per administration at specified intervals. See Drug Formulary, [Appendix 8](#), for additional information.
- b Monitor CBC regularly for Heinz body anemia.
- c For PO, administer in gelatin capsules with specific calculated dose; for SC, dilute lyophilate in 5 ml sodium chloride.
- d Until desired hematocrit is reached.

Given the identification of the role of the CXCR4 molecule in viral transmission, CXCR4 ligands such as stromal derived factor-1 have been developed and investigated for their anti-FIV potential, but inhibitory activity has been inconsistent, reflecting the likely existence of other molecules that play a role in cell infection.^{167,263} Bicyclams, a new class of compounds, selectively block CXCR4 receptors on feline and human cells. The prototype bicyclam, 1,1'-bis-1,4,8,11-tetraaza cyclotetradekan (AMD3100), effectively inhibited FIV replication in vitro¹⁶¹ and significantly reduced the virus load of naturally FIV-infected cats.⁵⁹⁸

Proteinase inhibitors, which have been used to successfully control illness in HIV-infected people, are retroviral specific. An experimental drug developed for FIV, known as TL-3, was effective in prevention and resolution of FIV-induced CNS disease.^{277a} Treatment had to be continued to maintain remission. In cats with specific clinical signs, such as stomatitis or disorders of the CNS, antiviral therapy such as AZT treatment may be a valid treatment consideration until protease inhibitors are available. For further information see Drug Formulary, [Appendix 8](#).

14.7.2 Immune Modulatory Therapy

Immunostimulatory agents such as acemannan, staphylococcus protein A, and *Propionibacterium acnes* have been advocated for use in retrovirus-infected cats to restore compromised immune function, thereby allowing the patient to control viral burden and recover from associated clinical syndromes. Most reports that appear in

Infectious Diseases of the Dog and Cat, 3rd Edition

the veterinary literature are difficult to interpret because of unclear diagnostic criteria, absence of clinical staging or follow-up, the natural variability in the progression of infection, the lack of placebo-control groups, the small number of cats used, and concurrent administration of other supportive treatments.³⁶² Thus no conclusive evidence from controlled studies has been found that immunomodulator or alternative drugs have any beneficial effects on the health or survival of asymptomatic or symptomatic FIV-infected cats.

14.7.3 Management of FIV-Infected Cats

In all cats, FIV status should be known because FIV infection affects long-term management. Management of FIV-infected cats should differ from that of noninfected cats. The strategy most likely to prolong the life of an FIV-infected cat is keeping the cat strictly indoors.³ Such a strategy prevents both exposure of the immunosuppressed cat to infectious agents carried by other animals and spread of FIV to other cats. Secondary diseases cause the majority of health problems in FIV-infected cats. Secondary infections cause clinical signs in FIV-infected cats, influence the clinical course of cats infected with FIV, and play a role in the progression of FIV infection.

If FIV infection is diagnosed, regular veterinary examinations should be encouraged at least semi-annually to promptly detect changes in health status. Annual evaluation of a CBC, biochemistry profile, and urinalysis have also been recommended.⁵²⁵ If FIV-infected cats are sick, prompt and accurate identification of the secondary illness is essential to allow early therapeutic intervention and a successful treatment outcome. Therefore intensive diagnostic testing should occur earlier in the course of illness for an FIV-positive cat than might be recommended for an uninfected cat. In addition to a thorough physical examination and laboratory database, thoracic and abdominal radiographs or abdominal ultrasonography may be required to identify disease. Consideration should be given to cytology and culture of pertinent samples (e.g. urine, blood, effusions, tracheal wash) as additional diagnostic tests and as guides to pharmacologic choices. Cats with cytopenias may require bone marrow aspiration or biopsy to identify underlying causes.

When underlying infections are identified in FIV-infected cats, treatment with appropriate antibiotics or antifungals is encouraged because no evidence suggests that the FIV-infected cat is incapable of responding to treatment. More prolonged courses of treatment may be required in some animals. Systemic fungal infections in FIV-infected cats should be treated the same as in noninfected cats. Itraconazole is useful for cryptococcal infections and is effective for treatment of dermatophytosis. FIV-infected cats with dermatophyte infections should not be treated with griseofulvin because this drug has been associated with the development of severe neutropenia in cats with naturally acquired FIV infection (see Drug Formulary, [Appendix 8](#)).

140

141

Treatment of FIV-associated stomatitis is often difficult. Repeated treatment with dental cleaning and antibiotics may offer palliative relief but is rarely sufficient to resolve the lesions. Although the pathogenesis of stomatitis is considered to be immune mediated, glucocorticoids should be avoided in FIV-associated stomatitis. In some cases, treatment with AZT can be beneficial (see [Table 14-6](#)). Topical bovine lactoferrin has also been beneficial for FIV-related stomatitis (see also [Chapter 100](#) and [Appendix 8](#)).⁵⁵² An effective treatment can be extraction of all teeth, paying careful attention to removal of all of the roots of the teeth ([Figs. 14-4, A, and 14-4, B](#)). In many cases, long-term resolution of inflammation is achieved, and cats return to eating a normal diet.

In those cats in which underlying causes of anemia are not found, consideration may be given to treating with erythropoietin (100 IU/kg, SC every other day until desired HCT is reached, then as needed to maintain the HCT). In one study of the use of hematopoietic factors, administration of recombinant human granulocyte macrophage colony-stimulating factor (rhGM-CSF), but not erythropoietin, was associated with increases in

Infectious Diseases of the Dog and Cat, 3rd Edition

virus production both in vitro and in vivo,¹⁶ and therefore potential benefits of administration of rhGM-CSF to neutropenic cats should be weighed carefully against potential risks. See [Chapter 2](#) and [Appendix 8](#) for further information.

Glucocorticoids have been administered to cats with acute and chronic experimental FIV infections, and although increases in plasma viremia and decreased CD8+ suppressor-cell activity were noted afterwards in acutely infected cats, beneficial effects have included delays in the onset of brain stem auditory-evoked potentials (BAEPs) abnormalities, or normalization of BAEPs in chronically infected cats.³² Because of the effects on viremia, indiscriminate treatment with glucocorticoids or other immunosuppressive drugs should be avoided unless a compelling indication for their use exists.^{11,361}

Fig 14-4 A, Stomatitis in the glossopharyngeal fauces in an FIV-infected cat before dental extraction. B, Stomatitis with less inflammation following dental extraction from the cat in Fig. 14-4 (Courtesy Julie Levy, University of Florida, Gainesville, Fla.)

Intact male and female FIV-infected cats should be neutered to reduce stress associated with estrus and mating behavior and the desire to roam outside the house or interact aggressively with other cats. Surgery is generally well tolerated by asymptomatic FIV-infected cats, although perioperative antibiotic administration should be considered. Because the virus lives only minutes outside the host, and is susceptible to all disinfectants, including common soap, simple precautions and routine cleaning procedures will prevent transmission while in the hospital. FIV-infected patients should be kept in individual cages and can be maintained in this manner in the general hospital population.^{11,361,525}

Opinions about general vaccination of FIV-infected cats differ. Experimental evidence shows that FIV-infected cats are able to mount immune responses to administered antigens,^{128,343} but responses may be impaired during the terminal phase of infection.¹⁹³ FIV-infected cats have developed illness with modified live virus (MLV)

Infectious Diseases of the Dog and Cat, 3rd Edition

feline panleukopenia vaccine (see Postvaccinal Complications, Systemic Illness, [Chapter 100](#)) so that inactivated boosters should be considered. Other studies suggest that immune stimulation helps stabilize CD4+ cell numbers.⁵²² In contrast, stimulation of FIV-infected lymphocytes is also known to promote virus production in vitro. In vivo, vaccination of chronically infected FIV-infected cats with a synthetic peptide was associated with a decrease in the CD4+/CD8+ ratio.³⁵⁰ Thus vaccination and antigenic stimulation may potentially be disadvantageous with a potential tradeoff of protection from infection for progression of FIV infection secondary to increased virus production, although this has never been proven in experimental studies. If FIV-infected cats are kept strictly indoors, the risk of being infected with other pathogens may be lower than the possible harmful effect of vaccination. If potential exposure to parvovirus, herpesvirus, or calicivirus cannot be excluded, only core vaccines (against panleukopenia and upper respiratory infection) and inactivated vaccines should be considered. The duration of immunity following vaccination of FIV-infected cats with inactivated products is unknown.

141

142

14.8 PREVENTION

One of the more prolific areas of FIV study has been in the area of vaccine development, spurred by use of the FIV model for development of HIV vaccines. A large number of different approaches have been taken in attempts to create FIV vaccines,^{165,215,614,641} including DNA and subunit vaccines with or without adjuvants such as cytokines,^{*} peptide or recombinant vector vaccines using various elements of the FIV virion,[†] mutant viruses,^{323,375} and fixed infected cells or inactivated or attenuated virus.[‡] Various routes of vaccine administration, including mucosal application and injection directly into a lymph node, have also been explored.^{179,180,600} One result of this work has been the introduction of an FIV vaccine marketed in the United States (Fel-O-Vax, Ft. Dodge, Fort Dodge, IA). The marketing of this vaccine has been met with controversy regarding its use, the interpretation of currently used FIV tests, and the extent of protection afforded by the vaccine.^{109,247,306,426} Using available serologic tests including immuno (Western) blotting, antibodies detected following vaccination cannot be distinguished from those caused by natural infection.²²⁰ In one study, vaccination of cats with a recombinant or the commercial vaccine caused a greater level of viremia and salivary shedding of virus in vaccinates as compared to the control animals.⁴⁸

One of the major obstacles in design of a widely effective vaccine against FIV infection is the large genetic diversity among viral isolates. Five known subtypes of FIV have been discovered, and sequence divergence within a subtype ranges from 2% to 15%, and that between subtypes ranges up to 26%. Single-strain vaccines have only provided adequate protection against homologous and closely related strains but not against moderately to greatly heterologous strains. Fel-O-Vax FIV®, the first vaccine licensed in the United States, is a dual-subtype vaccine containing inactivated FIV subtype A and subtype D with an adjuvant.^{516,630} The combination of two genetically distinct subtypes elicits strong anti-FIV cellular immunity and broad spectrum virus-neutralizing antibodies. So far, this vaccine has not been field tested against natural FIV infection, and the extent of protection against B subtype viruses, frequently found in the United States, is uncertain. Because the vaccine contains whole virus, cats respond to vaccination by producing antibodies that are indistinguishable from those produced during natural infection.⁶³⁰

The existing literature on FIV vaccines gives some reasons for scrutiny when using any FIV vaccine. First, although many vaccine studies have shown protection against FIV infection following challenge with either homologous, or in some instances, heterologous isolates, the results have been quite inconsistent. In a particularly telling study, cats vaccinated with inactivated whole virus were not protected against challenge with a heterologous isolate even though the isolates used in the study were within the same subtype (subtype A) as the

Infectious Diseases of the Dog and Cat, 3rd Edition

vaccine isolate.²⁶⁴ The isolates of this study were all of different pathogenicity, emphasizing the importance of understanding the challenge inocula and the vaccine strategy employed. The difficulties in developing FIV vaccines need to be understood by the clinician when evaluating vaccine claims, and for FIV, perhaps more facets need to be considered than with other infectious agents (Table 14-7). Although not demonstrated with the commercially available vaccine, in some instances, concern still exists that vaccination against FIV may enhance infection.^{209,310,311,527} For all the reasons previously noted, the best prevention of FIV infection remains segregation of FIV-infected from noninfected cats.³

Table 14-7 Factors to be Considered in the Evaluation of FIV Vaccine Efficacy

Vaccine type: DNA vaccine, subunit vaccine, inactivated vaccine
Route of vaccination: parenteral, mucosal
Origin of challenge isolates: homologous or heterologous, relatedness of challenge homologous isolates to vaccine strain, cell-culture adapted or field isolates
Type: cell-free versus cell-associated virus
Amount of challenge inoculum
Interval between vaccination and challenge
Route of challenge: parenteral, mucosal
Methods of detecting evidence of infection following challenge: PCR/RT-PCR, viral cultures
Tissues sampled for virus detection following challenge: peripheral blood cells, tissues
Sampling intervals
Duration of study or immunity
Number and relatedness of animals in challenge studies
PCR, Polymerase chain reaction; RT-PCR, reverse transcriptase polymerase chain reaction.

Other strategies for preventing infection have been explored. Protection against homologous isolates has been achieved by passive immunization and adoptive transfer of lymphocytes from vaccinated cats.⁵¹⁸ Kittens may be protected from infection if the queen has a high concentration of FIV-specific antibody, suggesting that stimulation of humoral immunity has a role in protection.^{257,517} Detection of cytotoxic T-lymphocyte activity after vaccination implicates a role for CMI in protection.^{192,518,608}

14.9 PUBLIC HEALTH AND OTHER CONSIDERATIONS

FIV is a feline pathogen, and no demonstrated evidence has been found that it can infect people, even those such as veterinarians who are at greater risk of exposure.⁹⁰ However, infection of human peripheral blood mononuclear

Infectious Diseases of the Dog and Cat, 3rd Edition

cells has been accomplished in vitro with a laboratory-maintained FIV isolate,^{296,299} and clinical disease was induced in cynomolgus monkeys after autologous transfusion with peripheral blood mononuclear cells infected in vitro.²⁹⁵ However, no evidence has been found to link FIV infection to any human disease, including AIDS. Investigations have failed to identify antibodies in people that have been bitten by infected cats or that have inadvertently injected themselves with virus-containing material.⁶⁷³ A large number of studies have investigated the potential of FIV to serve as a gene-delivery system with the ultimate goal of treating nonlentiviral diseases. Genetically manipulated isolates of FIV have shown some promise as a vector for gene transfer in a number of systems involving cell lines derived from people and other species.*

¹⁵CHAPTER 15 Feline Adenovirus Infection

Frances A. Kennedy

Clinically apparent disease caused by systemic adenoviral infection is most common in immunologically compromised animals.^{1,2} In studies of cats in Hungary, Scotland, the Netherlands, the Czech Republic, and the United States, serologic findings confirmed adenovirus in 15%, 10%, 20%, 25%, and 26% of cats, respectively.^{6,7,10} However, only one case of confirmed disseminated adenovirus infection in a cat has been reported.⁵ Inclusion body hepatitis reported in a black panther³ was suggestive of adenovirus infection; however, the causative agent could not be confirmed by electron microscopy (EM) or by virologic identification.

In the confirmed case of disseminated adenovirus infection, a comatose, 8-year-old, spayed, female, domestic shorthair cat had petechiae on the oral mucous membranes. Abnormal hematologic findings included leukopenia (2,100 cells/ μ l) and thrombocytopenia (73,000/ μ l). Treatment with intravenous (IV) lactated Ringer's solution, dexamethasone, and vitamin K produced no response. The cat died 4 hours after presentation.

Necropsy revealed that the abdominal cavity and pericardial sac were filled with serous fluid. Serosal and mucosal surfaces of the small and large intestines were diffusely dark red with scattered serosal petechiae, and the intestinal contents were fluid and dark red. The liver and kidneys were swollen, and the liver had an accentuated lobular pattern.

An undiluted sample of serous abdominal fluid gave a positive test result for the group-specific antigen (p27) of the feline leukemia virus (FeLV) and a negative result for antibody to the feline immunodeficiency virus (FIV). A specimen of ileum was positive for feline coronavirus by direct fluorescent antibody (FA) testing. An enzyme-linked immunosorbent assay (ELISA) test for feline panleukopenia virus was negative on specimens of liver, kidney, ileum, mesenteric lymph node, and spleen. An adenovirus particle was identified by EM examination of the intestinal contents.

Histologic examination showed that the endothelial cells were detached from the intramyocardial arteries, and the sloughed cells were large and spindle shaped, with occasional multinucleated cells (Fig. 15-1). Nuclei of these cells were large and pleomorphic, with intranuclear inclusion bodies. Multiple round eosinophilic inclusions were present in some nuclei, with amphophilic granular inclusions filling other nuclei. Some nuclei were almost filled with well-delineated basophilic inclusions, with margination of the small amount of surrounding chromatin. Some of the basophilic nuclei had indistinct borders, resulting in the appearance of "smudge cells." Their cytoplasm was eosinophilic. Minimal perivascular infiltrates of lymphocytes were present in the myocardium.

The stomach had diffuse, submucosal edema. Diffuse superficial necrotizing and hemorrhagic enteritis with submucosal edema was present in the small intestine. Necrosis was more severe in the ileum, with full-thickness mucosal necrosis over Peyer's patches. Moderate lymphoid depletion and peripheral hemorrhage in submucosal lymphoid tissue was noted. Sections of colon were comparably affected, with submucosal edema and particularly severe mucosal necrosis overlying areas of prominent submucosal lymphoid tissue. Submucosal and mesenteric blood vessels at all levels of the gastrointestinal (GI) tract had endothelial lesions as described in the heart. Similar vascular lesions were seen in small hepatic arteries, pulmonary arteries, trachea, thymic remnant, urinary bladder, thyroid gland, adrenal gland, bone marrow, spleen, lymph node, and kidney. Depletion of lymphoid follicles in the spleen and lymph nodes was noted.

Infectious Diseases of the Dog and Cat, 3rd Edition

EM examination of detached endothelial cells revealed intranuclear aggregates of viral particles measuring approximately 65 nm in diameter (Fig. 15-2). Some of these particles were roughly icosahedral, with dense central cores. In some areas, viral particles formed loose crystalline arrays.

144

Infectious Diseases of the Dog and Cat, 3rd Edition

Because adenoviruses have relatively narrow ranges of host specificity, the horses, dogs, and goat on the property of the infected cat (all of which were clinically normal) were considered to be unlikely sources of infection in this cat. Other cats on the property were clinically normal. It is possible that FeLV infection produced an immunodeficient state in the affected cat, predisposing it to develop disseminated adenovirus infection. Leukopenia may have been a consequence of FeLV infection, terminal endotoxemia, or both. The cat's thrombocytopenia was most likely associated with consumption secondary to vascular lesions, because the bone marrow had adequate numbers of megakaryocytes.

The positive direct FA test for feline coronavirus probably indicated a subclinical infection with feline enteric coronavirus. No gross or histologic lesions typical of feline infectious peritonitis were found.

Fig 15-2 Electron micrograph of an endothelial cell with intranuclear viral particles. Moderate autolytic change is responsible for disruption of adenoviral arrays ($\times 17,900$). (From Kennedy FA, Mullaney TP. 1993. *J Vet Diagn Invest* 5:273-276.)

Serologic studies have suggested that persistent, subclinical adenovirus infection exists in the feline population. Significant increases in rates of positive titers were found with increasing age and among cats with signs of respiratory or GI disease.¹⁰ In a group of five FIV-positive laboratory cats in Italy, serologic testing revealed that four were positive for adenovirus.⁷ However, to date, only one case of adenovirus infection in a cat has been confirmed by the polymerase chain reaction.^{8,9} The affected cat had a period of transient hepatic failure, and serologic testing confirmed adenovirus infection. Adenovirus hexon capsid nucleic acid was detected in two rectal swabs taken at a 1-year interval and a pharyngeal swab taken at the second sampling from this cat. This finding suggests that in addition to persistent subclinical infections, cats may be a source of persistent adenovirus shedding.

16 CHAPTER 16 Feline Respiratory Disease

Rosalind M. Gaskell

Susan Dawson

Alan Radford

16.1 ETIOLOGY

Feline infectious respiratory disease is most commonly seen in cats that are grouped together, as in multicat households, boarding catteries, and breeding establishments. The disease is multifactorial, with several etiologic agents involved and a significant number of other risk factors identified.^{3,4,94}

The majority of cases of infectious respiratory disease are caused by one of two viruses: feline herpesvirus-1 (FHV-1, or feline rhinotracheitis virus) and feline calicivirus (FCV). FHV-1 generally induces more severe disease than FCV does, but FCV appears to be relatively more common.^{7,27,60} This prevalence may relate to the antigenic diversity of the virus and the inability of current vaccines to protect equally well against all FCV strains.^{47,60}

Increasingly apparent is that *Bordetella bronchiseptica* is also a primary pathogen of the feline respiratory tract, although its precise contribution to disease in the field is not yet fully established.^{3,24,89} Interestingly, transmission of the organism between dogs and cats may occur, which has implications for disease control in both species.^{3,5,15,24}

Chlamydomydia felis (previously *Chlamydia psittaci* var. *felis*) is also involved in feline respiratory disease, although it is considered predominantly a conjunctival pathogen (see also [Chapter 30](#)). Other agents that have been implicated in the syndrome include mycoplasmas and other bacteria, feline reovirus, and cowpox virus.²⁷

16.1.1 Feline Herpesvirus-1

FHV-1 is a typical α -herpesvirus containing double-stranded DNA, with a glycoprotein-lipid envelope. As in most herpesviruses, FHV-1 is relatively fragile in the external environment and is highly susceptible to the effects of common disinfectants. It can survive for only up to 18 hours in a damp environment, less in dry conditions. It is also relatively unstable as an aerosol.

As well as infecting domestic cats, FHV-1 has been shown to infect several other members of the Felidae.^{13,70,104} The virus is also very closely related genetically and antigenically to canine herpesvirus-1 and phocine (seal) herpesvirus-1 (PhV-1), and cross-protection between feline and PhV-1 has been reported.^{55,110}

FHV-1 has little strain variation. Most isolates produce a relatively uniform disease, although some show reduced or increased virulence. Antigenically, all strains belong to one serotype, and apart from some minor differences, they are relatively homogeneous on restriction enzyme analysis of their DNA. Therefore no easy method is currently available to study the role of individual FHV-1 isolates in disease.

Infectious Diseases of the Dog and Cat, 3rd Edition

16.1.2 Feline Calicivirus

FCV is a small, unenveloped, single-stranded RNA virus, a member of the *Vesivirus* genus of the calicivirus family. Both domestic cats and other members of the Felidae family can be infected, and a similar virus has also been isolated from lions.^{13,45} Although dogs have their own genetically distinct calicivirus,^{56,82} caliciviruses antigenically and genetically related to FCV have also been detected in dogs (see [Chapter 8](#)),^{35,54,83} and some epidemiologic evidence suggests a link between the two.⁴

FCV is slightly more resistant than is FHV-1, surviving for up to a week in the external environment or possibly longer if conditions are damp. The virus is not as susceptible to the effects of disinfectants as FHV-1,²⁰ but a useful disinfectant for both viruses is bleach diluted 1 part in 32 in water with added detergent.

A large number of different strains of FCV exists, which vary slightly in antigenicity and pathogenicity, although they are all sufficiently cross-reactive to be classified as one serotype. Genetically, these strains appear to represent one large group or genogroup, although again, considerable variability may be seen between isolates, particularly in immunogenic regions of the viral capsid gene.* This genetic diversity is useful epidemiologically in that it allows differentiation between FCV strains.^{71,73-75,96}

Most strains of FCV are closely related enough to induce some degree of cross-protection, but cats can still be sequentially infected with different viruses and show varying degrees of clinical illness. Some isolates appear to be more immunogenic and cross-reactive than do others, and several such strains (e.g., the original vaccine strain F9 and strain 255) have been widely used in vaccines. However, no single strain is likely to protect equally well against all field isolates, and some evidence indicates that the percentage of isolates neutralized by such strains may be decreasing, possibly caused by immune selection pressures from widespread vaccine use.^{8,27,47,60} Routine monitoring of vaccine efficacy against current isolates would be useful.

* References 1, 30, 31, 40, 46, 72

16.1.3 *B. bronchiseptica*

B. bronchiseptica is an aerobic, gram-negative coccobacillus that is a well-known respiratory pathogen in dogs, swine, and rodents. It also causes occasional opportunistic infection in people: indeed, a case has been reported in a veterinary student.²⁴ (See Public Health Considerations, [Chapter 6](#), for further information on this risk.) In the past, *B. bronchiseptica* was thought to play only a secondary role in feline respiratory disease, but it is now established as a primary pathogen in cats. Respiratory disease has been reproduced in *Bordetella*-free, specific-pathogen-free (SPF) cats after aerosol or nasal challenge,^{12,42,44,109} and a large number of field cases have been reported.[†] However, a significant number of factors likely play a role in whether disease occurs in the field, and various risk factors for *B. bronchiseptica* infection in cats have been identified in epidemiologic studies.³

† References 41, 48, 89, 101, 108

16.1.4 Other Organisms

C. felis causes acute to chronic conjunctivitis in cats, although respiratory signs may also be seen. The prevalence of *C. felis* in cats with conjunctival or upper respiratory tract disease has been reported in studies

145

146

Infectious Diseases of the Dog and Cat, 3rd Edition

using polymerase chain reaction (PCR) to range between 14.3%⁹⁴ and 59%.⁷ The disease is discussed in more detail in [Chapter 30](#).

Reoviruses have been occasionally isolated from cats, and conjunctival and respiratory signs have been induced after experimental inoculation. However, no evidence has been found that reoviruses are important as respiratory pathogens in cats in the field.

Cowpox virus infection in cats causes primarily skin lesions, but occasionally respiratory or ocular signs may also be seen (see [Chapter 19](#)). The reservoir hosts of cowpox virus in Europe are small wild mammals, and cats occasionally become infected by contact through hunting. Other orthopoxviruses, that may infect cats, exist in other parts of the world.

The role of mycoplasmas in feline respiratory disease is not clear. Undoubtedly, they can be important as secondary pathogens, but their role as primary agents is more equivocal (see [Chapter 32](#)). Infection is common in both colony cats and household pets, and mycoplasmas have been isolated from both diseased and healthy animals. Increasing evidence indicates that mycoplasmas may be associated with disease in the lower respiratory tract; however, their role in upper respiratory tract disease is less clear.^{10,32,76} Mycoplasmas have been isolated in pure culture from cases of bronchopneumonia, which have responded to antimycoplasmal therapy.²⁵ Other bacteria such as *Staphylococcus* spp., *Streptococcus* spp., *Pasteurella multocida*, and *Escherichia coli* are thought to play a role as secondary invaders in feline respiratory disease.

16.2 EPIDEMIOLOGY

16.2.1 Feline Herpesvirus-1 and Feline Calicivirus Infections

FHV-1 and FCV are fairly widespread in the general cat population, with a higher prevalence in multicat households. The viruses are mainly shed in ocular, nasal, and oral secretions, and spread is largely by direct contact with an infected cat. Acutely infected animals are clearly one of the most important sources of virus, but infection also commonly occurs from clinically recovered carrier cats. In some situations, particularly within a cattery, indirect transmission may also occur. Contaminated secretions may be present on cages, feeding and cleaning utensils, and on personnel. However, because the viruses are relatively short lived outside the cat, the environment is usually not a long-term source of infection.

Aerosols are not thought to be of major importance for the spread of FHV-1 and FCV. Cats do not appear to produce an infectious aerosol for these agents during normal respiration, although sneezed macrodroplets may transmit infection over a distance of 1 to 2 meters.

Despite vaccination, carriers are widespread in the population and are probably the main reason why these viruses are so successful. An understanding of the FHV-1 and FCV carrier states is important to help determine strategies for control.

16.2.2 Carrier State for Feline Herpesvirus-1

As with other α -herpesviruses, virtually all recovered cats become latently infected carriers. However, intermittent episodes of detectable virus shedding (reactivation) may occur, particularly after periods of stress ([Fig. 16-1](#)). During such episodes, infectious virus is present in oronasal and conjunctival secretions, and cats

Infectious Diseases of the Dog and Cat, 3rd Edition

may infect other cats. The epidemiologic significance of PCR-positive cats, which are negative by traditional virus culture, is not clear, but they are likely to be less infectious.^{6,95,107}

Virus reactivation may occur spontaneously but is most likely after stress, for example, going into a boarding cattery, to a cat show, or to stud. Glucocorticoid treatment can also induce shedding, but using this drug to detect carriers is inadvisable because severe disease may occasionally result. Some carrier cats appear to shed virus more frequently than do others and therefore are of greater epidemiologic importance.

Shedding does not occur immediately after the stress; a lag period of approximately 1 week occurs, followed by a shedding episode of from 1 to 2 weeks. Thus carrier cats are most likely to be infectious for up to 3 weeks after a stress factor. In some cases, carriers show recrudescence of mild clinical signs while they are shedding, which can be a useful indicator that they are likely to be infectious.

The stress of parturition and lactation may also precipitate virus shedding in latently infected queens, but whether or not the kittens develop disease depends on their levels of maternally derived antibody (MDA). On some occasions, kittens with low levels of MDA may become subclinically infected and become latent carriers without showing clinical signs. Such a mechanism is obviously ideal for the virus because it can spread to the next generation without harming its host.

As with some other herpesviruses, FHV-1 remains latent in carriers in the trigeminal ganglia, although virus has also been detected by PCR in a large number of other tissues.^{81,107} The latent carrier state is almost certainly lifelong, but a refractory phase of several months occurs after a period of virus shedding when animals are less likely to experience another reactivation episode.

16.2.3 Carrier State for Feline Calicivirus

Unlike FHV-1 carriers, FCV carriers shed virus more or less continuously and are mostly therefore always infectious to other cats (Fig. 16-2). The virus persists in tonsillar and other oropharyngeal tissues. In some cats, the carrier state appears to be lifelong, but most animals at some point spontaneously recover and appear to eliminate virus. In some experimental studies, most cats were shedding FCV 30 days after infection, and by 75 days, approximately 50% of cats were still shedding. This proportion continues to decline, with only a minority of animals becoming long-term carriers. In other studies, carrier states have been difficult to reproduce, suggesting that virus strain differences or other factors may be involved. Some evidence indicates that preexisting feline immunodeficiency virus (FIV) infection may potentiate FCV shedding from carriers, either in terms of duration or titer of virus.^{16,79}

FCV carriers have been arbitrarily divided into high, medium, and low level, each shedding a fairly constant amount of virus that fluctuates around a mean for that individual cat. High-level shedders are very infectious and easily detected by oropharyngeal swabbing; low-level shedders are less infectious, and a series of swabs taken over several weeks may be necessary to identify them.

FCV carriers are very common, and prevalence rates are still similar to those reported some years ago, before the introduction of vaccination. Surveys have shown that approximately 20% to 30% of cats, depending on the population studied, are shedding FCV.^{4,27,74} Although many of these cats will be carriers, some may be undergoing reinfection, and others may be undergoing primary infection with a nonpathogenic strain. Vaccination protects against disease but not infection or the carrier state, and mathematical modeling studies suggest that a reduction in FCV prevalence is unlikely with the current levels of vaccine efficacy.⁷⁷

146

Fig 16-1 FHV-1 carrier state: epidemiology. (From Gaskell RM, Radford AD, Dawson S. 2004. Feline infectious respiratory disease, p 583. In Chandler EA, Gaskell CJ, Gaskell RM [eds], *Feline medicine and therapeutics*, ed 3, Blackwell Publishing, Oxford. Used with permission.)

16.2.4 B. bronchiseptica Infection

Serosurveys have shown that *B. bronchiseptica* is widespread in the cat population. Seroprevalence of between 24% and 79% and isolation rates of up to 47% have been reported, depending on the type and clinical status of the population tested.^{*} In a large-scale epidemiologic survey of cats in the United Kingdom with and without respiratory disease, 11% of 740 cats were found to be shedding *B. bronchiseptica* from the oropharynx, with a higher positive number in rescue catteries and in households with larger numbers of cats.³ An association between *B. bronchiseptica* infection and respiratory disease was found in the rescue cattery population, which fits with previous empirical observations that the organism is more likely to cause disease in stressful, crowded situations.

Infectious Diseases of the Dog and Cat, 3rd Edition

Also apparent is that transmission of this bacterium may occur between dogs and cats, which clearly has implications for control, especially where dogs and cats are housed on the same premises. Epidemiologic studies have shown that contact with dogs with recent respiratory disease was found to be a risk factor for *B. bronchiseptica* infection in cats.³ In addition, typing of isolates from dogs and cats using pulsed-field gel electrophoresis (PFGE) has shown that isolates from both species on the same premises are likely to be similar.^{5,24} Another report showed two cats developing respiratory disease following contact with two dogs with kennel cough, and *B. bronchiseptica* isolated from all four animals were found to be the same using PFGE.¹⁵ Interestingly, Foley and colleagues²⁴ noted that the majority of isolates circulating in dogs and cats in two shelters in the United States appeared to be similar to a canine and feline vaccine strain.

Epidemiologic evidence suggests that a carrier state may exist in cats with *Bordetella* infection, with 9% of clinically healthy cats shedding the organism.³ Experimental work has shown that *B. bronchiseptica* is shed in both oropharyngeal and nasal secretions, in some cases for at least 19 weeks after infection.¹² In the same study, *B. bronchiseptica* was detected in two seropositive queens after parturition despite being negative beforehand, suggesting the stress of parturition may have initiated shedding.

16.3 PATHOGENESIS

16.3.1 Feline Herpesvirus-1 Infection

The natural routes of infection for FHV-1 are nasal, oral, and conjunctival, and virus replication takes place predominantly in the mucosae of the nasal septum, turbinates, nasopharynx, and tonsils. Virus shedding can be detected in oropharyngeal and nasal swabs as early as 24 hours after infection and generally persists for 1 to 3 weeks.

147

Fig 16-2 FCV carrier state: epidemiology. (Flow diagram from Gaskell RM, Radford AD, Dawson S. 2004. Feline infectious respiratory disease, p 584. In Chandler EA, Gaskell CJ, Gaskell RM [eds], *Feline medicine and therapeutics*, ed 3, Blackwell Publishing, Oxford. Used with permission. Virus drawing courtesy of University of Georgia, Athens, Ga.)

Viremia is rare because virus replication is normally restricted to areas of lower body temperature, such as the respiratory tract. However, viremia has occasionally been reported, and generalized disease may be seen, particularly in debilitated animals or in neonatal kittens.

Infection leads to areas of multifocal epithelial necrosis, with neutrophilic infiltration and exudation with fibrin. In early infections, intranuclear inclusion bodies may be seen. Viral damage can also lead to osteolytic changes in the turbinate bones. Lesions normally take between 2 and 3 weeks to resolve, although bone damage to the turbinates may be permanent. Primary lung involvement may occur but is rare. Secondary bacterial infection can enhance the pathogenic effect of FHV-1; thus bacterial sinusitis or pneumonia is possible.

Infectious Diseases of the Dog and Cat, 3rd Edition

16.3.2 Feline Calicivirus Infection

Similar to FHV-1, the natural routes of infection for FCV are nasal, oral, and conjunctival. Virus replication mainly occurs in the oral and respiratory tissues, although some differences between strains can be found. Some strains have a predilection for the lung, and others have been found in the macrophages within the synovial membrane of joints.^{14,100} Virus may also be found in visceral tissues and feces and occasionally in the urine.

Oral ulcers are the most prominent pathologic feature of FCV infection. These ulcers begin as vesicles, which subsequently rupture, with necrosis of the overlying epithelium and infiltration of neutrophils at the periphery and the base. Healing takes place over 2 to 3 weeks.

Pulmonary lesions appear to result from an initial focal alveolitis, which leads to areas of acute exudative pneumonia and then to the development of a proliferative, interstitial pneumonia. Although primary interstitial pneumonia can occur in FCV infection, particularly with more virulent strains, it has probably been overemphasized in the past as a result of experimental studies using aerosol challenge rather than the more natural oronasal routes.

Lesions seen in FCV-infected joints consist of an acute synovitis with thickening of the synovial membrane and an increased amount of synovial fluid within the joint.

16.3.3 *B. bronchiseptica* Infection

In most species, the primary route of infection with *B. bronchiseptica* appears to be via the oronasal cavity where the organism colonizes mucosal surfaces. The bacterium uses several virulence factors to adhere to the cilia of the respiratory epithelium. Once attached, ciliostasis and destruction of the cilia occur, resulting in the failure of the mucociliary clearance mechanism and facilitating further colonization and persistence of bacteria. The release of toxins from *B. bronchiseptica* following colonization is responsible for local and systemic inflammatory damage.

148

In dogs, the organism appears to target mainly the mucosa of the trachea and bronchi, leading to tracheobronchitis. Although the precise pathogenesis of the disease in cats is unclear, upper respiratory tract involvement appears to be more common. However, clearly in some instances, the lower respiratory tract may also be targeted, given that bronchopneumonia and coughing may occur.

149

Although *B. bronchiseptica* may appear to be a primary pathogen in cats, undoubtedly other factors such as combined infections with the respiratory viruses and stress factors such as weaning, overcrowding, and poor hygiene and ventilation all play roles. Such factors may account for the severe cases of bronchopneumonia that have been reported in the field.

16.4 CLINICAL FINDINGS

Whatever the respiratory pathogen, the observed clinical signs will depend on a large number of factors, such as the infecting dose and strain of the agent, the general health and husbandry conditions of the cat, the nature of its microbial flora, and any preexisting immunity (Table 16-1). Concurrent infection with immunosuppressive viruses such as FIV and feline leukemia virus may lead to more severe disease.^{16,78,79}

Infectious Diseases of the Dog and Cat, 3rd Edition

16.4.1 Feline Herpesvirus-1 Infection

In susceptible animals, FHV-1 infection generally causes a severe upper respiratory disease. The incubation period is usually 2 to 6 days but may be longer with lower levels of challenge virus.

Early signs include depression, marked sneezing, inappetence, and pyrexia, followed rapidly by serous ocular and nasal discharges (Fig. 16-3). These initial clinical signs may be accompanied by excessive salivation with drooling. Conjunctivitis, sometimes with severe hyperemia and chemosis, typically develops, and copious oculonasal discharges occur. These discharges gradually become mucopurulent, and crusting of the external nares and eyelids can occur (Fig. 16-4). In severe cases, dyspnea and coughing may also develop. Oral ulceration can occur with FHV-1 infection, but it is rare. Occasionally, generalized infections and primary viral pneumonia may occur, particularly in young or debilitated animals.

a Strain variation.

b Often persistent.

c Slight wetness may be seen around the mouth if ulcers present.

Other manifestations of FHV-1 infection include ulcerative and interstitial keratitis and corneal sequestration; a possible association with uveitis has also been reported (Fig. 16-5).⁵¹ Improved diagnosis, for example, using PCR, has lead to greater recognition of such conditions.^{64,91} Skin ulcers and dermatitis syndrome in domestic cats and cheetahs,^{33,34,62a} and nervous signs have been described, but these are likely to be rare sequels to infection.

Although abortion is a feature of some other α -herpesvirus infections, experimental studies have suggested that, in FHV-1, the severe systemic effects of the illness, rather than a direct effect of the virus itself, are most likely

Infectious Diseases of the Dog and Cat, 3rd Edition

the cause of abortion. Indeed, in an investigation of a natural outbreak of FHV-1 in SPF cats, no cases of abortion were seen, even in severely affected pregnant queens.³⁷

In very young kittens or immunosuppressed cats, the mortality rate may be high, but on the whole, mortality with FHV-1 is low. Clinical signs generally resolve within 10 to 20 days. However, in some cats the acute damage may have been severe enough to lead to permanent damage to the mucosae and turbinates, leaving individual cats prone to chronic bacterial rhinitis, turbinate osteomyelitis, sinusitis, and conjunctivitis. Short-nosed purebred cats such as Persians or Himalayans appear to have an increased tendency to develop chronic upper respiratory complications, although the reasons for this are not yet clear.

Infectious Diseases of the Dog and Cat, 3rd Edition

16.4.2 Feline Calicivirus Infection

Strains of FCV can differ in tropism and virulence; therefore a wide range of clinical signs may be seen. Most strains induce a fairly characteristic, mild syndrome characterized by pyrexia, oral ulceration, and mild respiratory and conjunctival signs. Some strains of FCV, however, are nonpathogenic; others are more virulent and may induce more severe systemic disease. Several outbreaks of a severe acute systemic febrile disease with high mortality have been described, caused by particularly virulent strains of FCV.^{23,43,66,84}

In a typical case of FCV infection, early signs include depression and pyrexia, although cats typically stay brighter than with FHV-1 infection. Oral ulceration is the most characteristic feature of FCV infection and may be the only clinical sign present (Fig. 16-6). Ulceration is usually on the tongue but can occur elsewhere in the mouth, on the lips, and on the nose. Skin ulceration on other parts of the body occurs rarely.

Sneezing, conjunctivitis, and ocular and nasal discharges typically occur but are generally much less prominent compared with FHV-1 infection. Cats with oral ulcers may show hypersalivation with moisture on the fur around the mouth, but generally, no drooling of saliva occurs. Some of the more virulent strains can cause pneumonia with associated dyspnea.

Some FCV strains produce lameness and pyrexia.^{27,100} The lameness may or may not be associated with oral and respiratory signs, and it is likely that considerable overlap exists between the conditions.⁹⁹ Affected cats are often dull and anorexic. In most cases, full recovery occurs within 24 to 48 hours, and so far, no evidence can be found of any long-term effects on the joints. Acute lameness has also been observed after vaccination, and in some of these cases, viruses originating from live vaccines may be involved.⁷¹

Several outbreaks of the recently reported severe systemic syndrome have been described.^{23,43,66,84} Affected cats variably show facial and paw edema (approximately 50%), pyrexia (90%), classic signs of upper respiratory infection (50%), icterus (20%) and hemorrhages from the nose and in the feces (30% to 40%). Necropsy findings included pneumonia, hepatomegaly, pancreatitis, and pericarditis. Many of the affected cats were fully vaccinated, suggesting that, as with more typical strains of FCV, vaccines may not completely protect against these virulent systemic disease-producing isolates. The outbreaks were relatively well controlled with strict quarantine and isolation, but given that FCV is an inherently variable pathogen, clinicians must remain vigilant in the event of such viruses appearing again.

The chronic oral disease, lymphoplasmacytic gingivitis stomatitis complex (LPGS) has also been associated with FCV infection. In some studies, more than 80% of cats with chronic oral disease have been found to shed FCV compared with approximately 20% of controls,²⁷ but these figures probably depend on the criteria used to select clinical cases.⁹⁸ FCV infection has been associated with acute faucitis,⁸⁰ and in one colony of cats chronic stomatitis developed after the accidental introduction of FCV.¹⁰⁶ However, other agents, in particular FIV, and various host factors appear to be involved in the condition, and the pathogenesis is not yet fully understood (see Stomatitis, Chapter 89).

16.4.3 B. bronchiseptica Infection

In naturally occurring disease, a wide range of clinical signs have been reported in cats infected with *B. bronchiseptica*, varying from upper respiratory tract signs of sneezing, oculonasal discharge, and coughing to

Infectious Diseases of the Dog and Cat, 3rd Edition

severe dyspnea, cyanosis, and death caused by bronchopneumonia.* In general, coughing appears to be less marked in cats than it is in dogs infected with *B. bronchiseptica*. Young kittens appear to be most susceptible to disease, particularly bronchopneumonia.

In experimental studies using SPF cats, the main clinical signs of *B. bronchiseptica* infection were pyrexia, lethargy, coughing, sneezing, oculonasal discharge, and submandibular lymphadenopathy, which resolved after approximately 10 days.^{12,42,44,109}

* References 3, 15, 89, 101, 108.

16.5 DIAGNOSIS

Diagnosis may be attempted based on clinical signs alone. For example, predominantly oral ulceration might indicate FCV, whereas marked sneezing with more severe respiratory and conjunctival signs might suggest FHV-1 (see Table 16-1). With *Chlamydophila* infection, the main clinical sign is a marked persistent conjunctivitis (see Chapter 30).

Table 16-2 Therapy of Feline Respiratory Infections

DRUG	DOSE ^a	ROUTE	INTERVAL (HOURS)	DURATION (DAYS)	INDICATIONS
Iodoxuridine (0.1% solution)	One drop	Topical in eye	4–6	21	FHV-1 ulcerative keratitis
Interferon-α	30 U	PO	24	7 ^b	Acute respiratory and ocular herpesvirus infections
Interferon-α (25–50 U/ml solution) ^c	One drop	Topical in eye	4–6	prn	Ocular herpesvirus infections
L-lysine	200–500 mg	PO	12	prn	Acute and latent FHV-1 infections
Tetracycline	15–22 mg/kg	PO ^d	8	14–21	Bordetellosis, <i>Chlamydophila</i> infection
Doxycycline	5 mg/kg	PO ^d	12	14–21	Bordetellosis, <i>Chlamydophila</i> infection
Trimethoprim-sulfonamides	15 mg/kg	PO	12	7–14 ^e	Bordetellosis
Enrofloxacin	5 mg/kg	PO	24	7–14 ^f	Bordetellosis, <i>Chlamydophila</i> infection
Phenylephrine 2.5% solution	1 drop	Topical in each nostril	12	7	Nasal decongestion

FHV-1, Feline herpesvirus-1; U, units; PO, by mouth; prn, as needed.

- a Dose per administration at specified interval. For additional information on antimicrobial drugs, see Drug Formulary, Appendix 8.
- b Drug is given on and off on 7 day cycles for an indefinite period.
- c Note: use of IFN-ω topically has not been studied.
- d Tetracyclines, especially as the hydrochloride salts, can cause esophagitis unless precautions are taken. See Drug Formulary, Appendix 8.

Infectious Diseases of the Dog and Cat, 3rd Edition

- e This drug can be myelosuppressive or have nephrotoxicity in cats. Monitoring of complete blood count and renal function should be done with repeated or longer treatment intervals. See Drug Formulary, [Appendix 8](#).
- f This drug can cause retinal toxicity and blindness in cats when used at higher doses or for longer periods. See Drug Formulary, [Appendix 8](#).

Confirmatory diagnosis of FHV-1 and FCV can be made from oropharyngeal or conjunctival swabs by virus isolation in feline cell cultures, by immunofluorescence or enzyme-linked immunosorbent assay (ELISA) techniques, or by PCR.* PCR is more sensitive than virus isolation is for detection of FHV-1, although the significance of PCR-positive, isolation-negative cats are unclear. For FCV, reverse transcriptase polymerase chain reaction is not currently routinely used for diagnosis, but PCR and sequencing are useful for distinguishing between FCV isolates in investigating the epidemiology of the disease.^{71,73-75,96} Serology is generally not helpful in the diagnosis of FHV-1 and FCV infection because of widespread antibody from vaccination.

For diagnosis of *B. bronchiseptica* infection, oropharyngeal or nasal swabs should be taken and placed into charcoal Amies transport medium (Beckton Dickinson, Cockeysville, Md.) before plating at the laboratory on appropriate selective medium that prevents overgrowth by other respiratory flora.⁸⁹ Transtracheal wash specimens can also be used for the isolation of *B. bronchiseptica* from clinical cases. Serology is not widely available, and many healthy cats are seropositive in any case.

Diagnosis of *C. felis* infection is described in [Chapter 30](#). *C. felis* infection should be considered when conjunctivitis is the predominant clinical sign.

When an organism is isolated from an animal with respiratory disease, a reasonable assumption is that the agent has been involved in the disease process. However, especially for FCV and *Bordetella*, a relatively large number of clinically healthy cats will also be shedding the organisms. Isolation may therefore be a coincidental finding.

* References 36, [51](#), 71, 91, 92, 95, 97, 105, 107.

16.6 THERAPY

No antiviral drugs are in widespread use for the treatment of FHV-1 and FCV. Drugs such as acyclovir, given in human herpesvirus infections, do not seem to have good activity against FHV-1, and others are either toxic or awaiting evaluation.⁶³ However, in cases of ulcerative keratitis associated with FHV-1 infection, other antivirals have been used with some success, largely based on their efficacy in human ocular herpesvirus infections.^{11,90} See [Chapter 93](#) for further information of antiviral treatment of ocular viral infections. Interferon may also be useful for cats with acute respiratory viral infections, and for ocular herpes infections, although evidence for its success is limited.^{61,90} Some data from both in vitro and in vivo studies suggest that orally administered lysine may be useful in treating acutely and latently FHV-1-infected cats.^{50,53,93} For FCV, ribavirin has been shown to be effective in cell culture but was too toxic for in vivo use.^{68,69} For additional information on the use of these drugs, see [Table 16-2](#), Antiviral Chemotherapy, [Chapter 2](#), and Drug Formulary, [Appendix 8](#).

In viral respiratory disease, broad-spectrum antibiotic therapy should be given to help control secondary bacterial infection. Because swallowing solid tablets may be painful for cats, antibiotics can be given as pediatric syrups or long-acting injections. Cats should be reexamined after 4 to 5 days and, if necessary, bacterial culture and susceptibility tests performed.

Infectious Diseases of the Dog and Cat, 3rd Edition

In vitro studies have suggested that tetracyclines, and in particular doxycycline with its longer half-life, are the antibiotics of choice for the treatment of feline bordetellosis, although occasional resistance has been observed.^{24,88} However, limited experimental evidence suggests that treatment with doxycycline may not eliminate the organism from the cat during the later stages of infection. Notably, systemic tetracyclines are theoretically contraindicated in pregnant cats or young kittens in which dental development is occurring. This is potentially less of a problem with doxycycline, although other side effects associated with its use may occur, such as esophagitis.^{58,59} Also see Drug Formulary, [Appendix 8](#). Other antibacterials that have shown good in vitro activity against *B. bronchiseptica* include trimethoprim-sulfamethoxazole and enrofloxacin.^{9,24,88} Newer erythromycin derivatives such as azithromycin and clarithromycin have been effective against human *Bordetella* isolates³⁹ and might be effective against feline *B. bronchiseptica* that is resistant to the previously mentioned antimicrobials. However, these are not licensed for feline use in European Union countries.

151

152

Good nursing care is essential in cases of feline respiratory disease and, in milder cases, is generally best given at home by the owner. The cat should be encouraged to eat by offering strongly flavored aromatic foods. If eating is painful, baby foods or specialized proprietary or blended food may be helpful. Severe cases may require hospitalization and fluid therapy, and when anorexia is prolonged, a nasogastric or gastrotomy tube may be indicated. Nasal decongestants (e.g., phenylephrine) in the acute phase and mucolytic drugs (e.g., bromhexine hydrochloride) in the more chronic phase have been suggested to help clear airways, but conventional steam inhalation (e.g., placing the cat in steamy room) or nebulizing saline may also be useful.

16.7 PREVENTION

16.7.1 Immunity

For both FHV-1 and FCV, immunity has generally been measured by serum virus neutralizing (VN) antibody levels, although for FHV-1 cell-mediated immunity (CMI) is likely to be a better reflection of immune status. VN antibody has always been considered the hallmark of immunity for FCV and is certainly important in protection, as recent studies using mouse-cat chimeric antibodies have also shown.^{102,103} However, some cats with no detectable VN antibody have demonstrated immunity to rechallenge with a heterologous strain, and several types of CMI responses have been reported.²⁷ For both viruses, local immune responses are also likely to be important. The ultimate test of immunity is, of course, response to challenge.

In FHV-1 infection, just after the primary disease, cats are generally resistant to challenge, although VN antibody titers are generally low and in some cases undetectable. After 6 months or more, protection may be only partial, and indeed, carrier cats may develop recrudescence disease. After either reactivation or field challenge, VN antibody titers rise to more moderate levels and thereafter remain reasonably stable, independent of virus shedding episodes.

Most cats are protected following the use of modified live or inactivated FHV-1 vaccines. However, immunity is not necessarily complete in all animals, even if challenge takes place within 3 months of the initial vaccination.²⁸ Similar levels of protection have been reported after a year. More studies have shown that the relative efficacy of an inactivated vaccine decreased from 83% shortly after primary vaccination to 52% after 7.5 years.⁸⁶

Infectious Diseases of the Dog and Cat, 3rd Edition

With FCV infection, VN antibody titers are higher than those in FHV-1, and immunity is generally longer lived. However, some variation exists, depending on the virus strain involved and whether homologous or heterologous protection is being considered. Reinfection with a second strain will generally boost responses to both strains.

After vaccination against FCV, reasonable protection has been reported to last 10 to 12 months.²⁹ VN antibody levels tend to be higher compared with those in FHV-1, and in general, a better correlation exists with protection. In more studies, moderate levels of VN antibody have been shown to persist in a group of vaccinated cats for at least 4 years, although after 7.5 years, titers had declined to low or nondetectable levels.^{85,86} Protection against a homologous FCV challenge decreased from 85% 3 weeks after vaccination to 63% after 7.5 years.

MDAs (i.e., essentially colostral) in kittens may persist for 2 to 10 weeks for FHV-1, with mean levels falling below detectable levels (less than 1:2) by 9 weeks of age. For FCV, in most kittens, MDAs persist for 10 to 14 weeks. However, for both viruses, low levels of MDAs do not necessarily protect against subclinical infection. Interestingly, some animals with no detectable FHV-1 antibody appeared to be protected against disease but not infection.

Studies on immunity in *B. bronchiseptica* infection have concentrated on the measurement of IgG levels in serum as measured by ELISA. After primary infection, antibody levels rise by 4 weeks to reasonably high titers. Experimental studies with an intranasal (IN) feline *B. bronchiseptica* vaccine showed that protection against challenge was present within 72 hours of vaccination and lasted for at least a year.¹⁰⁹ MDAs for *Bordetella* have been detected in experimental cats, although these appear to be fairly short lived, lasting for only 2 to 6 weeks.²⁷

16.7.2 Vaccination

Vaccination has been available for many years against the two respiratory viruses and has been relatively successful in controlling disease. However, disease can still be a problem, especially when cats are kept grouped together and when kittens lose their MDAs before vaccination. Both viruses are very widespread in the cat population and carriers are common, ensuring plenty of exposure. Prevention and control therefore often require a combined approach of vaccination and management.

Three types of FHV-1 and FCV vaccines are commercially available: modified live virus (MLV) vaccines administered parenterally or IN and inactivated adjuvanted virus vaccines given parenterally. In addition, a significant number of genetically engineered vaccines for both FHV-1 and FCV have been reported.

For routine FHV-1 and FCV vaccination programs, all types of vaccine appear to be suitable. In previously unexposed cats, all vaccines induce reasonable protection against disease but generally do not protect against infection or the development of the carrier state.

Several FCV strains are used in commercial vaccines, including strains F9 and 255. Most of these strains seem to protect against the majority of FCV isolates but not as well against all. Some evidence suggests that multivalent vaccines may increase the proportion of strains neutralized.³⁸

Parenteral MLV vaccines should be administered carefully because clinical signs can be induced if the vaccine virus reaches the oral-respiratory mucosa (i.e., if the cat licks the injection site or if an aerosol is made with the

Infectious Diseases of the Dog and Cat, 3rd Edition

syringe). Vaccine virus should not generalize, but spread of the MLV-FCV component within the cat after parenteral inoculation may sometimes occur, possibly leading to disease in the individual cat and possibly spreading to other cats.^{67,71} However, genetic typing has shown that, although some cases of disease following vaccination may be caused by the vaccine virus, the majority are associated with coincidental field virus infection.^{71,73}

IN-MLV vaccine induces better protection but often induces slight side effects, such as sneezing and ocular and nasal discharges. IN vaccines, however, are useful for rapid (2 to 4 days) onset of protection. IN vaccines used in conjunction with parenteral vaccine on entry have reduced the severity of upper respiratory disease in cats maintained at contaminated shelters for 3 or more days.¹⁹

152

Inactivated adjuvanted vaccines can be reasonably effective, and modern adjuvants have led to improvements in immunogenicity (see [Chapter 100](#)). However, adjuvants can sometimes cause local or systemic reactions. Very rarely, feline vaccine-associated sarcomas may develop at the site of injection, particularly following the use of aluminium-based adjuvants.^{28,49,62} Inactivated vaccines are helpful in virus-free colonies because no risk of spread or reversion to virulence is present. Some inactivated vaccines are licensed for use in pregnant queens, and vaccination during pregnancy can help protect kittens by prolonging MDAs.

153

Boosters for FCV and FHV-1 vaccines are traditionally recommended every year, although evidence indicates that immunity may last longer in some cases.^{85,86} In view of this finding, and because of concerns over vaccine site reactions, it has been suggested that after the first annual booster, revaccination intervals may be extended up to 3 years.^{21,22} In addition, an individual risk-benefit assessment is proposed to determine the most appropriate vaccination strategy for a particular animal.^{28,29}

For *B. bronchiseptica*, an IN-MLV vaccine is available, which has been shown to have a duration of immunity of at least a year.¹⁰⁹ The vaccine is similar to IN products available for dogs. Mild respiratory signs such as sneezing and nasal discharge may occur following vaccination, as for the IN viral vaccines. The vaccine is indicated in cases in which cats are at specific risk of acquiring *Bordetella* infection, for example, in rescue shelters or boarding catteries, or where bordetellosis is known to be a problem.

An inactivated, fimbrial subunit-based vaccine has also been marketed in some countries, but the IN vaccine will likely replace this.

16.7.3 Disease Control

The following measures apply in general to both viral respiratory disease and *B. bronchiseptica* infection. Routine vaccination for the respiratory viruses is indicated, but *B. bronchiseptica* vaccination is probably best recommended primarily for high-risk situations, such as in boarding and shelter facilities. The possibility of transmission of *B. bronchiseptica* between dogs and cats should also be considered.

16.7.3.1 Household Cats

Pets should be vaccinated regularly. If the cat goes into a boarding cattery or other high-risk situations, it should be boosted every year. From the point of view of infectious disease, ideally, a friend or neighbor should feed the cat while the owner is on vacation. Individual cats should be protected from stress and social contact as much as possible to avoid exposure.

Infectious Diseases of the Dog and Cat, 3rd Edition

16.7.3.2 Boarding Catteries

All cats entering the cattery should have an up-to-date vaccination record, with annual boosters. When rapid protection is required, IN vaccine may be given. Clients should be aware that such vaccines themselves may induce mild clinical signs.

Cattery owners should not rely on vaccination alone for disease control because pathogens will inevitably be present either from the occasional cat incubating disease or from carriers. Thus measures should be taken to prevent spread of infection and reduce the concentration of infectious agents in the environment ([Table 16-3](#)). Such measures may appear complicated, but in practice, they are not difficult to implement and, in the authors' (RG, SD, AR) experience, can actually increase the efficiency within a cattery.

16.7.3.3 Shelter Facilities

In general, the same management measures apply as those with boarding catteries. Although this practice may be more difficult to achieve, molecular typing studies have demonstrated that limiting the spread of individual FCV isolates within a shelter is possible if good hygiene measures are used.⁷⁴ Because the immune status of the cats in a rescue shelter is often unknown, incoming animals should be quarantined and isolated from others. Those with clinical signs should be kept apart. Unless animals can be isolated on arrival for 3 to 4 weeks, parenteral vaccines may not have time to become effective. In these circumstances, using the IN vaccines may be advisable if available. Infected dogs, which can act as a source of *B. bronchiseptica* infection in cats, should be housed separately where possible, especially if an outbreak of canine infectious tracheobronchitis occurs.

16.7.3.4 Breeding Catteries

In disease-free colonies, cats should be vaccinated regularly if any contact, direct or indirect, occurs with other cats. Inactivated vaccines are preferable. Care should be taken to avoid bringing virus into the colony; any cat with a history of or contact with oral or respiratory disease may be a carrier. Vaccinated cats can be carriers, and kittens can be infected subclinically because of MDAs. Thus stud cats and new breeding stock should be from a respiratory disease-free colony. The risk of infection from cat shows is possible, but the greatest risk of infection to disease-free households is from stud cats and new breeding stock when exposure is prolonged.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 16-3 Recommendations to Prevent the Spread of the Respiratory Viruses in a Boarding Cattery

Admit only fully vaccinated cats.

House cats individually with solid partitions between pens, unless cats are from same household.

Ensure that frontages are at least 1 meter apart.

Put known carriers or cats with history of respiratory disease in a separate section or at least at one end of the cattery; and feed last.

Ensure that surfaces of pen are easily washable and that food and litter bowls can be easily removed without entering the pen (i.e., do not handle cats more than necessary).

Feed cats in same order each day and attend to each pen completely before moving on to the next.

Either disinfect hands between each pen or have individual rubber gloves for each pen, for use only with that pen. Disinfect gloves thoroughly before use with a new boarder. Alternatively use disposable gloves.

Wear rubber boots and step into a disinfectant bath if it is necessary to enter a pen.

Either use disposable food trays or have two sets of food bowls used on alternate days. Soak used set in a 1:32 bleach solution with detergent for several hours and then rinse and allow to dry until reuse 24 hours later.

Prepare food in a central area.

Use similar system to food bowls for litter trays.

When a cat goes home, thoroughly disinfect cage, allow to dry, and preferably leave empty for 2 days before reusing.

Reduce concentration of virus in the environment by providing adequate ventilation, low relative humidity, and optimal environmental temperatures.

Table 16-4 Feline Respiratory Disease Control Program in a Breeding Cattery with Endemic Disease

<p>Provide regular vaccination programs.</p> <p>Give booster vaccinations to queens either before mating or during pregnancy (inactivated vaccine only).</p> <p>Keep cats as stress free as possible, and use good management practices to reduce spread of viruses within the colony.</p> <p>Avoid breeding from queens with a history of oral or respiratory disease in their kittens.</p> <p>Move queens into isolation at least 3 weeks before term so that the kittens are not exposed to carriers in the colony and that any shedding episode from the queen, as a result of the move, will end before parturition.</p> <p>Wean kittens into isolation away from the queen as soon as feasible (ideally at 4 to 5 weeks before MDAs wane if it is likely she is a carrier).</p> <p>Vaccinate all kittens as soon as MDAs are at a noninterfering level (normally 9 or more weeks), and keep them in strict isolation until a week after the second dose (normally at 12 weeks).</p> <p>Earlier FHV-1 and FCV vaccination schedules with IN or parenteral vaccines may be used, although these are not always licensed for early use and should be used with care. Parenteral vaccines can be given from 6 weeks of age, at 3 week intervals until 12 weeks of age. IN vaccination should be carried out 7 to 10 days or so before disease has been occurring and then again at 12 weeks. Some evidence indicates that multiple doses are not necessary, although they were originally advocated.</p> <p><i>MDAs</i>, Maternally derived antibodies; <i>FHV-1</i>, feline herpesvirus-1; <i>FCV</i>, feline calicivirus; <i>IN</i>, intranasal.</p>
--

Cats entering the disease-free colony should be quarantined for 3 weeks to identify animals incubating the disease. Cats should be swabbed for virus detection at least twice a week during this time. This practice increases the probability of detecting FHV-1 excretion and low-level shedding FCV carriers. Even so, the risk still exists of importing a latent FHV-1 carrier or a low-level FCV carrier that may be a source of infection. Oropharyngeal swabs may also be tested for *B. bronchiseptica* infection.

In breeding colonies where the disease is endemic, achieving or maintaining virus-free or *Bordetella*-free status is difficult. For both respiratory viruses and *B. bronchiseptica*, carriers are common providing a frequent source of infection. For most situations, the only reasonable course is to attempt disease control (Table 16-4).

17 CHAPTER 17 Feline Foamy (Syncytium-Forming) Virus Infection

Craig E. Greene

17.1 ETIOLOGY

Feline foamy virus (FeFV), previously known as “feline syncytium-forming virus,” has been classified in the family *Retroviridae*, subfamily *Spumavirinae*. Host-specific viruses of this genus have been isolated from many other mammals. The prevalence of FeFV infection is high in normal and diseased cats. Virus has been isolated from primary cultures of tissue and body secretions in up to 90% of a population of cats.⁶ More typically the prevalence of infection in a cat population varies between 4% and 50%, depending on the age, geographic location, and local environment of the cats.^{11,13} Fifty percent or more of kittens born to FeFV-infected queens are infected at birth,¹³ and 15% of cultures of fetal cats are positive for the virus, suggesting that it can be transmitted vertically.⁵ In utero infection probably occurs by the transfer of infected maternal leukocytes across the placenta, but infection is not transmitted through milk of lactating animals.¹³

155

In contrast to most feline infectious diseases, the FeFV infection rate in cat colonies is actually lower than that in the random cat population. Roaming or outdoor cats have the highest prevalence, suggesting transmission through bite wounds.

FeFV is a nuisance to virologists and manufacturers of feline vaccines because it is found in many normal feline tissues and cell cultures that have been subjected to multiple passages. In vitro, it is not host specific; in addition to cat cells, it infects cells of dogs, chickens, humans, and bats.¹⁶ It is not usually present in primary cell cultures.¹⁰ FeFV is difficult to distinguish morphologically from feline leukemia virus (FeLV), which is visualized only as it buds from the cell. FeFV forms a recognizable nucleocapsid within the cytoplasm before budding. The suitability of FeFV as a vector for feline vaccine antigens has been studied.²¹

FeFV was given its prior name of syncytium-forming virus because it produces multinucleated syncytia within 1 to 2 weeks of growth in certain rapidly multiplying tissue cultures. Cell lysis is rarely if ever noted, and intranuclear inclusions are never seen. Only in some instances has malignant transformation been noted in tissue culture. Syncytium formation in cell culture is not unique to this feline virus; it has also been associated with a variant of FeLV.¹⁷ A genetic insertion in the envelope glycoprotein gene was responsible for this cytopathic effect.

17.2 PATHOGENESIS

FeFV has not been associated with any disease; many cats have been infected naturally and experimentally and had no clinical illness. This scenario is typical of host adaptation because these viruses are apathogenic in their respective hosts.¹⁹ Virus replication appears to be moderated by the infected cat. Reports about its pathogenicity are controversial and confusing. The presence of the virus in 100% of cats affected with chronic progressive polyarthritis has been reported.¹⁵ Concurrent FeLV infection was found in 70% of these cats. The prevalence of infection with both viruses was 2 to 10 times greater than that in age-matched cats not having chronic progressive polyarthritis. By altering the host immune system, FeLV may potentiate the ability of FeFV to produce disease. Therefore one of Koch's postulates has not been fulfilled. Other factors must be involved as well because the disease cannot be induced by inoculation of FeFV alone. Combined infections with FeFV and feline immunodeficiency virus (FIV) are also frequently found. Coinfection with FeFV and FIV did not increase the

Infectious Diseases of the Dog and Cat, 3rd Edition

severity of FIV-induced illness in the early stages of the disease.²³ A combined infection is most likely a result of a common mode of transmission rather than a mutual pathogenic mechanism. In vitro FeFV strains infect lymphoblastoid cells, producing altered replication, syncytia formation, and fragmentation of cellular DNA.⁸ These features of apoptosis may be responsible for independent immune alterations in infected cats.

Arthritis, which is thought to result from chronic antigenic stimulation and immune complex deposition, is characterized histologically by lymphoplasmacytic infiltrates and is temporarily responsive to immunosuppressive therapy. An inherent genetic tendency may explain the reason certain male cats are more prone to developing disease despite the high prevalence of these viral infections in the general population.

17.3 CLINICAL FINDINGS

Most infected cats are asymptomatic. Chronic progressive polyarthritis of cats generally affects males between 1.5 and 5 years of age.^{12,14,15,22} Two forms of the disease have been described: one with osteoporosis and periarticular periosteal proliferation, the other with periarticular erosions, collapse of the joint space, and joint deformities. Lymphadenomegaly, swollen joints, and stiff gait are caused by both types.

17.4 DIAGNOSIS

Joint fluid abnormalities consist of increased numbers of neutrophils and large mononuclear cells. That FeFV stimulates antibody production in infected hosts has been used as the basis for immunodiffusion and indirect fluorescent antibody testing for antibody.^{1,15} Serology can be performed in addition to blood cultures to screen cats for infection. Infected kittens can be detected at birth by culturing buffy coat cells from their peripheral blood. Animals are infected for life and develop persistent, nonprotective antibody titers to the virus. For this reason, cats showing a serologic response to the virus are presumed to be infected. Several strains may exist, and the actual prevalence of infection may be higher than indicated by seropositivity. Neonatal kittens born to infected queens lose their maternal antibody by 6 to 8 weeks of age if they are not infected. Serum antibody titers increase after this time if they become infected.⁵

Virus can be isolated from most tissues but requires one to four passages in vitro. Actually, FeFV is detected only in vivo in cells and secretions of the oropharynx. Despite genetic material being supplied by the host, viral replication is suppressed. Latency can be expressed by cocultivating buffy coat white blood cells with fetal cat cells or by exposing cells to oropharyngeal secretions.

17.5 THERAPY AND PREVENTION

Chronic progressive polyarthritis has no known cure, and the clinical and pathologic changes it causes usually are temporarily responsive for weeks to months to immunosuppressive therapy such as prednisolone (10 to 15 mg/day per cat) and cyclophosphamide (Cytosan, Bristol-Myers Squibb, Princeton, N.J.; 7.5 mg/day per cat for 4 days each week). Cats identified as having polyarthritis should be eliminated from research projects and removed from vaccine production and specific-pathogen-free colonies.

18 CHAPTER 18 Feline Paramyxovirus Infections

Craig E. Greene

Hans Lutz

Viruses of the family *Paramyxoviridae* (genera *Paramyxovirus*, *Morbillivirus*, and *Hendra virus*) have been shown to cause infections in the central nervous system (CNS) of domestic and large exotic Felidae, although none of the viruses in this group are known to be primarily feline viruses.

18.1 AVIAN NEWCASTLE VIRUS INFECTION

Avian Newcastle disease virus (*Paramyxovirus*) has been experimentally inoculated into the CNS of domestic adult cats and kittens, producing disseminated encephalomyelitis.^{12,17} Neonatal kittens can also be infected by intraocular or intranasal exposure to large quantities of virus. The incubation period of oculonasally administered virus was relatively long (11 to 17 days) compared with that following direct CNS inoculation (3 to 4 days). Clinical signs of encephalomyelitis were seizures, head tilt, and myoclonus. Progressive lower motor neuron paralysis developed in limbs and cranial nerve musculature. In some affected animals, behavioral alterations were present. A disseminated nonsuppurative meningoencephalitis was found histologically; virus appeared to spread throughout the nervous system along descending and ascending neuronal pathways.

18.2 UNTYPED PARAMYXOVIRUS INFECTION

A paramyxovirus-like agent has also been isolated from the CNS of naturally infected cats that had focal demyelinating encephalitis and inclusion body formation.⁹ The virus was isolated from affected cats by co-cultivating CNS tissue with fetal feline kidney cell lines. The isolated virus, serologically unrelated to known paramyxoviruses, was inoculated into the CNS of neonatal mice that developed a similar encephalitis 5 months later.

Paramyxovirus-like nucleocapsids have also been observed by electron microscopy (EM) in explant cultures of CNS tissue from clinically healthy cats or those with demyelinating optic nerve lesions that were co-cultured with feline kidney or Vero cell lines.³⁴ The significance of these ultrastructural findings is uncertain.

Nonsuppurative encephalitis has been reported in an adult Siberian tiger (*Panthera tigris*), in which intranuclear inclusion bodies detected on light microscopy and nucleocapsid material detected on EM were found to be similar to those of viruses of the family *Paramyxoviridae*.¹¹ These observations could represent infections with canine distemper virus (CDV) or a variant, but definitive information is unavailable.

18.3 CANINE DISTEMPER VIRUS INFECTION

CDV, a *Morbillivirus*, has been shown to infect a wide variety of terrestrial carnivores. Domestic cats were experimentally inoculated, but clinical signs were absent (see Epidemiology, [Chapter 3](#)). In contrast to domestic cats, large exotic Felidae appear to be more susceptible to infection with CDV. Isolates appear to be immunologically similar to virulent isolates from other carnivores, but this finding does not exclude differences in viral biotypes.⁵ Mutant viral strains, originating from wildlife and domestic dogs in close proximity to the large

Infectious Diseases of the Dog and Cat, 3rd Edition

cats, are the most likely explanation for outbreaks of CDV infection in large cats.⁸ A chronic, progressive, nonsuppurative meningoencephalitis, clinically and pathologically similar to that caused by CDV in dogs, has been described in a Bengal tiger (*P. tigris*).¹² Marked increases in serum and cerebral spinal fluid (CSF) antibodies against CDV were found. Myoclonus was similar to that seen in other paramyxovirus-type infections in dogs and cats. CDV was suspected as the cause of respiratory and neurologic disease in two snow leopards (*Uncia uncia*) that had simultaneous feline panleukopenia.¹⁰ CDV was not isolated; however, histologic lesions, intranuclear inclusions, virus ultrastructure, immunofluorescence, and serologic testing were all positive for CDV infection. Feline panleukopenia virus (FPV)-induced immunosuppression was presumed to have allowed development of CDV infection.

Canine distemper outbreaks have occurred in captive leopards (*P. pardus*), tigers, lions (*P. leo*), and a jaguar (*P. onca*) in North America.^{5,36} Initial illness was manifest systemically by anorexia, gastrointestinal or respiratory signs (or both), followed by CNS signs of ataxia, myoclonus, seizures, and coma. The source of infection for one epizootic was CDV-infected raccoons and skunks having a concurrent outbreak. Viruses isolated from the affected cats were identified as CDV by monoclonal antibody testing and genetic analysis. The isolates were linked to strains from the feral nonfelid hosts and not vaccine virus.¹⁵ CNS lesions were focal and mild, consisting of nonsuppurative polioencephalitis, lymphocytic meningitis, and mild microgliosis in white matter. These lesions were less extensive and severe and did not have the demyelination and perivascular cuffing as typically observed in infected dogs. These features are more typical of acute CDV infection in susceptible carnivores (see [Chapter 3](#)).³¹

In 1994, an outbreak of CDV infection occurred in lions in the Serengeti in Tanzania.^{20,26,29} Clinical signs included seizures, myoclonus, and other neurologic symptoms. Pathology revealed encephalitis and pneumonia. Histopathology typical for CDV infection was seen in 18 of 19 lions examined. Inclusion bodies immunologically cross-reacting with CDV proteins were identified in 14 of 19 lion samples that were available for examination. Of 83 serum samples tested for anti-CDV antibodies, 71 were found to be positive for CDV.²⁶ To determine the genetic relationship of the virus involved in the disease outbreak with other *Morbilliviruses*, buffy coat cells collected from two lions with neurologic signs were subjected to reverse transcriptase-polymerase chain reaction (RT-PCR), and the nucleotide sequence of the conserved P gene was determined.²⁶ These tests suggested that the lion CDV isolate was closely related to the Onderstepoort strain of CDV. The belief holds that the lion distemper outbreak originated from distemper infections in domestic dogs living around the Serengeti parks. However, for transmission between dogs and lions, hyenas were probably responsible. Based on neurologic signs, several hyenas were found to be affected and were also proved to be infected with CDV. In addition, hyenas, in contrast to lions, are known to roam into the villages of the local inhabitants, where they may have come into contact with domestic dogs. Natural exposure or infections with CDV have been shown in wild canids in Africa.^{1,28} To determine whether the presence of other lion viruses may have favored the susceptibility to CDV, serum samples were tested for presence of antibodies to feline immunodeficiency virus (FIV), feline herpesvirus (FHV-1), feline rhinotracheitis virus (FRV), feline calicivirus (FCV), FPV, and feline coronaviruses. No relationship between the occurrence of CDV and antibodies to these other pathogens was found. Despite the apparent recent appearance of outbreaks of CDV infection in exotic Felidae, retrospective analysis of cases indicated infections as far back as 1972.²³

To reduce the probability of future outbreaks of CDV in these lions, a program to vaccinate the domestic dogs living around the parks has been initiated and is recommended for all captive large Felidae. Inactivated distemper virus vaccine has been recommended to protect large exotic Felidae against infection with this virus.⁵ However, the efficacy of inactivated vaccines in dogs and other exotic carnivores, not to mention cats, has not been

Infectious Diseases of the Dog and Cat, 3rd Edition

documented. Because chick embryo-adapted (Onderstepoort strain) vaccines are generally safer than tissue culture-adapted (Rockborn strain) ones, they should be considered for evaluation in large Felidae.^{4,5}

18.4 HENDRA VIRUS (EQUINE MORBILLIVIRUS) INFECTION

In September 1994, an outbreak of acute respiratory disease in horses occurred in Hendra, a suburb of Brisbane, Queensland, Australia.²¹ The horses developed pneumonia that was clinically characterized by anorexia, depression, pyrexia, tachypnea, and ataxia. Terminally, head pressing and a frothy nasal discharge occurred. A stable hand and horse trainer became ill with an influenza-like illness. The stable hand was ill for 6 weeks, and the trainer died of respiratory distress. A novel virus, closely related but distinct from *Morbillivirus*, was isolated from both the horses and the people. Another episode was retrospectively identified in Mckay, a town in North Coastal Queensland in a farmer who developed an acute progressive encephalitis.²⁷ The farmer had assisted with treatment and subsequent necropsy of the affected horses. Most interestingly, the horses developed myoclonic twitches similar to those observed in dogs with canine distemper. Meningoencephalitis has subsequently been documented in experimentally infected horses.³⁵

The predominant pathologic lesions in horses from the Hendra outbreak were in the lungs, which were congested and edematous. Histologically, interstitial pneumonia with pneumocyte and capillary degeneration was apparent. Virus was immunologically detected in the endothelial cells by direct fluorescent antibodies. In the Mckay episode, virus was detected by positive PCR in CSF and in the Hendra episode, in brain tissue and serum.²⁴

The equine *Morbillivirus* (EMV) was unusual in its ability to grow in cell cultures originating from a significant number of animal species, including submammalian vertebrates. A large number of laboratory animal species, including dogs and cats, were experimentally inoculated subcutaneously with the virus.³³ The dogs and cats were vaccinated for common viral diseases but notably the dogs for CDV. The dogs did not become ill, but the cats developed inappetence and tachypnea by the fifth day postinoculation (PI) and died on the sixth and seventh days PI. The cats had gross lesions of pulmonary edema, hilar lymphadenomegaly, pneumonia, and pleural effusion. Histologic lesions of vasculitis matched those in affected horses. The virus was isolated from the lungs, spleen, kidney, and brain. Surviving cats did not develop specific serum viral neutralizing antibody. Cats have also been experimentally infected via intranasal and oral exposure to virus and by direct contact with previously infected cats.¹⁶ Because EMV is so genetically distinct from other *Morbilliviruses*, it is suspected to have existed for a long time and to have been acquired from a mammalian reservoir host. Of all laboratory species inoculated, cats were most susceptible and developed an illness that matched that in horses and in people.

A limited serosurvey of cats in the metropolitan Brisbane area did not reveal detectable antibody to the virus.³³ Subsequent studies in cats have shown that they can be infected by nonparenteral routes and that the virus can spread naturally among cats.³² Of many wildlife species tested, *Pteropus* bats have serum antibodies to the virus and may be the reservoir species.³⁷ Transmission from bats to another species, such as the horse, may be required for human exposure.

In contact, transmission studies have shown that the virus is not highly contagious. Horses in direct contact with experimentally infected cats and infected horses in contact with other horses or cats did not transmit infection.³⁵ Similarly experimentally infected cats did not transmit the infection to horses. In experimentally infected animals, regardless of species, organisms were most prevalent in the kidney and urine, which suggests urinary transmission as the means of spread.³⁵ The organism was isolated for up to 3 weeks following infection of a horse and 14 months in a human developing infection, suggesting viral persistence and a carrier state.

Infectious Diseases of the Dog and Cat, 3rd Edition

18.5 NIPAH VIRUS INFECTION

An outbreak of fatal human encephalitis during 1998 and 1999 was attributed to a newly recognized paramyxovirus acquired from swine. Pigs, people who were predominantly pig farmers, dogs, and cats were infected. Although illness resulted in the other species, the disease in pigs was self-limiting and, in some cases, subclinical. Human infection was attributed to close contact with pigs. The role of dogs or cats as secondary sources of infection could not be excluded. In cats, Nipah virus was very similar in its behavior to that of closely related *Hendravirus*. Two cats were oronasally infected with Nipah virus from an outbreak in pigs that caused respiratory and neurologic signs.¹⁸ Respiratory and neurologic disease was observed in the cats, and virus was found in secretions of the oropharynx and excreted in urine. The virus causes a widespread vasculitis in many organs, especially the respiratory tract and CNS. Eosinophilic, predominantly cytoplasmic, inclusions are seen within neurons. Pulmonary lesions are giant cell pneumonia, and the secretions and tissues contain large amounts of virus.

19 CHAPTER 19 Poxvirus Infection

Malcolm Bennett

Rosalind M. Gaskell

Derrick Baxby

19.1 ETIOLOGY AND EPIDEMIOLOGY

The best described and most common poxvirus infection of cats is cowpox, caused by an *Orthopoxvirus* organism,² but infections with *Parapoxvirus*¹⁶ organisms and uncharacterized poxviruses in India and North America²⁸ have been reported. Poxviruses are relatively environmentally stable and can remain infective in dry conditions for several months to years. However, they are readily inactivated by many disinfectants, especially hypochlorites.

Cowpox virus is found only in Eurasia.² In western and northern Europe, the reservoir hosts are voles (*Clethrionomys* spp. and *Microtus* spp.),^{*} whereas in Turkmenia and Georgia the reservoir hosts are ground squirrels (*Citellus fulvus*) and gerbils (*Rhombomys opimus* and *Meriones libicus*).²

Although the domestic cat is the most frequently recognized incidental host,^{6,7,23,25} cowpox virus can also infect humans,^{3,14} cattle, and various captive exotic mammals.² A small number of cases have also been reported in domestic dogs.⁷ Rats (*Rattus norvegicus*) and house mice (*Mus musculus*) also may be rare incidental hosts.

Feline cowpox is seen primarily in rural cats that hunt rodents, and most cases are seen in summer and autumn^{5,7} when the opportunities for infection from the wildlife hosts are greatest. No sex or age predisposition to infection exists. Occasional cat-to-cat transmission occurs, as does cat-to-human transmission.³

Reports of natural orthopoxvirus infection in wild or domestic dogs are rare, although specific antibodies were found 6% to 20% of foxes in Germany.^{19,23} Intradermal inoculation of 2×10^5 PFU of cowpox virus into red foxes (*Vulpes vulpes*) produced mild skin lesions with minimal viral replication.⁸ No lesions were found after oral inoculation of virus. Another orthopoxvirus, murine ectromelia, has caused congenital disease in farm-raised silver foxes (*Vulpes vulpes* winter coat), blue foxes (*Alopex lagopus* winter coat), and mink (*Mustela vison*) in the Czech Republic.²² Orthopoxvirus infection was identified in a dog, a cat, and the owner in a household in Germany.³⁵ The infection was presumed to have spread from the cat, with lesions in the dog healing after 1 to 4 months. A natural orthopoxvirus infection, characterized by ulcerative dermatitis at the site of a suspected rat bite, was identified in a domestic dog in the United Kingdom.³³ This infection was likely caused by cowpox because this has been the only orthopoxvirus in the United Kingdom since smallpox was eradicated. The natural reservoir of ectromelia virus is not known.

* References 4, 9, 12, 13, 18, 20.

Infectious Diseases of the Dog and Cat, 3rd Edition

19.2 PATHOGENESIS

The usual route of cowpox infection in cats is skin inoculation, probably through a bite or other skin wound, although oronasal infection is also possible. Local viral replication produces a primary skin lesion, and spread to the draining lymph nodes and a leukocyte-associated viremia give rise to widespread secondary skin lesions. During the viremic period, virus can be isolated from the respiratory tract.

19.3 CLINICAL FINDINGS

19.3.1 Cats

Feline cowpox usually causes widespread skin lesions, but most cats have a history of a single primary skin lesion, generally on the head, neck, or forelimb. Primary lesions often are accompanied by a concurrent bacterial infection and may vary in appearance from a small, superficial scabbed-over wound to a large abscess or area of cellulitis.

Although some cats may have only a single, primary lesion, most develop secondary skin lesions within 1 to 3 weeks. First apparent as randomly distributed, small epidermal nodules, the lesions increase in size (1-cm diameter) over 3 to 5 days to form well-circumscribed ulcers, which soon become scabbed (Figs. 19-1, A and B). These gradually dry and after 4 to 5 weeks, they exfoliate (Fig. 19-1, C). New hair growth soon occurs, although some lesions may result in small, permanently bald patches.^{6,7,24,27}

Fig 19-1 Various stages of cowpox lesions on the heads of three cats. **A**, Secondary papules. **B**, Scabbed secondary lesions. **C**, Healing lesions after scabs dropped off. (Courtesy Malcolm Bennett, University of Liverpool, Liverpool, England.)

Many cats show no clinical signs other than skin lesions. Signs of systemic illness are usually mild and occur during the viremic period just before development of secondary skin lesions. Cats may be pyrexia, inappetent, or depressed; a few may have coryza or transient diarrhea. More severe disease is rare in domestic cats and is often associated with severe bacterial infection or immune dysfunction often resulting from feline leukemia

Infectious Diseases of the Dog and Cat, 3rd Edition

virus or feline immunodeficiency virus infection or from glucocorticoid treatment.⁶ However, in exotic felids (e.g., cheetahs) a rapidly fatal pneumonia frequently develops. Severely ill cats have a poor prognosis, and euthanasia may be advised.

Feline parapoxvirus infection, probably from sheep or goats, also causes multiple crusty skin lesions, which heal over a few weeks. Anecdotal accounts of similar conditions exist in North America.

19.3.2 Dogs

Infection in dogs is similar to the cat infection, except that in the few cases seen only a small number of lesions develop. Orthopoxvirus infections should be suspected in animals with ulcerative skin lesions, especially if they have had contact with rodents.

19.3.3 Humans

In humans, a single painful skin lesion develops at the site of inoculation, although more severe and widespread lesions may develop in those with preexisting skin diseases or who are immunosuppressed in some way.

No clinical signs are usually seen in rodent hosts, although infection may be associated with reduced fecundity and survival.³⁴

19.4 DIAGNOSIS

Dried scab material can be sent in a sealed container without transport medium to a laboratory by mail. Cowpox virus can be readily isolated in various cell cultures, and virions often can be seen in scab homogenates by electron microscopy (EM). EM is the easiest way to recognize parapoxviruses because of their characteristic morphology and because they are difficult to grow in cell culture. Some laboratories now use the polymerase chain reaction routinely to diagnose cowpox virus infection.³⁰ Serum antibodies can be detected by various methods; we routinely use an immunofluorescent assay for cowpox (see [Appendix 5](#)).¹³

19.5 PATHOLOGIC FINDINGS

The histologic appearance of feline cowpox includes epithelial hyperplasia and hypertrophy, with multilocular vesicle formation and ulceration. Many infected cells contain intracytoplasmic, eosinophilic inclusion bodies.⁴ Immunostaining is a useful aid to histologic diagnosis.

19.6 THERAPY AND PREVENTION

Broad-spectrum antibiotics are recommended to control secondary bacterial infections, and general supportive therapy, including fluids, may be necessary. Glucocorticoids are contraindicated because they may exacerbate the condition. Cidofovir has been shown active against cowpox virus in cell culture and some animal systems^{10,32}; however, the authors (MB, RMG, DB) are unaware of any reports of its use in cats. The drug had to be given early in the course of experimental infection and to immunocompetent animals to be most effective.

Infectious Diseases of the Dog and Cat, 3rd Edition

No vaccines are available, but vaccinia virus may be considered for valuable zoo collections at risk for cowpox infection. Vaccinia virus appears to be of low infectivity and pathogenicity for cats and cheetahs, but its ability to provoke a protective immune response is unknown.

19.7 PUBLIC HEALTH CONSIDERATIONS

19.7.1 Cowpox

Cowpox is a zoonotic virus. In addition to a painful skin lesion, it usually causes systemic illness, which may require hospitalization but rarely causes death.^{3,14} People with a preexisting skin condition or immune deficiency seem particularly at risk of more severe disease. Human cowpox is rare (with one or two cases occurring each year in the United Kingdom), but cats are thought to be the source of more than 50% of these cases.³ The risk of cat-to-human transmission is small if basic hygienic precautions are taken. With few exceptions the illness does not warrant euthanasia of the cat. Even a recent smallpox vaccination is unlikely to provide protection for humans against the primary cowpox lesions, although it might help prevent more severe disease.¹

159

19.7.2 Vaccinia

160

Vaccinia is an orthopoxvirus that originally infected cattle and was later developed as a vaccine strain for smallpox in humans. It has no natural reservoir host. Most mammals, including domestic species, are susceptible to vaccinia virus. With the advent of widespread vaccination for smallpox, there is concern that domestic pets might become infected from people and act as transport hosts. Interspecies transmission from vaccinated people to dogs and cats can be minimized if lesions are protected and dressings disposed of properly.²⁹ Secondary generalized vaccinia infections, especially in children, may occur after vaccinia vaccination. This condition, known as *eczema vaccinatum*, is characterized by diffuse dermatitis with open vesicles, fever, lymphadenomegaly, and rarely encephalitis.³¹ Vesicles contain large amounts of virus that may contaminate the environment and put humans and pets at risk. This risk is extreme for humans with immunosuppression, such as those infected with human immunodeficiency virus. Experimental and epidemiologic evidence show that infections in pets are self-limiting.

Vaccinia has been used as a vector for rabies virus glycoprotein in the oral bait programs being used to control wildlife rabies throughout the world. A human developed a localized and self-limiting infection after inadvertent self-inoculation with the oral bait vaccine (see Oral Vaccination of Wildlife, Rabies, [Chapter 22](#)). A similar problem was experienced by a laboratory worker preparing vaccine virus.²⁵ Humans who are immunocompromised develop more progressive and disseminated lesions.¹¹

19.7.3 Canarypox

Canarypox has been used as a vector in a number of new vaccines available for dogs and cats, including a rabies vaccine (Purevax, Merial, Duluth, Ga.) in cats and distemper vaccine (Recombitek, Merial, Duluth, Ga.) in dogs. The canarypox virus is not associated with any known public health risk.

Infectious Diseases of the Dog and Cat, 3rd Edition

19.7.4 Monkey Pox

Monkey pox is found in the tropical rain forests of countries in western and central Africa. The reservoir is arboreal squirrels. Monkey pox developed in a young child within 2 weeks of a bite from a pet prairie dog (*Cynomys* spp.). The prairie dog was sold from a pet shop where it may have come in contact with a Gambian pouched rat (*Cricetomys gambianus*) from Africa. The family contacts became systemically ill and developed multifocal skin lesions. One family member developed vesiculation around a scratch from a household cat; however, this vesicle may have been incidental to the systemic infection acquired from the child. For more information see http://research.marshfieldclinic.org/crc/files/MonkeyPox_MarshfieldWI_ClinicalPhotos_v3.pdf. Dogs and cats are not considered hosts for this disease, but various rodents are cause for concern.

19.7.5 Other Poxvirus Infections

Other poxviruses, including many parapoxviruses, may also be zoonotic, but the risk of animal-to-human transmission of these viruses is unknown.

20 CHAPTER 20 Feline Viral Papillomatosis

Herman F. Egberink

Marian C. Horzinek

20.1 ETIOLOGY AND EPIDEMIOLOGY

Papillomavirus (PV), a genus of the *Papovaviridae* family, contains small nonenveloped viruses with icosahedral symmetry and double-stranded circular DNA genome. They are widespread in nature and infect many species of mammals and birds.¹⁴ These viruses also cause benign cutaneous and mucosal proliferations that are usually self-limiting and only rarely progress to malignant tumors.^{1,18} All members of the genus share at least one antigenic determinant.¹⁵ PVs are highly species specific, transmission having so far been reported only within a single animal species or between closely related hosts. In one isolate that had its genome completely sequenced, the virus was closely related to the canine PV.^{20,22} In several studies of papillomatous and hyperplastic lesions in cats, papillomaviral antigen was not demonstrated in the lesions, and only a few reports indicate that papillomavirus infection was proven.^{2-4,9} This sparse occurrence may be the result of the inconspicuous nature and uncharacteristic morphology of the lesions, which preclude a clinical diagnosis by analogy. Besides a few case reports of individual cats with papillomas, a series of papillomatous lesions was published.¹⁹ PV infection has been confirmed by immunohistochemical staining of lesions in six species of felids: the domestic cat, mountain lion (*Felis concolor*), Florida panther (*Puma concolor coryi*), bobcat (*Felis rufus*), Asian lion (*Panthera leo persica*), snow leopard (*Uncia uncia*), and clouded leopard (*Neofelis nebulosa*).^{12,19} In most of these animals, the lesions were localized in the oral cavity, especially on the tongue.

161

PVs may be involved in the development of other feline tumors. A novel PV was cloned from hyperkeratotic cutaneous lesions of a Persian cat.²⁰ PVs were also identified in squamous cell carcinomas in situ. PV antigen could be demonstrated in skin biopsies in 30 out of 63 cats showing these skin lesions.⁷ Cutaneous PV infections were also demonstrated in association with fibropapillomas.^{11,21} Using polymerase chain reaction (PCR), investigators in these two studies found PV in 17 out of 19 and 9 out of 12 feline tumors with clinicopathologic features similar to equine sarcoids. Although the DNA was detected, PV antigen was not expressed suggesting a nonproductive viral infection of connective tissue.²¹ This strong association suggests a causal relationship. However, also reports on fibropapillomas in cats are rare,⁵ and evidence of a viral origin is mostly not provided.

Serologic studies to determine the prevalence of subclinical infections in the feline population have not been reported. A spill-over from another reservoir species (e.g., from a prey animal, similar to the epidemiology of poxviruses) cannot be excluded but is unlikely. In the case of equine sarcoids, an association with bovine papillomavirus (BPV) types 1 and 2 has been suggested.¹ A similar association was suggested for the feline fibropapillomas, given that 11 of the 20 cats in that study had known exposure to cattle and all but one were living in an area known for its dairy farms.¹¹ Additionally, in the case of feline cutaneous fibropapillomas, the nucleotide sequence of the amplified DNA from the feline tumor was distinct from, but similar to, BPV type 1.

Although the feline papovavirus has not been fully characterized, it was shown to be different from other PVs. A unique staining pattern using a panel of monoclonal antibodies against papillomavirus capsid protein epitopes may

Infectious Diseases of the Dog and Cat, 3rd Edition

be demonstrated.^{7,8} Interestingly, genetic and antigenic studies of the papillomas of exotic cats revealed that each species was infected with a different virus, underlining the high species specificity of PVs.

20.2 PATHOGENESIS

In general, papillomas will develop after introduction of virus through lesions or abrasions of the skin. Experimental infection of healthy cats with material from wartlike lesions of affected cats did not result in papilloma development. PVs have a specific tropism for squamous epithelial cells. The basal layer of the epithelium is infected, and early gene expression can be detected there. However, protein synthesis and virion assembly are restricted to the most terminally differentiated keratinocytes at the surface of the papilloma. After infection, hyperplasia in the stratum spinosum occurs, and proliferation of the epithelium becomes clinically evident 4 to 6 weeks postinoculation.

Host immunity is important in the development of viral papillomas. Age resistance is unknown. Lesions in 6- to 7-month-old kittens have been reported, but most cases were in cats 6 to 13 years of age.^{4,19} Papillomas are more prevalent in animals and humans under conditions that impair T-cell functions.^{4,10,18} Immunodeficiency seems to be a factor, increasing the chance of clinical manifestation; indeed, the first reports of papillomas in cats concerned animals under immunosuppressive therapy or infected with feline immunodeficiency virus.²⁻⁴

20.3 CLINICAL FINDINGS

The macroscopic appearance of feline lesions is not typical of papillomas seen in other domestic animals.^{2-4,19} Although the surface of the lesions is verrucous, they appear as slightly raised plaques rather than warts (Fig. 20-1). The plaques are several millimeters in diameter; elongated lesions can sometimes be noticed. Plaques can be white or pigmented, scaly and greasy to the touch (Fig. 20-2). The wartlike lesions are located on the head, neck, dorsal part of the thorax, and abdomen. The oral papillomas seen in exotic felids are as multifocal, small, soft, light-pink, oval, slightly raised flat, sessile lesions. They are localized mainly on the ventral lingual surfaces. In some animals (snow leopards), lesions are also present on the tip and dorsal surface of the tongue, as well as the buccal mucosa.¹⁹ The signs of systemic illness are not induced by the PV infection but are the consequence of a concurrent immunodeficiency.

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 20-2 An elongated papillomatous growth on the ear margin of a cat. (Courtesy University of Georgia, Athens, Ga.)

20.4 DIAGNOSIS

A full-thickness biopsy of an entire lesion with adjacent normal tissue should be taken and processed for histopathologic, immunohistochemical, or electron microscopy (EM) examinations.

Histologic examination of cutaneous squamous papillomas reveals pigmented, hyperplastic epidermal plaques with defined boundaries. Proliferation of all layers is evident. The epidermal hyperplasia is characterized by acanthosis and hypergranulocytosis with hyperkeratosis. No inflammatory cells are observed in either the plaques or the adjacent stroma. Ballooning degeneration of cells in the stratum spinosum and stratum granulosum with nuclear changes can be observed. In the upper part of the former and in the stratum granulosum, solitary cells with large, irregularly shaped amphophilic inclusion-like structures occur. These are found in the cytoplasm, but ill-defined, probably intranuclear inclusions have also been reported. By EM, intranuclear papillomavirus-like particles are demonstrated in keratinized cells in the superficial epithelial strata of the plaques. The cytoplasmic inclusions appear as keratohyalin-like granules. The histology of feline fibropapillomas is virtually identical to that of equine sarcoids and is characterized by fibroblastic proliferation, hyperplasia of the overlying epidermis and rete ridges.¹¹

161

162

For definite identification, immunohistochemical staining can be performed on sections through selected skin lesions using a broad-reactive, genus-specific antiserum (see [Appendix 5](#)). Staining of PV group-specific antigens is found mainly in the stratum granulosum and stratum corneum of the papilloma; some cells in the stratum spinosum also retain stain. Immunoreactivity predominates in the nuclei; however, weak staining of the cytoplasm is sometimes noticed, possibly after injury of the nuclear membrane. Besides the detection of PV antigen, a PCR can be performed to demonstrate the presence of PV DNA in the lesions. PCR can also be used for specific identification of the viral strains.

Infectious Diseases of the Dog and Cat, 3rd Edition

20.5 THERAPY

No specific treatment is known. The location and the number of papillomas will often not warrant surgical excision. In analogy with papillomas in other species such as dogs, spontaneous regression can be expected (see [Chapter 9](#)).

21 CHAPTER 21 Miscellaneous Viral Infections

21.1 HANTAVIRUS INFECTION

Craig E. Greene

Anna-Lena Berg

Bruno B. Chomel

21.1.1 Etiology

Hantaviruses are enveloped spherical RNA viruses in the family *Bunyaviridae*, which contains three other major genera that can be distinguished genetically, morphologically, and antigenically. Unlike other members of the *Bunyaviridae*, transmission of hantaviruses does not require arthropod vectors (for comparison, see *Bunyaviridae*, [Chapter 26](#), Arboviral Infections). Each strain of *Hantavirus* is uniquely adapted to its respective subclinically infected rodent reservoir. This evolutionary relationship is a product of millions of years of coadaptation. The genus *Hantavirus* comprises many strains that are pathogenic for humans. In the Old World, Hantaan, Seoul, Dobrava, and Puumala viruses are associated with hemorrhagic fever with renal syndrome, whereas in the New World, Sin Nombre virus (SNV) is the main virus involved in human cases of hantavirus pulmonary syndrome in North America. However, Monongahela, New York, Bayou, and Black Creek Canal viruses also cause HPS and are found in eastern Canada and the eastern and southeastern regions of the United States. In South and Central America, several hantaviruses have been identified as causing HPS, including Andes virus in Argentina and Chile; Andes-like viruses such as Oran, Lechiguanas, and Hu39694 in Argentina; Laguna Negra virus in Bolivia and Paraguay; Bermejo virus in Argentina; Juquitiba virus in Brazil; and Choclo virus in Panama ([Table 21-1](#)).⁷²

21.1.2 Epidemiology

Aerosol transmission from excreta of infected rodents is the principal means by which hantaviruses are transmitted; however, bite transmission between rodents and inadvertent transmission to humans has been documented. Aerosolized virus is the likely means of spread of infection between rodents and humans. Direct physical contact with the rodents is not required. Hantavirus infections of domestic and wild rodents are subclinical. Species differences exist among rodents in the length of salivary excretion, with times ranging up to 1 year. Infected rodents are thought to harbor the virus in their lungs and kidneys for life. The disease peaks during seasons and years when population densities of rodent colonies are highest and have the greatest chance of contacting human populations. The greatest incidence of infection in humans occurs when their work or recreational activities expose them to rodents. Infections occur on farms, in suburbs, and in residential areas, depending on the habitat of the reservoir host. In laboratory rats in the United States, the disease has been controlled by serologic testing and by producing rodents from cesarean-derived stock maintained under strict barrier conditions.

163

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 21-1 Comparison of Features of Some Zoonotic Hantavirus Infections

DISEASE	VIRAL STRAIN	GEOGRAPHIC DISTRIBUTION	RESERVOIR HOST	USUAL CONTACT
Hemorrhagic fever with renal syndrome (HFRS)	Hantaan	Korea, China, eastern Soviet Republics, Balkans	<i>Apodemus agrarius</i> (Striped field mouse)	Agricultural activities
Nephropathia epidemica (milder HFRS)	Puumala	Scandinavia, western Soviet Republics, Europe,	<i>Clethrionomys glareolus</i> (Bank vole)	Forests and agricultural hedge rows, rural and suburban gardens, high forest crop
	Dobrava/Belgrade	Germany, Balkans, Russia, Estonia	<i>Apodemus agrarius</i> (Striped field mouse) <i>Apodemus flavicollis</i> (Yellow-necked field mouse)	Outdoor activities
Milder HFRS, chronic hypertensive renal failure	Seoul	Worldwide	<i>Rattus norvegicus</i> (Norway rat) and <i>Rattus rattus</i> (Roof rat)	Farms and residential areas, laboratory rats outside U.S.
Hantavirus pulmonary syndrome	Sin Nombre ^a	Western and southwestern United States, Canada	<i>Peromyscus maniculatus</i> (Deer mouse)	Human dwellings and outbuilding
Acute cardiopulmonary syndrome	Andes ^b	Argentina, Chile,	<i>Oligoryzomys longicaudatus</i> (long-tailed pygmy rice rat)	Rodent contact, person-to-person
	Laguna Negra	Paraguay, Bolivia	<i>Calomys laucha</i> (Vesper mouse)	Rodent contact
	Juquitiba	Brazil	Unknown	Unknown

HFRS = hemorrhagic fever with renal syndrome.

- a Closely related strains are New York, *Peromyscus leucopus* (white-footed mouse) (Eastern US); Monongahela, *Peromyscus maniculatus* (deer mouse) (Eastern US and Canada); Black Creek Canal, *Sigmodon hispidus* (cotton rat) (Florida); Bayou, *Oryzomys palustris* (rice rat) (Southeastern US).
- b Closely related strains are: Oran, *Oligoryzomys longicaudatus* (Northwestern Argentina); Lechiguanas, *O. flavescens*, (Central Argentina) HU39694, unknown reservoir (central Argentina).

Although hantavirus infections in humans receive the most attention, the viruses have a wide potential host range among other mammals. Any role of the cat or dog in the transmission of hantaviruses from rodents to humans is quite unlikely as indicated by a relatively low seropositive rate. The possibility of cats being a risk for hantavirus infection was initially raised by an epidemiologic study in China that indicated an increased risk factor of cat ownership for humans who developed hantavirus infection.⁷⁷ Several studies conducted in Europe showed the presence of hantavirus antibodies in domestic cats. Five percent of outdoor cats in Austria were found to be seropositive, with higher titers against Puumala than the Hantaan strain.⁵⁵ Similarly, serologic studies with cats in Great Britain showed an overall positive rate of 9.6%.⁵ The seropositive rate was much higher (23%) for cats with various chronic illnesses. Cats that are allowed to roam or hunt outdoors have the highest seroprevalence. Among 100 such cats, immunofluorescent detection of hantavirus antigen (using three different polyclonal anti-Puumala serum specimens) in lungs and kidneys showed the virus in specimens of lung from two cats.⁵⁸ A serosurvey of rural cats and dogs from the southwestern Canadian prairie found a 2.9% seroprevalence rate for cats, whereas virus-specific antibodies were not found in dogs.⁴⁰ In the United States the Four Corners states (Arizona, Colorado, New Mexico, and Utah) have been the location of the majority of

Infectious Diseases of the Dog and Cat, 3rd Edition

the human infections. In a serosurvey for hantavirus infection in Arizona, dogs and cats had a low prevalence (3.5% and 2.8%, respectively) of seroreactivity to nucleocapsid proteins of SNV.⁴⁹ Polymerase chain reaction (PCR) testing of a few animals failed to amplify any hantavirus sequences. Neither coyotes nor dogs or cats appear to have a major role in the maintenance and transmission of SNV. Like humans, they likely acquire their infection from rodents and rodent excreta.

21.1.3 Pathogenesis

Different strains of the virus worldwide are associated with pulmonary or renal dysfunction or both. In infected humans the pulmonary syndrome is a result of acute pulmonary edema and shock. Viral antigens in pulmonary capillaries cause a sudden onset of interstitial pulmonary edema, cardiopulmonary compromise, and death. Renal insufficiency also has been found in patients.

163

21.1.4 Clinical Findings

No clinical signs have been attributed to hantavirus infection in cats. It is likely that their infection is asymptomatic because of the low carriage and quantities of virus.⁵⁸

Clinical signs in humans vary according to the strain causing infection. Signs of Hantaan, Seoul, and Puumala infections are fever, headache, abdominal pain, renal dysfunction, and hemorrhagic diathesis. The pulmonary syndrome of SNV begins with fever and flulike symptoms that progress to signs of pulmonary edema and shock. Radiographs reveal acute bilateral pulmonary interstitial infiltrates, which have been attributed to pulmonary vasculitis. Most deaths associated with HPS are related to cardiac failure rather than pulmonary failure, therefore the term *Hantavirus acute cardiopulmonary syndrome* is more appropriate than *Hantavirus pulmonary syndrome*.⁷²

164

21.1.5 Diagnosis

The diagnosis in humans is made by serologic demonstration of antiviral IgM and IgG in serum and cerebrospinal fluid (CSF). Diagnosis in rodents and carnivores (cats, dogs) is made by serologic testing (IgG). Culture can be performed because rodents excrete virus in their saliva, urine, and feces. Some excrete virus in the saliva for short periods, and others excrete it in the urine for up to 1 year.

21.1.6 Therapy

Intravenous ribavirin, the RNA-inhibitory antiviral drug (see [Chapter 2](#)), has been effective in the treatment of human hantavirus infections when used early in the illness. Excessive fluid administration must be avoided because it may lead to severe edema and increase the severity of the pulmonary edema.

21.1.7 Public Health Considerations

Most humans become infected by the aerosol route when inhaling dust after disturbing nests or closed spaces inhabited by infected mice. A few cases have been documented in which infection resulted from contact with urine-contaminated garbage and/or rodent bites. Avoiding contact with rodents and their excreta or insect vectors are the most effective ways to reduce the prevalence of disease. Rodent-infested structures and soil contaminated with feces must be avoided because harmful aerosols can spread infection. Masks, and in some

Infectious Diseases of the Dog and Cat, 3rd Edition

cases respirators, should always be worn by people cleaning rodent-infested areas. Feral rodents should not be kept in captivity, and care should be taken when entering or cleaning closed buildings infested with rodents. Areas to be cleaned should be thoroughly soaked with disinfectants such as dilute sodium hypochlorite before they are mopped. Vacuuming and sweeping should be avoided to minimize dust. Although cats have been found to be subclinically infected and test seropositive for exposure, it is unlikely that cat-to-cat or cat-to-human transmission occurs. An epidemiologic link between cat ownership and hantaviral disease has not been suspected in North America or Europe.⁵⁸ Serologic studies in coyotes and domestic cats and dogs in the southwestern United States indicated seropositive rates of 0%, 2.8%, and 4.7%, respectively.⁴⁹ The data suggest that these animals are not important in viral maintenance or in transmission of the infection to humans.

21.2 FOOT-AND-MOUTH DISEASE

Craig E. Greene

Foot-and-mouth disease is a highly contagious illness of wild and domestic cloven-hoofed animals and is caused by strains of an *Aphthovirus* organism in the family *Picornaviridae*. It occurs worldwide; however, eradication has been variably successful in Australia, New Zealand, Japan, the British Isles, and North America. Carnivorous animals are relatively resistant to infection and do not play a major role in spreading or harboring the disease under conditions of natural exposure. The virus has been propagated in canine cell cultures.⁶⁷ Dogs and cats can be experimentally infected²⁷; however, no epizootics have been found among carnivores. These animals may become incidentally infected during outbreaks in herbivores by contacting these animals or their offal. Reports have been made of dogs that became infected by scavenging remains of dead animals.^{35,64}

As a result of epizootics, guidelines have been established for dog owners in areas known to have infected animals.³ Dogs must be kept under control—on a leash or within an enclosure—at all times. Dogs should not be walked across farmland and should have minimal contact with livestock and wild animals. Certain sporting activities involving dogs should not be allowed in quarantined areas. Minimal restrictions have been placed on cats, although they should be kept indoors as much as possible. Disinfectants suitable for inactivating the virus are 4% sodium carbonate, 0.5% citric acid, 2% formalin, or 2% sodium hydroxide.⁶² Phenolic disinfectants, quaternary ammonium compounds, and biguanides are not effective. Halogens such as sodium hypochlorite or iodine are less effective because of inactivation by organic matter.

21.3 VESICULAR EXANTHEMA

Craig E. Greene

A calicivirus that causes vesicular exanthema of swine produces lesions on the mouth, lips, snout, and feet is often confused with foot-and-mouth disease. Dogs have developed clinical signs of illness characterized by vesicular eruptions when outbreaks of vesicular exanthema virus infection have occurred in swine.⁴ Virus was not definitely isolated in these cases. However, in other studies, experimentally infected dogs developed fever within 24 hours after inoculation and vesicular eruptions on their tongue and in their oral cavity.⁴ These lesions healed within a few days. Virus was isolated from the spleen of a dog that became febrile after inoculation.

21.4 HEPATITIS E VIRUS INFECTION

Craig E. Greene

Infectious Diseases of the Dog and Cat, 3rd Edition

Hepatitis E virus (HEV) is an unclassified virus that causes an acute self-limiting hepatitis in humans. It is the most common form of acute hepatitis in adults in regions of Asia. It has been reported in developing countries in southeast and central Asia, the Middle East, and North Africa. More sporadic outbreaks have occurred in Mexico and the United States and other countries in the Western Hemisphere. The virus is spherical and nonenveloped, ranging from 30 to 32 nm in diameter, with its nucleic acid in a single-stranded positive sense RNA molecule. Although its structure resembles that of a calicivirus, its genome is closest to that of rubella virus, a member of the *Togaviridae* family. The strains found worldwide can be classified into three major genotypes.

Experimentally the virus has a broad host range. Chimpanzees, Old World and New World monkeys, pigs, rodents, and sheep have been experimentally infected. One swine isolate has been shown to have the broadest host range. In one report a person from Japan with hepatitis E had not traveled and was suspected to have become infected in the home environment.³⁹ Fever, malaise, icterus, and brown-colored urine were observed in the family members. They were seronegative; however, the patient's cat had a high HEV IgG titer.

Anti-HEV globulins have been detected in species of wild and domestic animals. The virus is shed in feces and can be detected by genomic methods. The epidemics of HEV infection in humans have generally been foodborne or waterborne. For prevention, animal feces must be handled with care in endemic areas. General sanitation helps prevent the infection. 164
165

21.5 RABBIT HEMORRHAGIC DISEASE

Craig E. Greene

Rabbit hemorrhagic disease (RHD) is an acute fatal disease of European rabbits (*Oryctolagus cuniculus*) caused by an RHD virus of the family *Caliciviridae*. The disease has been reported in Asia, Europe, Africa, and Americas. Feral cats in New Zealand have antibodies to RHD virus, and nested reverse transcriptase PCR (RT-PCR) has identified virus in the liver of one seropositive cat.⁷⁹ Cats fed rabbit livers infected with RHD virus developed serologic titers to the virus, and RHD viral RNA was detected in the tonsils, mesenteric lymph nodes, spleen, and liver. Even though large amounts of virus were found, clinical disease was not observed. Active replication of RHD virus was not demonstrated.

21.6 LYMPHOCYTIC CHORIOMENINGITIS

Craig E. Greene

Lymphocytic choriomeningitis (LCM) virus is an arenavirus of mice that is transmitted in utero or at birth and persists for life in high concentrations in various tissues. Outbreaks of rodent LCM infections have prompted concern that domestic dogs or cats might serve as reservoirs or vectors of the virus. Puppies (8 to 12 weeks old) did not develop clinical illness after parenteral or cerebral inoculation.²⁰ Challenged animals had increased neutralizing antibody titers to the virus, and infection was transmitted from infected to noninfected puppies. Except for intranuclear inclusions in the adrenal cortex, pathologic changes were not observed in the animals indicating the infection was subclinical. It is unlikely that dogs or cats become infected or spread the virus by natural exposure, because most human infections have resulted from direct contact with rodents.

21.7 BORNA DISEASE MENINGOENCEPHALOMYELITIS

Craig E. Greene

Infectious Diseases of the Dog and Cat, 3rd Edition

Anna-Lena Berg

21.7.1 Etiology and Epidemiology

Borna disease virus (BDV) is an enveloped, nonsegmented, negative-stranded RNA virus of the family *Bornaviridae* in the order Mononegavirales.²² Other members of this order include *Paramyxoviridae* and *Rhabdoviridae*. BDV persistently infects the central nervous system (CNS) after experimental infection of various animal species, ranging from birds to primates. BDV naturally infects horses, cats, sheep, cattle, rabbits, ostriches, and numerous other species, probably including humans.^{42,65} Cases of classic BDV encephalomyelitis, known as *Borna disease (BD)*, in horses, sheep, and cattle are restricted to endemic regions in Germany, Switzerland, and Austria. Naturally occurring feline BD, characterized by behavioral and motor dysfunction (*staggering disease*), was first described in Sweden.^{30,47} Although BDV infection has been reported in cats with ataxia and other neurologic signs in the United Kingdom⁶³ and Japan,^{53,60} a direct etiologic role of BDV has not been established in these cases. One case of feline BD, verified by immunohistochemistry, has been reported from Switzerland.¹³ Two dogs have been reported as having BD, one from Austria and the other from Japan.^{59,75} A large wild cat (*Lynx lynx*) in Sweden was also diagnosed with classic BD.²¹

Specific BDV antibodies have been detected in horses and cats in various regions of the world. The disease in horses may be largely subclinical because the prevalence of antibodies in sera is much greater than clinical illness.⁶⁹ Based on serologic and nucleic acid screening, many feline infections are also subclinical.⁵⁴ Serologic studies indicate that in addition to Europe, cats have been subclinically exposed in the Philippines, Indonesia, Iran, Turkey, and Japan.^{31,32} BDV antibodies have also been detected in cats with a wide variety of clinical signs.³¹ Although the clinical manifestations may not be directly caused by BDV, they may indicate that the virus is an opportunistic pathogen. In two studies, twice as many FIV-positive cats had antibody titers to BDV as did cats with negative FIV test results.^{31,33} In one of these instances, domestic cats kept indoors had twice the infection rate (57%) of feral cats (26%).³¹

Disease associated with BDV occurs most frequently in spring and summer and thus arthropod transmission has been suspected. Viral nucleic acid has been detected in salivary, nasal, and conjunctival secretions of horses and sheep; animals may become infected by direct contact with these secretions or fomites such as contaminated food or water.^{65,74} A definitive reservoir host has not been documented, but rodents and birds are suspected.^{9,69} Infection does not appear to spread readily between cats. Epidemiologic studies suggest that risk factors for infection in cats are highest for intact males that hunt mice in rural woodland environments.⁸

21.7.2 Pathogenesis

The virus is highly neurotropic and probably gains access to the CNS by transmucosal entry into nerve endings terminating in the olfactory, oropharyngeal, or gastrointestinal mucosae.⁶⁵ Similar to rabies virus, BDV spreads into and throughout the CNS by intraaxonal transport and from there spreads centrifugally into peripheral nerves.²⁸ Unlike rabies virus the replication rate of BDV is slow. The immune response to viral antigens is not protective but incites an immunopathologic response. Neutralizing antibodies appear in the serum and CSF. This response fails to clear the infection; the inflammation subsides, and BDV persists at low levels in the CNS

Infectious Diseases of the Dog and Cat, 3rd Edition

of the host.⁴¹ BDV infects neurons, astrocytes, oligodendrocytes, and ependymal cells.⁷⁰ Infection of feline astrocytes has been shown to impair their glutamate uptake function, a proposed mechanism for additional neuronal injury.¹⁰

In experimentally infected rats, acute phase immunity is cellular, with T cells as the predominant cell infiltrate. With chronic infection, plasma cell infiltrates and antibody titers increase and may magnify the inflammatory reaction.⁷⁰ These findings are similar to those found with naturally infected cats with staggering disease-feline BD, in which T cells predominate in the CNS and peripheral circulation.⁷ Cytotoxic CD8+ T cells are thought to induce this immune response against the virus. Antibody titers increase with persistent infection of the CNS. Vaccination of rats before infection reduces the viral load in the CNS but increases their inflammatory reaction to the virus and resultant degree of neurologic impairment.⁴¹

Experimentally and naturally infected cats develop humoral immune responses to the BDV proteins p24 and p40. A Japanese group also reported serum antibodies to another BDV protein, p10, in cats with ataxia.⁶⁰ In addition to the systemic humoral response, BDV-specific antibodies are produced intracerebrally in naturally and experimentally infected cats.³⁶ Intracerebral inoculation of BDV produces high antibody titers against the immunodominant proteins in CSF; however, natural infections induce a weak humoral immune response in cats, primarily directed against BDV p24.³⁶

21.7.3 Clinical Findings

Clinical signs of staggering disease-feline BD include paraparesis and ataxia, mental alteration, anorexia, hypersalivation, hypersensitivity to light and sound, visual impairment, and seizures. The signs progress within 1 to 4 weeks until the clinical condition either deteriorates to complete paralysis and death or stabilizes, leaving most cats permanently afflicted with motor dysfunction, personality changes, or both (Figs. 21-1 and 21-2). Leukopenia is the only hematologic abnormality, and mononuclear pleocytosis and increased protein typical of viral inflammation are noted with CSF analysis. Treatment with glucocorticoids, especially when initiated at an early stage of disease, is sometimes beneficial.

(Courtesy Anna-Lena Berg, AstraZeneca R&D, Södertälje, Sweden.)

21.7.4 Pathologic Findings

The inflammatory reaction in the CNS is characterized by a nonsuppurative meningoencephalitis in the gray matter of the olfactory bulb, cerebral cortex, hippocampus, basal ganglia, and brainstem. The spinal cord is affected to a lesser degree. Perivascular mononuclear cell infiltrates consisting of lymphocytes and macrophages accompany neuronal degeneration (Fig. 21-3). BDV antigen and nucleic acid persist in brain tissue of cats, particularly within astrocytes, causing chronic inflammatory lesions (Fig. 21-4). In one cat, large amounts of virus but no inflammation were found within neurons, presumably from viral persistence by infection at an early age.¹

BD in dogs has been characterized by a rapid onset of progressive intracranial CNS deficits that are similar to canine distemper.^{59,75} Histopathologic lesions, which predominated in the forebrain and midbrain, were a nonsuppurative meningoencephalitis with perivascular cuffing and diffuse mononuclear cell infiltrates of adjacent neuropil. Viral antigen was present in neurons as demonstrated by immunohistochemistry. In situ hybridization detected BDV RNA in the nucleus and cytoplasm of neurons. Inflammatory cells in the cuffs largely comprised CD3+ T cells.

21.7.5 Diagnosis

Controversy exists regarding the diagnosis and relative significance of BDV infection in animals.⁶⁹ There is little doubt that BDV can be pathogenic because isolates have been inoculated intracerebrally into specific-pathogen-free cats, resulting in neurologic signs and encephalitis.⁴⁴ However, the mere presence of BDV in an animal is not sufficient to confirm that clinical disease is a result of BDV infection because many animals may have subclinical infections. Presence of antibody titers in sera merely suggests exposure, and nucleic acid detection by RT-PCR in peripheral blood mononuclear cells or nonneurologic tissues may represent a carrier state. The extremely high sensitivity of nested PCR can also result in laboratory contamination. Another problem is the possibility of false-negative results with RT-PCR because of sequence differences of target genes.⁵⁶ For this reason, detection in the CNS of BDV antigen by immunohistochemistry, of BDV RNA by in situ hybridization, or both in combination with neurohistopathologic alterations is considered the most reliable method of confirming active CNS disease (classical BD). The virus can be isolated in cell culture and by inoculation of rats.³⁰

166

167

Although some investigators have suggested that lesions of feline BD resemble those of feline polioencephalomyelitis, no evidence suggests that these disorders are related. The histologic and clinical features of BD should be contrasted with feline polioencephalomyelitis, which predominantly affects the spinal cord, causing progressive lower motor neuron dysfunction with milder brainstem involvement (see [Chapter 84](#), Neurologic Disease of Suspected Infectious Origin).

21.7.6 Public Health Considerations

BDV has been examined as a cause of human neuropsychiatric illnesses.^{15,23} Antibodies to the virus have been detected in sera of patients with psychiatric disorders in Germany, Japan, and the United States. Similar to cats with FIV infection, humans with HIV infection have an increased risk of acquiring opportunistic infections. The prevalence of BDV-specific antibodies is fourfold higher in patients with HIV infection as compared with control patients.¹²

As with some aspects of the diagnosis in animals, findings regarding the significance of BDV infection in humans are controversial.⁶⁶ The potential contamination risks when using nested RT-PCR applies to humans as well as to animals. Isolation and immunologic detection of BDV in seropositive patients has been inconsistent. In the most definitive work, BDV-specific antigen and RNA were found in the brain of humans with hippocampal sclerosis.^{19,24} The modes of transmission of BDV to humans are unknown. Although no formal proof of direct cross-species transmission exists, the potential of BDV as a zoonotic agent should be taken into consideration.

22 CHAPTER 22 Rabies and Other Lyssavirus Infections

Craig E. Greene

Charles E. Rupprecht

22.1 ETIOLOGY

Rabies virus is the prototype of the genus *Lyssavirus* in the family *Rhabdoviridae*.⁵⁵ The agents are enveloped, bullet-shaped RNA viruses that usually measure 75 × 180 nm (Fig. 22-1). The single strand of nonsegmented RNA (negative-sense) encodes five structural proteins: a nucleocapsid (N) protein, a phosphoprotein (P), a matrix (M) protein, a glycoprotein (G), and a RNA-dependent RNA polymerase (L). These viruses have been isolated worldwide and were originally considered to belong to one common antigenic type. However, techniques using monoclonal antibodies (mabs) produced against viral proteins and gene-sequencing techniques have provided evidence for antigenic and genetic differences (variants) among various isolates from major wildlife and domestic animal hosts within a given geographic region. Analysis of sequences from the nucleoprotein gene of worldwide virus isolates supports studies of mab typing, which suggest that rabies may have spread to the Americas, Asia, and Africa from European colonization.^{203,204} Infection in imported domestic dogs may have contributed to sylvatic species spread, with establishment of enzootic foci in these areas.

Rabies virus replicates by budding from the host cell membranes, and viral nucleocapsid develops in the cytoplasm. Complete viral particles may be formed at the cell surface, but, more commonly, they bud from intracytoplasmic membranes. Free virus particles infect new or adjacent cells by fusing their envelopes with the host cell membrane, which allows direct entry of viral genetic material.

As an enveloped virus, rabies is inactivated by various concentrations of formalin, phenol, alcohol, halogens, mercurials, mineral acids, and other disinfectants. The virus is extremely labile when exposed to ultraviolet (UV) light and heat.

Rabies virus can remain viable in a carcass for several days at 20° C, although it may survive much longer when the body of the victim is refrigerated.¹⁴³ Immunofluorescent testing, commonly used for rabies diagnosis, does not depend on the presence of viable viral particles. Viral antigen may be detected at times beyond the presence of viable virus. Virus survival for isolation by mouse inoculation can be greatly increased in unrefrigerated tissue by storing it in 50% glycerol in phosphate-buffered saline at room temperature (20° C). Preservation can also be enhanced if a 20% suspension of infected tissue or virus culture is made with a solution that is high in protein or amino acids. Storage at ultra-low temperatures (−30° to −80° C) prolongs viral activity for years in untreated fresh-frozen tissue. However, freezing samples in a household-type freezer with subsequent defrosting cycles will damage the tissue and destroy the virus for subsequent detection. Inactivation of specimens may also be possible for diagnostic purposes using genetic detection (see later discussion, Submission of Specimens). A modified-live Evelyn-Rokitniki-Abelseth (ERA) strain oral rabies virus vaccine was found to be stable for 28 days under field conditions; however, the product life was maintained at −30° C before use.¹⁴⁰

168

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 22-1 The bullet-shaped rhabdovirus. (Courtesy University of Georgia, Athens, Ga.)

Besides rabies virus, at least six other *Lyssavirus* genotypes have been described, with more to follow as surveillance is enhanced, particularly among bats.¹⁶

22.2 EPIDEMIOLOGY

22.2.1 Susceptibility

All warm-blooded animals are vulnerable to infection with rabies virus, but mammals are the only known vectors and reservoirs in nature. Factors such as the viral variant, the quantity of virus inoculated, and the bite site affects susceptibility. In addition, the degree of species susceptibility varies considerably. Foxes, coyotes, jackals, wolves, and certain rodents are among the most susceptible animal groups. Skunks, raccoons, bats, rabbits, cattle, and some members of the families Felidae and Viverridae have a high susceptibility. Groups with only moderate susceptibility include domestic dogs, sheep, goats, horses, and nonhuman primates. Birds and primitive mammals such as the opossum may have low susceptibility. Cats are actually more resistant than dogs are to experimental infection with some canine rabies virus isolates but are much more prone to develop infection with some field isolates from wildlife and with vaccine virus. Younger animals are usually more susceptible to rabies infection than are older ones.

22.2.2 Transmission

The disease is nearly always caused by the bite of an infected animal that has rabies virus in its saliva. Other modes of transmission are infrequently involved in infections of the dog and cat but may serve to maintain

Infectious Diseases of the Dog and Cat, 3rd Edition

infection in wildlife. Transmission from exhaled or excreted virus has been suggested for spread between animals in extremely large colonies of cave-dwelling bats and by infections following laboratory exposures.^{74,105} Such airborne infections probably involve large quantities of aerosolized virus under conditions of poor ventilation and a susceptible exposed host. Rabies can occasionally result from ingesting infected tissue or secretions.⁸² Suspected transplacental rabies infections in skunks, bats, and a cow have been reported.⁵⁷ Environmental transmission by fomites is rarely, if ever, involved. Human rabies is usually caused by a bite but has been acquired by corneal transplantation. The disturbing number of human cryptic rabies cases in which no obvious source of exposure can be determined argues against complacency with this disease. Infections with salivary shedding of virus before obvious clinical signs have been observed so that the absence of dramatic neurologic abnormalities cannot be used to rule out absolutely the possibility of rabies infection.

22.2.3 Hosts and Range

More than 27,000 cases of animal rabies are reported yearly in the world. The estimated actual number of cases is many times greater. The World Health Organization (WHO) reported 31,223 cases of human rabies for 1993, with additional cases from nonreporting countries. Total estimates are closer to 50,000 deaths annually.¹⁷⁹ Reports suggest that more than 25,000 human rabies deaths may occur in India alone. Most affected regions are tropical countries in Africa, Asia, and South America. Many island or peninsular nations, such as Antarctica, New Zealand, Taiwan, some of the Caribbean islands, Ireland, Norway, Finland, Sweden, Iceland, Hawaii, and Japan, are reportedly free of rabies. In Western Europe, countries such as Spain, Portugal, Italy, and Greece have become free of terrestrial rabies at considerable cost through oral vaccination of wildlife, especially the red fox (*Vulpes vulpes*), with a continual risk of importation. Compulsory parenteral vaccination and serologic testing for imported domestic animals have also been instituted in some areas to help maintain this status. Rabieslike European bat *Lyssavirus* (EBLV) strains still exist in these regions and occasionally infect terrestrial mammals as a “spill-over.” No evidence has been found that these infections have resulted in adaptation to these inadvertent hosts. Although once boasting a rabies-free status, some isolated nations such as Great Britain and Australia have *Lyssavirus* strains in bats.^{70,118,229} The role of these rabieslike bat *Lyssavirus* strain in the spread of infection to people is thought by some researchers to be marginal.²³² However, a fatal human rabies caused by EBLV type 2a was reported in the United Kingdom in an unvaccinated bat handler.¹⁶¹ This was the first indigenous classical case of rabies in a person within the United Kingdom in over 100 years.

Seven genotypes of *Lyssavirus* are known (Table 22-1): rabies virus, Lagos bat virus, Mokola virus, Duvenhage virus, and two EBLVs.²¹² The seventh *Lyssavirus* has been identified in fruit bats (“flying foxes”) in Australia,⁷¹ and it has been identified in all species of wild and some captive Australian bats.^{68,226} It has been termed Australian bat *Lyssavirus* (ABLV) or *Ballina* virus. Fatal infections in two people have been reported.⁶ Serologic evidence suggests a closely related virus exists in the Philippines.¹⁸ Because of the close antigenic relationship of ABLV with rabies virus, cross-protection from vaccination is presumed effective.²¹² EBLV type 2 (EBLV-2) occurs in mainland Europe; however, it has been identified from four Daubenton's bats (*Myotis daubentonii*) in England.^{70,118,229} Transmission of EBLV-2 to terrestrial mammals is rare. However, an infection occurred in a person handling a Daubenton's bat (see previous discussion). A serosurvey conducted on Daubenton's bats in Scotland indicated between 6% and 19% of the bat sera had positive test results for antibodies to *Lyssavirus*,¹⁵ indicating an endemic reservoir.

Fig 22-2 Principal animal vectors of rabies for major regions of the world. Some countries are reportedly free of rabies (see Hosts and Range in text). (Courtesy University of Georgia, Athens, Ga.)

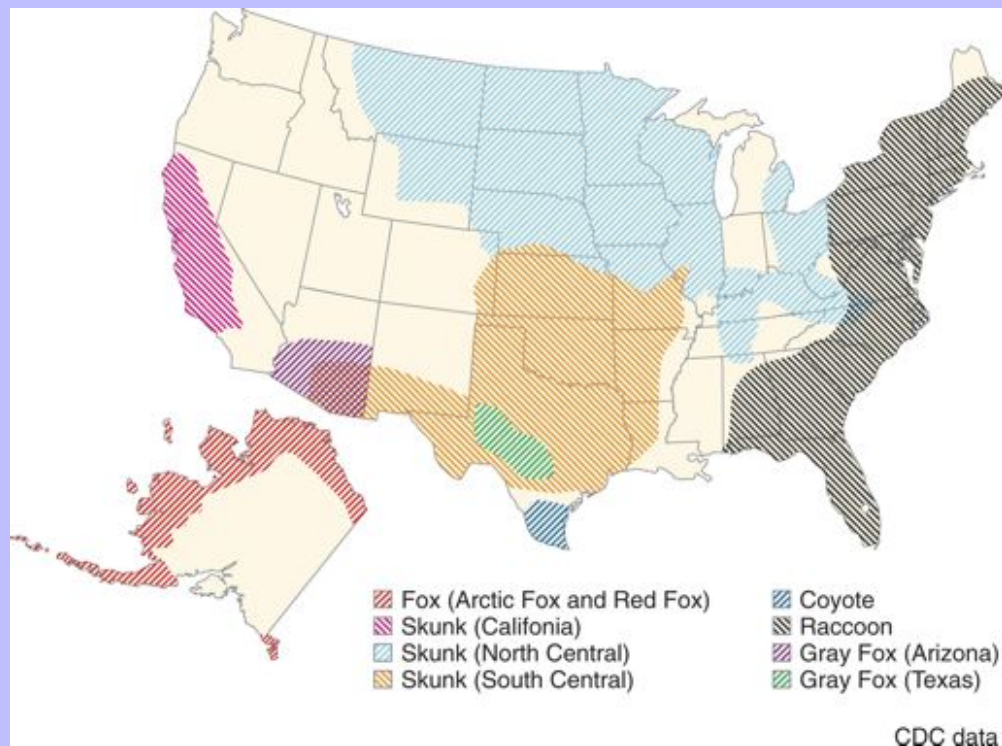

Although all mammals are susceptible to rabies virus, members of Canidae, Viverridae, and chiropteran species are the most capable vectors of the disease. Throughout the world, in most of the Northern Hemisphere, rabies is predominately a sylvatic disease of wildlife, whereas in the Southern Hemisphere, the feral dog in urban areas is the primary species involved in the transmission of the disease (Fig. 22-2). Turkey is the only country in Europe where dog rabies exceeds that in wildlife species.¹⁴⁶ Despite the fact that all warm-blooded animals are susceptible, rabies virus in a given enzootic area is usually a distinct variant that adapts itself to a single dominant reservoir host. Therefore independent host-specific enzootic cycles of infection exist among individual host species. For example, wildlife reservoir species in various geographic areas of the United States are raccoons, skunks, foxes, coyotes, and insectivorous bats (Fig. 22-3). In Europe and parts of Asia, the

Infectious Diseases of the Dog and Cat, 3rd Edition

primary species are foxes and raccoon dogs (*Nyctereutes procyonoides*), whereas in South Africa and certain Caribbean nations jackals (*Canis adustus* and *C. mesomelas*) and mongooses (*Suricata suricata*) predominate, respectively. Although bats can transmit their infection to terrestrial carnivores, the genotypes affecting bats or carnivores also remain distinct.

Fig 22-3 Currently recognized areas of endemic rabies in wild terrestrial animals in the United States. (Data adapted from maps provided by the Centers for Disease Control and Prevention, Atlanta, Ga.; map courtesy University of Georgia, Athens, Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 22-4 Rabies cases in dogs, cats, and wildlife in the United States from 1955 to 2005. The prevalence in dogs has decreased because of vaccination, and cats now have a greater occurrence of rabies. (Data from records maintained at the Centers for Disease Control and Prevention, Atlanta, Ga.; Drawn courtesy University of Georgia, Athens, Ga.)

Rabies in enzootic areas appears to be cyclic. It spreads into unexposed, susceptible wildlife populations in a region; subsequent decreases and increases in the prevalence of disease are caused by population mortality and immunity, which periodically cycles in the wildlife population. These wild animals serve as maintenance hosts for virus transmission to dogs, cats, cattle, and horses. Most human exposures result from contact with these domestic species.

22.2.3.1 Dogs and Cats

The highest occurrence of dog and cat rabies in the United States generally occurs in areas where wildlife rabies is endemic. Most dogs and cats are infected with the predicted terrestrial rabies virus variant associated with the dominant wildlife reservoir host in their respective geographic region.¹⁵⁰ Although the prevalence of wildlife rabies has been on the increase, cases of rabies in dogs and farm animals have been decreasing (Fig. 22-4). Vaccination of dogs and animal control programs has been the main factors responsible for this decline. Although cases of dog rabies have declined, dogs account for the majority of reported animal bites in the United States (see Bite Infections, Chapter 53). Many of these bites result in people seeking antirabies prophylaxis. In the United States, Texas had the greatest occurrence of dog rabies in recent years because of the problem with rabies in coyotes (*Canis latrans*) (Fig. 22-5).¹³⁶ Worldwide, domestic and feral dogs account for most of human rabies deaths and postexposure prophylaxis.⁴⁴ In less developed nations, where dog rabies has not been controlled, the prevalence of canine and human rabies is

Infectious Diseases of the Dog and Cat, 3rd Edition

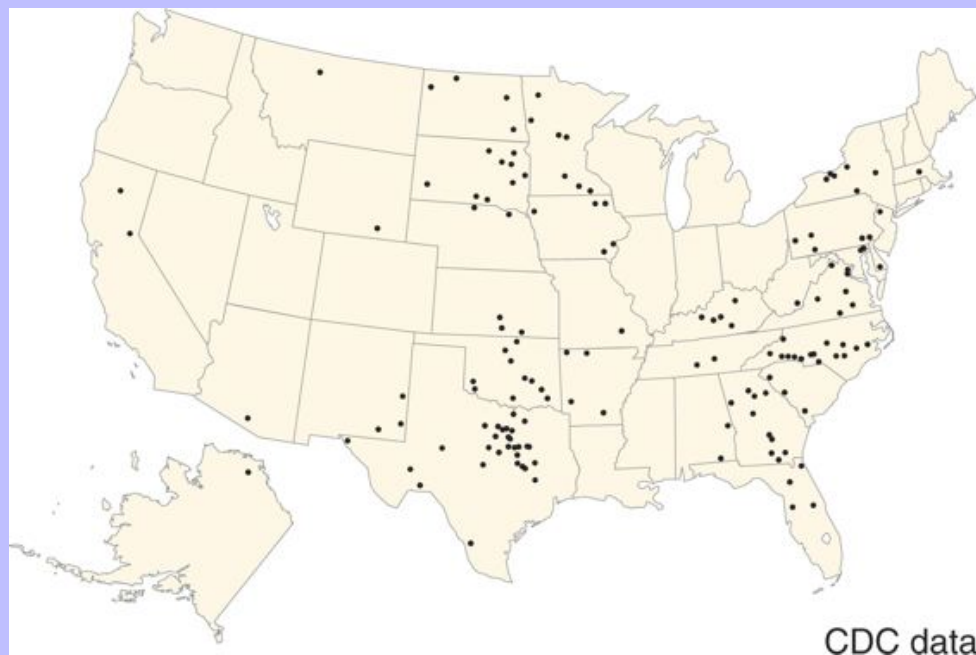

quite high. Adequate vaccination of at least 50% to 70% of dogs in a given population may be necessary to block the occurrence of rabies epidemics.⁵⁰

An increase in cases of rabies in cats usually is related to spill-over of infection from wildlife because no specific virus variant attributed to cats has been reported. The relative importance of rabies in cats as a source for human exposure in a given geographic area depends on whether canine rabies is being controlled by vaccination. In the United States, since 1979, rabies in cats has shown a slight increase over the previous 7-year period. Beginning in 1981, more cases of rabies in cats than in dogs have been reported annually. This increase probably reflects the low number of cats vaccinated for rabies and the epidemics of wildlife rabies in the mid-Atlantic and Northeast regions of the United States (Fig. 22-6). Numerically, cats have been the most important domestic animal affected since 1992.¹⁹¹ Most cases of rabies in cats are from states where the raccoon variant of virus is present. The frequency of human rabies exposures attributed to rabid cats is now increasing at a greater rate than those from dogs. Rabid cats, which usually are reclusive, often become aggressive and may attack humans and other animals when disturbed.⁶⁰

Fig 22-6 Reported cases of rabies in cats in the United States for 2002. (Data courtesy the Centers for Disease Control and Prevention, Atlanta, Ga; map courtesy University of Georgia; Athens, Ga.)

22.2.3.2 Wild Carnivores

The striped skunk (*Mephitis mephitis*), the most common skunk in the United States, is one of the most important species in perpetuating wildlife rabies in the United States. Studies based on antigenic typing have demonstrated the existence of at least three distinct variants in skunks: one in the south central states, another in the north central states, and another in California, extending into Canada. Although the spotted skunk (*Spilogale* sp.) presented a serious rabies threat in the western United States during the 1800s, the involvement of this small, secretive animal is relatively minor today.

The threat to people from rabid skunks is based on the animal's susceptibility to the virus, the high prevalence of rabies infection in the population, their ability to live in proximity to humans, and the excretion of relatively large quantities of virus in their saliva during the prolonged period of clinical illness. Rabid skunks often attack anything that moves with extreme fury and frequently roam during daylight hours, which is unusual behavior for this nocturnal animal.

Foxes are important reservoirs in the ecology of wildlife rabies throughout the Northern Hemisphere, although they account for relatively few human exposures. In North America, fox rabies occurs throughout the range of the red fox, the gray fox (*Urocyon cinereoargenteus*), and the Arctic fox (*Alopex lagopus*). An outbreak occurring among red foxes in 1990 in upstate New York was probably an extension of a Canadian fox epidemic. Coyotes have a role in the maintenance of the disease in southern Texas. A focus of another variant of rabies virus in gray foxes has been found in Arizona and Texas. The prevalence of the disease

Infectious Diseases of the Dog and Cat, 3rd Edition

seems to decline when fox populations are reduced to levels in balance with available resources through either natural mortality or fox population–reduction programs. Oral vaccination programs, using modified live virus (MLV) or recombinant vaccine placed in bait, had considerable success in control of red fox rabies in Europe and Ontario, Canada, and are now being used to control gray fox and coyote rabies in Texas. Despite wildlife vaccination in Europe, the nidus of infected foxes from Eastern Europe maintains the infection cycle.¹⁷⁶

Rabid foxes may exhibit either furious or paralytic forms of the disease; however, regardless of form, the disease is invariably fatal. Despite the shorter course of clinical illness, foxes can effectively transmit the virus to other species, but the need for human postexposure prophylaxis from direct exposure to rabid foxes has been extremely low.

Before the mid-1950s, rabies was not a serious problem among raccoons in the United States. However, from 1950 to 1970, the occurrence of rabid raccoons began to rise dramatically in Florida and Georgia and soon spread to Alabama and northward to South Carolina.

In the mid-Atlantic Coast states, a major epidemic began in the late 1970s caused by the apparent translocation of infected animals from the Southeast. The mid-Atlantic outbreak spread throughout the northeastern states and southward into North Carolina by the mid-1990s. Foci from this and the Florida-Georgia-Alabama epidemic have now merged. The epidemic had spread west into Ohio from Pennsylvania.¹⁰ Raccoons have adapted well to suburban and semiurban environments; thus the number of rabies cases in cats and dogs and other domestic animals in the Northeast has dramatically increased.³⁴ The danger of human exposure to rabid raccoons has also increased, and at least one human death directly associated with rabid raccoons has been confirmed in Virginia. Exposure of people to rabid domestic animals such as the cat, which commonly become infected by raccoon attacks, has resulted in the greatest public health risk. Oral bait vaccination of raccoons in these regions has been shown to be effective in reducing the spread of rabies within the zone of immunization.¹⁸¹ Occasionally, raccoons may be co-infected with canine distemper virus, which may alter the immune response within the nervous system and confuse the diagnosis as to the cause of neurologic dysfunction.⁸⁴

22.2.3.3

Bats

Lyssaviruses have been identified in bats in the Americas, Africa, Australia, and Eurasia. Because of their mobility and the opportunity for bats to infect new areas, no geographic region can be truly considered free of Lyssaviruses.³³ Rabies in North American insectivorous bats was first recognized in the early 1950s, but studies suggest that rabid bats were in this region much earlier. The range of bat rabies is widespread throughout North America. In the United States, less than 1% of randomly caught bats are infected, and 5% to 15% of dead or ill bats submitted for examination may have rabies.²² Bats that interact with humans are more likely to have rabies than those avoiding people; bats that bite people have the highest prevalence.¹⁷³ Rabid bats may develop paresis or paralysis. They may be disoriented and fly into obstacles. Aggression has been observed in some cases. In the United States, most wild bats are insectivorous. Subclinical infection has been suggested in fruit bats in zoological gardens in Europe, but additional investigation is needed.^{185,196}

Although multiple co-circulating variants of rabies virus can be found in insectivorous bats, most submissions and rabid bats are from only a few of the common species (primarily *Eptesicus fuscus*, *Myotis lucifugus*, *Lasiurus borealis*, and *Tadarida brasiliensis*). Phylogenetic studies have shown that bat rabies

Infectious Diseases of the Dog and Cat, 3rd Edition

virus variants found in terrestrial animals are distinct, and variants identified in different bat species are also quite distinct. From 1970 to 2002, 66 persons have died from rabies in the United States. Brain tissues from most of them have been examined by MAB or gene-sequencing techniques, or both. Variants associated with insectivorous bats were identified most frequently, usually associated with the silver haired bat (*Lasionycteris noctivagans*) or eastern pipistrelle (*Pipistrellus subflavus*), but victims had no history of bite. Bats are small and cause tiny lesions, and people may not realize that exposure has occurred.^{74,154,155,202} Therefore reported infection of people from nonbite exposure is higher for bats as compared with terrestrial carnivores, not the least related to public education and perceived greater concern and prophylaxis associated with bite lesions. Despite these reports in people, few authenticated cases of rabies transmission have been reported from insectivorous bats (*E. fuscus*) to cats and even fewer cases of transmission to dogs.¹⁷¹ Rabid bats seldom attack; bat bites usually occur from bats found paralyzed or semiparalyzed or from normal-appearing bats found in buildings.

Vampire bats, which feed exclusively on blood, are a major rabies threat to people and animals in Mexico, Central America, and parts of South America. More than 100,000 cases of rabies in cattle attributed to vampire bats occur annually in Latin America. The routine nightly feeding of vampires makes them extremely effective in transmitting rabies virus, and the presence of rabies in vampire bats parallels that seen in insectivorous bats and terrestrial animals. The vampire bat is not found in North America, except for Mexico. Use of the same cave by vampires and other species of bat may be a source of transmission between species. Genetic characterization of rabies isolates from vampire bats and dogs in Brazil indicated two independently maintained cycles of infection.¹⁰⁶ A focus in Colombia in domestic dogs and people was found to be caused by virus variants found in insectivorous bats.¹⁷¹ In addition, an independent focus in marmosets (*Callithrix jacchus jacchus*) has been associated with human infections.⁶⁴

22.2.3.4 Rodents and Lagomorphs

The prevalence of clinical rabies among rats, mice, squirrels, and rabbits and hares is virtually nonexistent. Rodents and rabbits account for a high percentage of animal bites to people, but no cases of human rabies have ever been associated with these species, probably because they are extremely susceptible to infection and generally will not survive the attack by a rabid carnivore. For such reasons, these species are not routinely examined for rabies in public health laboratories. In the United States, rabies has been reported among large rodents such as woodchucks (*Marmota monax*) and beavers (*Castor canadensis*); most cases have been in the eastern states where raccoon epizootics exist.¹⁴ Therefore unprovoked encounters with large aggressive rodents should be considered as a possible source of rabies exposure.

22.3 PATHOGENESIS

The incubation period is influenced by the age of the bitten individual, the degree of innervation of the bite site, the distance from the point of inoculation to the spinal cord or brain, the variant and amount of virus introduced, postexposure prophylaxis, and other factors. The virus may be undetectable in local tissues following the bite, and it does not enter the blood. Rabies is unique in that the incubation period, which is relatively prolonged compared with that of other infectious diseases, is primarily a result of the route of virus entry into and spread within the central nervous system (CNS) (Fig. 22-7).

Infectious Diseases of the Dog and Cat, 3rd Edition

22.3.1 Entry of Virus

After intramuscular (IM) inoculation, virus may enter peripheral nerves directly or replicate locally in nonnervous tissue. Virus may enter neuromuscular junctions and neurotendinal spindles after a variable period of days, weeks, or months.⁴¹ Rabies virus glycoprotein has homology to certain neurotoxins and attach to axon terminals through lipoprotein receptors, including those for acetylcholine. Virus spreads passively by intraaxonal flow in peripheral nerves at a rate of up to 100 (range, 10 to 400) mm per day. Both motor and sensory fibers may transport virus. The greater the degree of innervation at the site of the bite, the shorter the incubation period. In naturally occurring cases of rabies, ranges of incubation periods before CNS signs have been reported to be 3 to 24 weeks (average, 3 to 8 weeks) in dogs, 2 to 24 weeks (average, 4 to 6 weeks) in cats, and 3 weeks to 1 year or more (average, 3 to 6 weeks) in people.

172

173

Fig 22-7 Pathogenesis of rabies virus infection. Rabies virus enters peripheral nerves, or may replicate in myocytes and spread to motor nerve endings (A) Retrograde intra-axonal (centripetal) spread to the CNS occurs in peripheral nerves (B) Virus replicates in spinal cord neurons and spreads rapidly throughout the nervous system, causing progressive lower motor neuron paralysis (C) Virus enters the brain, causing cranial nerve deficits and behavioral changes. Virus spreads centrifugally in peripheral and cranial nerves, from which it enters the salivary glands and saliva (D) and other tissues. (Courtesy University of Georgia, Athens, Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Although uncommon, infection by routes other than by bite is possible. After intranasal (IN) exposure, virus enters the trigeminal nerves and ganglia in its course to the CNS. The cribriform plate and olfactory bulbs have been suggested as a route of spread, but this is not well documented. After ingestion, the virus can infect cells of the oral mucosa, taste buds, pulmonary system (by aspiration), and intestinal mucosa. From these sites, virus migrates up branches of the cranial nerves and spreads to the brain stem.

Rabies virus variants may vary in their ability to be transmitted by nonbite means. In comparing the dog and coyote strains with silver-haired bat viruses, the latter was better able to infect epithelial cells, replicate at lower temperatures, and have neuroinvasive tendencies.^{72,92,158}

22.3.2 Spread in the Central Nervous System

Interneuronal spread of virus corresponds to the progression of clinical signs that are noted. The virus enters the spinal cord or brain stem ipsilateral to the site of initial virus inoculation by retrograde axoplasmic flow. Once in the CNS, virus spreads by intraaxonal means to involve the contralateral neurons and ascends rapidly and bilaterally, in the spinal cord or brain stem to the forebrain. Damage to the motor neurons causes progressive lower motor neuron (LMN) disease, which, in turn, produces the typical ascending flaccid paralysis of rabies. Damage to the CNS caused by rabies virus has mainly been attributed to direct viral invasion of the nervous system. Damage to neural tissue is visibly limited for the degree of paralysis; inhibition of function or synthesis of neural transmitters is suspected. Apoptosis, or genetically induced premature cell death, may be important in the limited amount of observed neuronal necrosis.¹⁰⁹ Host immune responses to rabies virus may accentuate the inflammation and degeneration of nervous tissue. Interference with cardiorespiratory control results in death.

22.3.3 Spread from the Central Nervous System

After replication within the CNS, the virus moves outward to other body tissues via the peripheral, sensory, and motor nerves at a rate of 100 to 400 mm per day. Both visceral and somatic portions of cranial and spinal cord nerves become involved, including the autonomic nervous system. Virus also spreads via cranial nerves to the acinar cells of the salivary glands at this time. The presence of virus in saliva demonstrates that the brain has already been infected. Although virtually every tissue may be infected, outward spread in the peripheral nervous system does not occur in all cases. The rate (20% to 88% positive) of salivary gland infection also varies, depending in part on the species infected and the virus variant. Death may occur before salivary gland involvement.

22.3.4 Recovery

Recovery from rabies has been exceedingly rare.¹¹⁰ In many instances, demonstrating the presence of virus may be difficult. During the early incubation period, rabies virus may be sequestered at the site of inoculation while replicating in myocytes and nerves. The long period between exposure and clinical signs may be the result of local replication and has been associated with high titers of antirabies virus antibody in the cerebrospinal fluid (CSF) and CNS tissue. Adequate serum titers of antirabies virus antibody, acquired by active or passive immunization, have been correlated with protection against infection and restricted viral replication. Effective cell-mediated immunity is essential to the eventual elimination of rabies virus. Recovery should be regarded as of extremely minor importance in the epidemiology of the disease and not relevant in public health considerations.

Infectious Diseases of the Dog and Cat, 3rd Edition

22.3.5 Excretion of Virus

Typically, virus excretion occurs for a brief period before the onset of neurologic signs and continues until the animal dies within a few days. Most public health laws require a 10-day observation period after a bite from a suspected dog or cat because the period of virus shedding before onset of neurologic signs in naturally infected animals is generally between 1 and 5 days. Dogs that develop neurologic signs and die suddenly actually may have lower concentrations of virus in their brains and salivary glands than do those that live longer. Typically, excretion of virus in experimentally infected cats has started from 1 to 2 days before to 3 days after the onset of clinical signs.

22.4 CLINICAL FINDINGS

Rabies virus infection has classically been divided into two major types: furious and paralytic. The classification and progression of infection is artificial because rabies can be quite variable in its presentation, and atypical signs are commonly seen. Not all animals progress through all the clinical stages. The initial history may reveal that the pet has a wound history. Because of the severity of wounds, signs may not always be suspected as coming from a bite.

22.4.1 Dogs and Cats

During the prodromal phase in dogs, which usually lasts 2 to 3 days, apprehension, nervousness, anxiety, solitude, and variable fever may be noted. Friendly animals may become shy or irritable and may snap, whereas fractious ones may become more docile and affectionate. Pupillary dilation with or without sluggish palpebral or corneal reflexes may become apparent. Most animals will constantly lick the site of viral inoculation. Some dogs may develop pruritus at the site of exposure and claw and chew at the area until it is ulcerated. The behavior of cats during the prodromal period is similar to that of dogs; however, cats more typically show fever spikes and unusual or erratic behavior for only 1 or 2 days.

The furious or psychotic type of the disease in dogs usually lasts for 1 to 7 days and is associated with forebrain involvement. Animals become restless and irritable and have increased responses to auditory and visual stimuli. They frequently become excitable, photophobic, and hyperesthetic and bark or snap at imaginary objects. As they become more restless, they begin to roam, usually becoming more irritable and vicious. Dogs may eat unusual objects (pica), especially wood, that become gastrointestinal foreign bodies. They may avoid contact with people and prefer to hide in dark or quiet places. When caged or confined, dogs often try to bite or attack their enclosure. They usually develop muscular incoordination, disorientation, or generalized grand mal seizures during this phase. If they do not die during a seizure, they may experience a short paralytic stage and then die (Fig. 22-8).

Cats may develop more consistently the furious phase of the disease, showing erratic and unusual behavior.

These cats are described as having anxious, staring, wild, spooky, or blank looks in their eyes.⁶⁹ When confined in cages, they may make vicious, striking movements and attempt to bite or scratch at moving objects. In addition, they may have muscular tremors and weakness or incoordination. Some cats may run continuously until they seem to die of exhaustion.

The paralytic or dumb type of rabies usually develops within 2 to 4 days (range, 1 to 10 days) after the first clinical signs are noted. LMN paralysis usually progresses from the site of injury until the entire CNS is involved. Cranial nerve paralysis may be the first recognizable clinical syndrome if the bite occurs on the face.

173

174

Infectious Diseases of the Dog and Cat, 3rd Edition

When the brain stem becomes affected, a change in the tone of the bark, resulting from laryngeal paralysis, may be observed. Dogs, which more commonly show this type of disease, may begin to salivate or froth excessively as a result of the inability to swallow and the deep labored respiration that occurs. A “dropped jaw” develops as a result of paralysis of the masticatory muscles (Fig. 22-9). Dogs may make a choking sound, which convinces an owner that something is caught in the animal's throat. Owners or veterinarians may then become exposed to the virus in the saliva while attempting to remove a suspected foreign object. The course of the paralytic phase usually lasts 2 to 4 days. The animal often goes into a coma and dies of respiratory failure.

Fig 22-8 Dog with paralytic stage of rabies in sternal recumbency with torticollis. (Courtesy CDC, Atlanta, Ga.)

Fig 22-9 Dog with rabies. Note open jaw and visible tongue with excessive salivary secretions resulting from the inability to swallow. (Courtesy CDC, Atlanta, Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

The paralytic disease in cats often follows the furious form of the disease and begins around day 5 of clinical illness. Although the total course of illness may last 10 days, rabid cats often die after 3 to 4 days.¹⁹¹ As in dogs, initial paralysis of the bitten extremity can progress to paraparesis, incoordination, and ascending or generalized paralysis, terminating in coma and death. Mandibular and laryngeal paralysis is less common in cats. Increased frequency of vocalization is a commonly reported sign in cats, and owners often recognize a change in the pitch of the cat's voice.⁶⁹ Cats occasionally develop the paralytic form directly after the prodromal phase with little or no signs of excitement.

Atypical, abortive forms of rabies virus infection with recovery may occur but are considered very rare phenomena. Experimentally infected dogs that developed acute progressive LMN paralysis have shown clinical improvement a few days to months later. Survival with chronic infection has been reported to rarely occur after experimental rabies infection in cats, but clinical recovery from paralysis has not been observed.

22.4.2 People

The clinical syndrome of rabies in people is similar in duration and variability to that in dogs and cats. Genetic studies of viral isolates from human rabies indicate that clinical manifestations such as encephalitic or paralytic rabies are not determined by different virus variants but by other factors such as the site of the inoculation and spread of virus within the nervous system.⁹⁷ Fever, headache, anxiety, nervousness, and hyperesthesia at the bite site have been reported. As the syndrome progresses to the excitable phase, clinical signs consist of excitability, restlessness, hyperkinesia, and violent behavior. Humans salivate incessantly and may refuse to drink water. They experience painful pharyngeal spasms when attempting to swallow fluids, which gives rise to the term hydrophobia. As disorientation and excitability continue, some patients die in convulsive episodes, whereas others develop generalized LMN paralysis and respiratory arrest. Although the rare instance of recovery has been reported after extraordinary efforts, the disease is considered to be invariably fatal after the onset of clinical signs.

22.5 DIAGNOSIS

Rabies is often suspected because of neurologic abnormalities in an affected animal. However, because of the atypical nature of the clinical signs now recognized, rabies should be considered in any animal that suddenly develops profound behavioral changes or features of LMN paralysis, or both.

For a review of the diagnosis of rabies, also see the Centers for Disease Control and Prevention (CDC) web site at www.cdc.gov/ncidod/dvrd/rabies/. The definitive diagnostic test is the demonstration of rabies virus antigen by the direct fluorescent antibody (FA) test in suitable brain tissue.³⁰ No premortem diagnostic tests are sensitive enough to be consistently reliable for rabies diagnosis in animals. Nevertheless, there may be some limited indications for testing serum, CSF, or biopsy specimens before the death of the animal. No hematologic or serum biochemical changes are characteristic or specific for rabies. Biochemical changes in CSF have been minimal in experimentally infected dogs and have been rarely reported in natural infections. Increased CSF protein (110 to 150 mg/dl) and leukocytes (120 to 1140 cells/ μ l), with small lymphocytes predominating, have been reported in dogs with postvaccinal rabies encephalomyelitis.^{25a} Cats with postvaccinal rabies also have had increased CSF protein (55 to 80 mg/dl) and increased CSF lymphocyte count (5 to 17 cells/ μ l).

Infectious Diseases of the Dog and Cat, 3rd Edition

22.5.1 Direct Fluorescent Antibody Testing of Dermal Tissues

This method has been predominantly used to diagnose rabies antemortem in people. Because virus enters extraneural tissues via outward spread from the CNS, it arrives at nerve endings in the skin and at the salivary glands simultaneously. Because of the heavy sensory innervation, the skin at the nape of the neck (in humans) and the sensory vibrissae on the maxillary areas (in animals) may be selected for direct FA testing. Direct FA testing of a skin biopsy has a 25% to 50% probability of being positive about the time that clinical rabies develops; accuracy is increased as the disease progresses. Of all dogs and cats tested that were confirmed to be rabid by positive results of brain immunofluorescence, neurologic signs developed within 10 days of the biting incident.^{209a} Inactivated or recombinant rabies vaccines commonly used in dogs and cats do not give false-positive results. The skin biopsy technique should never be substituted for brain examination of an unvaccinated animal with suspect neurologic signs. This test appears to be accurate if the virus is present, but a negative test result does not rule out the possibility that the animal is infected. Use of this method is restricted at present to human diagnostics and has not been approved for routine laboratory diagnosis of rabies in animals.

174

175

22.5.2 Testing of Saliva for Virus

Salivary tests for rabies virus have been used as one test to diagnose rabies in people. Rabies virus has been detected in dog saliva by slide agglutination using latex particles coated with polyclonal immunoglobulin.¹²¹ The load of viral particles in saliva is lower than it is in brain tissue, and negative results must be confirmed by more reliable means such as the direct FA procedure on brain. Increased sensitivity and specificity can be achieved by using virus isolation or genetic detection methods (see later discussion).

22.5.3 Serologic Testing

Serologic tests are rarely used for epidemiologic surveys or for diagnosis because of the low percentage of animals surviving that have time to develop postinoculation antibody. Serologic tests are used to determine vaccine immunogenicity. Some countries require a positive antibody titer for importation.⁹ Mouse inoculation was performed historically for serologic testing but has been replaced by cell culture methods. The rapid fluorescent-focus inhibition test (RFFIT), can quantify concentrations of specific rabies virus antibody in serum. Other tests for rabies virus antibodies, based on enzyme-linked immunosorbent assay (ELISA, or fluorescent antibody virus neutralization [FAVN] test), have been proposed to augment the RFFIT for serodiagnosis or support of immunization.*

During incubation, antibody responses are not usually observed, and the virus may be hidden from the immune system. After neurologic signs develop, antibodies appear in serum and later in the CSF.¹⁷⁹ Testing dogs or cats for serum antibodies to rabies virus to determine recent exposure to rabies virus can be ambiguous because elevated titers can result from vaccination or from past or recent exposure to virus. Therefore a serologic response can in no way be definitively differentiated from vaccination or infection. Testing for rabies virus antibody in CSF is a possible means of documenting rabies infection because antibody is locally produced, and CSF titers may increase 2 to 3 weeks or more after the onset of clinical rabies. Because of this delay, a negative titer result does not eliminate rabies infection as a possibility.

Infectious Diseases of the Dog and Cat, 3rd Edition

22.5.4 Documentation of Rabies Immunization with Antibody Titers

The WHO and the Office International des Epizooties have developed minimum guidelines as supportive evidence of rabies immunization in animals. This measurement has been adopted as one requirement for importation of animals into rabies quarantine areas (see later discussion, Quarantine and Shipment of Animals). In an update of these guidelines, the RFFIT test has been augmented by the FAVN test.⁸ This latter test has become another international standard for shipment of animals. No difference has been observed in sensitivity or specificity for either method in comparing sera of vaccinated or unvaccinated animals.^{36,199} Modification of the FAVN using mabs and peroxidase conjugates has allowed automation of the procedure for dogs.¹⁰⁴ A titer of 0.5 IU/ml has been used as the standard level expected for an adequate titer in people and animals. Although parenteral vaccination may more readily achieve this level, oral vaccination with the SAG2 strain did not always induce this level of seroconversion.¹⁹² Nevertheless, dogs showing any measurable titer after vaccination were protected. A titer of 0.5 IU/ml is required for animals exported to most rabies-free areas. No “protective” titer has been found in animals. Individual interpretation is the responsibility of the veterinarian submitting the specimen and the agency requesting the test be done. See [Appendix 5](#) for laboratories that perform these assays.

22.6 PATHOLOGIC FINDINGS

22.6.1 Submission of Specimens

Selection and submission of proper specimens are critical for accurate rabies diagnosis. Handling live, suspected rabid animals must be done with extreme care. Heavy protective gloves must be worn, and catchpoles, cages, and other equipment often facilitate capture and transport of such animals. The animal must be euthanized by a humane method, and the brain must be protected from damage. The use of an ax or power saw should be discouraged when opening the skull, because these may create hazardous aerosols. A procedure to remove the brain of a suspected rabid animal has been published.²¹³ Small specimens such as mice and kittens may be submitted whole. A technique for retroorbital removal of brain specimens for collection of material for epidemiologic studies has been described.¹⁵⁶ Complete brain removal is still indicated when human exposure has occurred. When brain tissue has been inadvertently damaged or destroyed, the spinal cord is an alternative but less desirable substitute.

The head (or body) of an animal suspected of having rabies that has died or been euthanized should be cooled immediately and maintained chilled (wet ice) or refrigerated until examined. The head or brain should not be frozen because this delays examination, and the thawing process causes brain tissue damage. A complete history should accompany each specimen. Various approved shipping containers are available from public health or animal control facilities and must protect the specimen, as well as those handling the container. The container should always indicate that hazardous laboratory specimens are enclosed.

Specimens must be sent to the laboratory as quickly as possible. Postexposure treatment is often delayed while awaiting laboratory results. Recommendations are that specimens be delivered personally or by courier whenever possible to minimize delay or potential loss.

A method of submitting brain tissue, dried on filter paper, has been described that permits submission of specimens without refrigeration.²²² Brains from rabid and control dogs were spotted on filter paper which was

Infectious Diseases of the Dog and Cat, 3rd Edition

dried and stored for up to 222 days. Analysis was performed by nucleic acid sequence-based amplification and reverse transcriptase-polymerase chain reaction (RT-PCR).

22.6.2 Gross and Microscopic Lesions

No gross lesions are detectable in the CNS with rabies infection. Despite the dramatic neurologic signs and high mortality, neuropathologic changes are mild. Pathologic changes depend on the severity and duration of infection at the time of examination. Acute poliomyelitis characterized by minimal neuronophagia, neuronal degeneration, and nonsuppurative inflammation is seen very early in the course of the disease. Necrotizing encephalitis is seen in the next phase of infection and corresponds to a gradually increasing titer in the serum and CSF. Chronic infections are characterized by focal or widespread lymphocytic and plasmacytic perivascular cuffing and focal mononuclear cell infiltrates in the CNS. Ganglioneuritis is usually present. The longer the course of illness, the more pronounced is the nonsuppurative inflammatory response in the brain and spinal cord. In some cats, spongiform lesions appear as vacuolation in the neuropil of the gray matter, most commonly in the thalamus and inner layers of the cerebral cortex.

175

176

22.6.3 Direct Fluorescent Antibody and Immunohistochemical Testing of Nervous Tissue

This postmortem test is both rapid and sensitive and is currently the most widely used and preferred and reliable method of diagnosing potential rabies infection in animals.⁹¹ False-negative results are rare with this test when compared with those of mouse inoculation.²⁰⁹ Thin touch impressions of the medulla, cerebellum, or hippocampus are used for this test. In decomposing canine brains at room temperature of 25° to 29° C, the direct FA test result remains positive in most cases for up to 96 hours; the corresponding mouse inoculation test usually becomes negative by 48 hours.⁵ Unless it is completely decomposed, the head should be submitted because specific fluorescence may still be detected. Rabies virus has also been detected by immunoperoxidase techniques on formalin-fixed, partially autolyzed and paraffin-embedded tissue.^{19a,83,139,224} Animals need not show neurologic signs at the time of examination, and all animals excreting virus in the saliva will have detectable virus in the CNS by immunohistochemical examination.

22.6.4 Genetic Detection of Virus and Genetic Sequencing

Rabies virus RNA has been detected in nervous tissue by RT-PCR.* Amplified sequences have included the phosphoprotein, nucleoprotein, and glycoprotein genes. PCR has been used as a confirmatory test in direct FA-negative samples or in decomposed brain tissue that is difficult to evaluate with direct FA methods or virus culture,^{54,94} but the predictive ability of a negative result has not been discussed. In situ hybridization can detect rabies virus genomic RNA in paraffin-embedded brain tissues.^{111,224} For detection of rabies in living human patients, RT-PCR has been used on saliva, CSF, and urine^{53,164,220,221}; however, it is not considered a desirable alternative in animals, in which the brain tissue is preferred. In people, RT-PCR analysis of saliva has been the most accurate means of antemortem diagnosis of rabies when compared with other detection methods and is as accurate as is brain biopsy.¹⁶⁴ Direct sequencing of PCR products along with automated gene sequencing can also help distinguish between virus variants to determine the most probable wildlife reservoir for an isolate from human or animal infection.

* References 81, 95, 107, 120, and 224.

Infectious Diseases of the Dog and Cat, 3rd Edition

22.6.5 Intracellular Inclusions

The classic test for the presence of rabies is to examine the brain for the presence of intracytoplasmic inclusions, known as Negri bodies, in larger neurons (Fig. 22-10).¹³⁷ They are most commonly found in the thalamus, hypothalamus, pons, cerebral cortex, and dorsal horns of the spinal cord. Negri bodies are most common in neurons of the hippocampus in carnivores and in Purkinje's cells of herbivores. Negri bodies in tissue sections or impressions of brain tissue are best demonstrated with Seller's or van Gieson's stains, in which they stain magenta. Unfortunately, Negri bodies take time to develop and cannot be found during all stages of infection and in all infected cats. They usually cannot be detected until neurologic signs are apparent; therefore premature killing of the animal may reduce the chances of finding these inclusions. Negri bodies may be found in approximately 50% of the samples that test positive by direct FA. In some cases, nonrabid tissues have displayed inclusions that resemble Negri bodies. Cytoplasmic inclusions that are confused with Negri bodies can be found in the brain of healthy cats.^{37,38} They occur in the pyramidal cells of the hippocampus and in neurons of the dorsal part of the lateral geniculate nucleus. This test is no longer used in most developed nations for routine diagnostic confirmation.

Fig 22-10 Negri body (*arrow*) in a neuron within the CNS. (Courtesy Elizabeth Howerth, University of Georgia, Athens, Ga.)

22.6.6 Mouse Inoculation and Virus Isolation

Intracerebral inoculation of laboratory mice with fresh or fresh-frozen homogenized tissue is a confirmatory test for rabies but is not widely conducted for routine diagnosis of suspected rabies cases in the United States. Specific neutralizing antibody is incubated with extracted tissue before its inoculation to confirm that rabies virus is responsible for the observed neurologic signs. Brain tissues from infected mice are examined for virus by direct FA. This test does not distinguish between virulent and vaccine viruses because, regardless of attenuation, many of the virus strains produce a similar illness in mice. Replacement of mouse inoculation by

Infectious Diseases of the Dog and Cat, 3rd Edition

viral inoculation into tissue culture (TC) is now feasible because virulent virus can now be grown in various cell lines.¹⁸⁷

22.6.7 Monoclonal Antibody

MABs produced against specific rabies virus nucleocapsid and glycoprotein moieties are able to distinguish various antigenic variants. Strains of virus to be tested are grown in TC or are found in tissue sections and are tested by direct FA to determine the antigenic composition of the virus. The pattern of staining with different mabs is compared with that of reference strains of virus. This technique is extremely valuable in distinguishing between vaccine and virulent strains of rabies virus, especially in cases of human exposure to animals with postvaccinal neurologic disease.

176

22.7 THERAPY

177

Supportive care for rabies-infected animals is not recommended because no therapy has proved effective in this fatal encephalitis. An asymptomatic dog or cat suspected of contracting rabies should be quarantined as recommended (see Compendium of Animal Rabies Vaccines, [Appendix 4](#))¹¹⁶ or, as for all other species, appropriately euthanized and the brain submitted for examination.

22.8 PREVENTION

For control of rabies in dog populations, vaccinating a minimum of 50% to 70% of dogs is theoretically necessary.^{50,153} Eliminating unvaccinated feral dog populations alone has not proved effective and is expensive. Eliminating wildlife populations is nearly impossible and is expensive. Therefore the control measures centered on vaccination of dogs and cats are most appealing and effective.

22.8.1 Vaccine Types

22.8.1.1 Parenteral Modified Live Vaccines

No measure has helped reduce the incidence of human rabies as effectively as the widespread vaccination of the domestic dog population. Early vaccines were developed from virus grown in nervous tissue and later in avian embryos. Low egg passage vaccine virus was produced by approximately 50 serial passages of the virus in chicken embryos (CEOs). The virus lost its viscerotropic properties but retained some of its neurotropic traits. Vaccine-induced rabies was occasionally reported if the product was given to cats. High egg passage CEO vaccine was produced by approximately 180 passages of the virus. It no longer caused neurologic signs in laboratory mice, except when neonates were injected intracerebrally. The vaccine was safe for dogs and only occasionally caused encephalomyelitis in more susceptible species such as cats and cattle. Newer MLV vaccines were produced in TC. These products produced fewer allergic reactions compared with CEO vaccines. Despite better immunity produced by MLV vaccines compared with inactivated vaccines, occasional postvaccinal rabies is still a distinct disadvantage. No MLV rabies vaccines are currently available in the United States. They are still being used to control rabies epidemics in countries in which domestic dogs are rabies reservoirs, and financial resources for more expensive products are limited.^{28,29,141,167}

Infectious Diseases of the Dog and Cat, 3rd Edition

22.8.1.2 Oral Modified Live Vaccines

Although they are uncommonly used for parenteral vaccination, several modified-live strains are being used for oral vaccination of feral or wild animals. The SAD B19 strain has been used for many years. In fox cubs less than 8 weeks of age, maternally derived antibody (MDA) inhibited the immune response to oral SAD B19 strain vaccine.¹⁵⁹ A newer SAG2 strain, isolated as an escape mutant by selection with mabs, is derived from the SAD strain.¹³⁸ The SAG2 strain is avirulent following intracerebral inoculation of immunocompetent mice. This strain protected a majority of vaccinated dogs against challenge that killed all unvaccinated controls.^{85,168,192} It also has been useful in the protection of African wild dogs (*Lycaon pictus*), which have been problematic because of their high susceptibility to the disease.¹²⁴ The SAG2 vaccine produces no clinical illness in vaccinees and is difficult to isolate from the oral cavity, even within the first 24 hours of administration.^{67,168} This virus will not likely be transmitted to other hosts.

22.8.1.3 Parenteral Inactivated Cell Culture Vaccines

To develop effective inactivated rabies virus vaccines, the virus had to be produced in high concentrations, which was initially done by growing it in the nervous system of suckling mice. Neonatal mice were chosen because they lacked the antigenic myelin responsible for allergic encephalomyelitis produced by early nervous tissue origin vaccines. An important advance in the development of inactivated rabies vaccines has been the production of less allergenic but more immunogenic products by their production in TC cells, thereby producing large quantities of virus. Newer adjuvants have increased the immune response to the antigen in these products but have also caused some problems with allergenicity and oncogenicity (see Vaccine-Induced Complications, [Chapter 100](#)).

22.8.1.4 Oral or Parenteral Recombinant Vaccines

A Vaccinia virus—rabies virus glycoprotein recombinant (V-RG), capable of expressing the glycoprotein of rabies virus, has immunized most major carnivore reservoirs. For example, the V-RG vaccine was effective in producing a serologic response in captive fox cubs (*V. vulpes*)³² and some control of infection in wild coyotes (*C. latrans*).⁶⁵ MDA did not interfere with oral vaccination in fox cubs. Purified subunit rabies vaccines may be the recommended vaccines in the future. With purified glycoprotein vaccines, 5 to 50 times the quantity of purified glycoprotein alone is required to produce an immune response compared with intact virion vaccines. Some theories suggest that incorporating glycoprotein on lipid complexes would greatly increase the potency of subunit vaccines. Recombinant vaccines, using other poxviruses or adenoviruses as vectors, have been developed. After oral use, these vaccines induce the synthesis of rabies virus glycoprotein in infected cells, virus neutralizing (VN) antibodies, and protection in susceptible animals.^{56,237} Transgenic plants have also been made, which express rabies virus antigens.

A replication-defective recombinant adenovirus expressing rabies virus glycoprotein was effective in inducing increased VN titers against rabies virus by 10 days after parenteral vaccination.²¹⁴ Titers following a recombinant herpesvirus-vectored vaccine expressing glycoprotein were higher compared with those with a commercial inactivated vaccine.²³⁶ In some countries, recombinant parenteral rabies virus vaccine using a canarypox virus–vector is commercially available for cats.^{39,208} (See also Rabies, [Chapter 100](#) and [Appendices 2, 3, and 4](#).)

Infectious Diseases of the Dog and Cat, 3rd Edition

22.8.1.5 Nucleic Acid Vaccines

IM immunization with bacterial plasmid DNA vectors encoding rabies virus glycoprotein has protected dogs against a lethal challenge with a wild-type dog rabies virus variant.¹⁷⁸ Neutralizing antibodies were detected against rabies virus and EBLVs; however, the titers to the latter viruses were low. In other studies, the serologic response of dogs was higher by IM immunization; cats had a greater response by the intradermal (ID) route.¹⁶⁹ However, sera passively administered to mice from dogs vaccinated ID in the ear pinnae elicited elevated and long-lasting levels of neutralizing antibody that protected mice to challenge following passive transfer of immune sera.¹⁴⁴ In mice, a single dose of DNA vaccine was shown to be as effective as five injections of cell culture-derived vaccine.²⁵ The versatility of DNA recombinant methods makes it possible to generate chimeric *Lyssavirus* glycoproteins to protect against the many strains in the wild, and these products may be licensed in the near future, particularly if a single dose is needed for efficacy.

22.8.2 Antirabies Virus-Specific Agents

Certain oligodeoxynucleotides complementary to rabies virus genomic or messenger RNA have been shown to interfere with rabies virus replication in cultures.⁷² These in vitro studies are promising; however, treatment of active infections is a distant possibility, especially for people.¹¹⁰

177

22.8.3 Vaccine Recommendations

178

22.8.3.1 Preexposure Prophylaxis

Many vaccines are currently marketed in the United States for preexposure rabies prophylaxis in dogs and cats. All currently licensed products must protect at least 88% of animals vaccinated against challenge with virulent virus, whereas at least 80% of those not vaccinated are challenged and develop rabies. In preventing rabies epizootics, the WHO recommends that 70% of dogs in a population should be effectively immunized.⁵⁰ Currently available inactivated vaccines have been shown to be safe and effective when administered in neonatal puppies and kittens. However, because of the potential interference by MDA blockade and a relatively poor immune response in the young, the first rabies vaccination is given at a minimum of 3 months of age and then repeated 1 year later (Table 22-2).² Subsequent vaccinations are repeated every 1 or 3 years, depending on the product and local public health regulations. The total dose should be given to each animal, regardless of its size, in a route as recommended by the manufacturer. The current Compendium of Animal Rabies Vaccines (Appendix 4) and Appendices 1 and 2 and Chapter 100 should be consulted for canine and feline rabies vaccination protocols.¹¹⁶ The latest compendium can be found online at www.avma.org/pubhlth/rabcont.asp. Studies have shown that one injection of inactivated rabies vaccine to a naive animal does not produce a lasting antibody titer in a significant proportion of dogs.^{194,210} However, serum antibody titers can be misleading as a measure of protection because previously vaccinated dogs usually show an anamnestic response to boosters, even when antibodies are no longer detectable in their sera. Nevertheless, the second vaccination 1 year after the primary inoculation is extremely important. A multiple-dose primary canine rabies vaccination schedule with annual boosters may be considered for dogs in rabies endemic countries in which the disease has been a high risk for people. Booster vaccinations are recommended for dogs and cats whenever vaccination history cannot be established

Infectious Diseases of the Dog and Cat, 3rd Edition

because of the potential for vaccine failures.^{51,69,114} A very small proportion of dogs and cats identified with rabies have had at least one rabies vaccination during their lifetime. No available vaccine is 100% effective; therefore an immediate booster dose is recommended to the previously immunized dog or cat after a known rabies exposure. However, current vaccines in one country may not help protect against imported rabies virus variants from abroad. Therefore vigilance in monitoring is essential. Fortunately, current veterinary vaccines are cross-protective against some newly identified strains such as the *Lyssavirus* reported from Australia.¹⁸⁹ Fortunately, current veterinary vaccines are cross-protective against the *Lyssavirus* identified in Australia.⁷⁵

Table 22-2 Recommendations for Rabies Vaccination of Animals and People in the United States^a

ANIMAL EXPOSED	RECOMMENDATION
Preexposure	
Dogs and cats	Vaccinate at 3 months of age; revaccinate 1 year later and every 1 or 3 years thereafter, depending on product recommendations
Ferrets	May be vaccinated at 3 months of age and revaccinated annually with an approved vaccine
Wildlife	Discourage ownership; no parenteral vaccine is approved for use; oral vaccination in government programs
People	Three doses of an FDA-approved vaccine given as 1 ml IM, based on manufacturer's recommendation, in the upper deltoid on days 0, 7, and 28; booster based on risk group
Postexposure	
Dogs and cats	<i>Previously unvaccinated:</i> euthanize immediately or quarantine in secure enclosure for 6 months; vaccinate 1 month before release <i>Vaccination not current:</i> evaluate on case-by-case basis <i>Vaccination current:</i> revaccinate immediately and keep under owners' control for 45 days
Ferrets	Euthanize if not vaccinated; if vaccinated with an approved vaccine and vaccine is current, revaccinate immediately and place in strict isolation for 45 days
Wildlife	Regard as rabid and euthanize for examination
People	<i>Previously unvaccinated:</i> H-RIG ^b , 20 IU/kg, infiltrated at site of bite once on day 0–7; FDA-approved vaccine ^c given at recommended dose IM in the upper deltoid on days 0, 3, 7, 14, and 28; ID use not appropriate <i>Previously vaccinated:</i> two doses of an approved vaccine at recommended dose IM in upper deltoid on days 0 and 3; no H-RIG
FDA, U.S. Food and Drug Administration; IM, intramuscular; ID, intradermal; H-RIG, human rabies immune globulin.	

- a For most current preexposure information for people, consult the Advisory Committee on Immunization Practices (ACIP) recommendations online at www.avma.org/pubhlth/rabprev.asp. For most current pre- and postexposure information for animals, consult Compendium of Animal Rabies Vaccines, Appendix 4 or online at www.avma.org/pubhlth/rabcont.asp.
- b Imogam®RabiesHT (Connaught Laboratories, a subsidiary of Pasteur-Merieux Serum et Vaccins, Marnes La Coquette, France); BayRab™, (Bayer Corp, Research Triangle Park, N.C.).
- c Approved rabies products are: (1)human diploid cell rabies vaccine (HDCV), IM (Imovax® Rabies, Pasteur-Merieux Serum et Vaccins, Connaught Laboratories); (2) rabies vaccine adsorbed (RVA), IM (Rabies Vaccine Adsorbed, Bioport Corporation); (3) purified chick embryo cell vaccine (PCEC), IM, (RabAvert™, Chiron Corporation).

22.8.3.2 Oral Vaccination of Feral and Wild Animals

Despite the widespread reservoir of rabies in wildlife, rabies in domestic, feral, or wild dogs is the greatest single human health risk. Parenteral vaccination of dogs has helped reduce the threat of rabies for humans;

178

179

Infectious Diseases of the Dog and Cat, 3rd Edition

however, it is financially and practically difficult in many countries. Oral ingestion of rabies virus might result in infection; however, it often stimulates an immune response. Using an attenuated strain of rabies virus, a protective immune response is more certain. Oral vaccination via dispersion of safe and effective baits has been beneficial in reducing the threat from wildlife and various dog populations.¹⁶⁶ Vaccines for this purpose must be living so as to penetrate the mucosae. The modified live SAD B19 strain, the V-RG recombinant, and SAG2 vaccines have been employed for this purpose.²³ Contact of people with V-RG containing bait-vaccine units does not pose a major public health risk for Vaccinia virus exposure.¹⁴⁹ However, infection with vaccine virus has occurred and such exposures should be reported.¹⁹⁰ For additional information on the concern of vaccinia poxvirus transmission to people, see Poxvirus Infections, [Chapter 19](#).

22.8.4 Postvaccinal Complications

For additional information on the complications discussed next, the reader should consult Postvaccinal Complications, [Chapter 100](#). Encephalomyelitis in cats and dogs, caused by rabies MLV vaccine, has been observed in the past. As a result, such vaccines are no longer available in many countries. The most frequent nonneurologic complications associated with rabies virus vaccine are local soreness, lameness, and regional lymphadenomegaly in the injected limb. Fever and systemic signs or anaphylaxis are sometimes noted. These signs have been more frequently observed with the newer inactivated TC rabies vaccines because of the need for higher antigenic mass and adjuvants to produce an immune response equal to that of the older MLV products. Focal cutaneous vasculitis and granulomas have been described in dogs, occurring within 3 to 6 months after inoculation. They consist of well-circumscribed, subcutaneous inflammatory reactions that involve the overlying dermis. Similar reactions result in palpable nodules in cats that can be detected by clients or veterinarians.¹⁹⁷

Sustained inflammatory reactions that develop at vaccination sites are considered to be precursors of sarcoma, which may develop months to years later.^{59,102,122} Postvaccinal sarcomas can develop in dogs and cats but have been more frequently documented in cats. Sarcomas that develop after vaccination are often aggressive and invasive. For a further discussion, see Vaccine Site–Associated Sarcomas in Cats, [Chapter 10](#)

Autoimmune polyradiculoneuritis has been observed with inactivated suckling mouse brain–origin rabies vaccines and theoretically can result following any type vaccination. A small proportion of dogs that were vaccinated with these products developed acute diffuse LMN paralysis with intact pain sensation and hyperesthesia (see [Chapter 100](#)).

22.8.5 Control of Epizootics

Where rabies epizootics have occurred, vaccination programs have been shown to reduce greatly the spread of an outbreak. Management of stray and unwanted cats and dogs is essential, and unclaimed animals should be humanely euthanized. Leash laws must be enforced. Reduction in the population of wildlife vectors has been used on a limited scale when epidemics of rabies in dogs and cats have been traced to a particular wildlife reservoir species, but this has been largely ineffective. Control through trapping and poison baits not only is difficult, but may also cause public resentment, as well as ecologic repercussions. As previously described, oral vaccination of wild carnivores has worked on a limited basis worldwide and may be expanded in the future.

Infectious Diseases of the Dog and Cat, 3rd Edition

22.8.6 Postexposure Management for Dogs and Cats

Management of a dog or cat that has been bitten or scratched by a potentially rabid mammal is difficult when the biting animal is not available for testing, because the dog or cat must be considered as having been exposed to a rabid animal (see [Table 22-2](#) and Compendium, [Appendix 4](#)). Differences in management depend on whether the exposed animal has been previously immunized and local public health laws. The final decision concerning the management of exposed animals generally is made by local or state public health authorities. The current Compendium of Animal Rabies Control ([Appendix 4](#)) and local public health officials should be consulted when such circumstances arise.

22.8.6.1 Postexposure Vaccination

The National Association of State Public Health Veterinarians recommends euthanasia or 6 months confinement for unvaccinated dogs and cats exposed to a rabid animal, with rabies vaccination 1 month before release (see Compendium, [Appendix 4](#)). Although not widely accepted for animals, postexposure prophylaxis (PEP) has been instituted in Texas because of adverse emotional and monetary consequences if an animal must be euthanized.²³¹ In that protocol, immediate vaccination against rabies was followed by a strict isolation period of 90 days with rabies boosters during the third and eighth weeks of the isolation period. With such measures, four failures were observed out of 830 animals, including 621 dogs and 71 cats, given PEP. Experimental PEP of dogs has been less than ideal.⁸⁷ In contrast, immediate vaccination combined with mabs against rabies virus glycoprotein provided protection to the dogs. Unfortunately, such immunoglobulin is not available commercially.

22.8.7 Disposition of Animals That Bite Humans

Dogs and cats with current rabies vaccinations are of less concern as a transmission risk, although current vaccination status does not eliminate the need for follow-up ([Table 22-3](#)). Any illness or neurologic disease in quarantined animals must be immediately reported to local public health authorities. Management of potentially rabid animals other than dogs or cats depends on the species, the circumstances of the bite, and the epidemiology of rabies in the area.

22.8.8 Quarantine and Shipment of Animals

The current standard for shipment of animals into “rabies-free” areas involves a four part plan of identification, health examination, vaccination, and blood testing ([Table 22-4](#)). Embassies should be consulted regarding the latest requirements for rabies.

22.9 PUBLIC HEALTH CONSIDERATIONS

22.9.1 Prevention in Dogs and Cats

Worldwide, more than 30,000 people die from rabies each year, with many more undocumented cases, and 10 to 12 million receive postexposure treatment.⁵⁸ These statistics have been reduced through the years by public health practices. Parenteral vaccination of dogs has been the single most important means of controlling rabies in people throughout the world. In addition, rabies incidents involving dog or cat bites or scratches monopolize

Infectious Diseases of the Dog and Cat, 3rd Edition

scarce public health resources. Efforts of large-scale vaccination of dogs by inoculation or distribution of vaccine in oral baits may offer other solutions. Having animals well vaccinated for rabies minimizes the postexposure recommendations for involved people. Cats have now replaced dogs in the United States as the most commonly rabid domestic animal. Increased awareness and vaccination of cats will help reduce the need for PEP, especially in states involved with raccoon rabies epizootics.¹⁶² Restricting the free-ranging behavior of dogs and cats that are too young for vaccination will reduce their chance of becoming infected. As vaccination for dogs and cats becomes more uniform and oral vaccination of terrestrial carnivores becomes more widespread, the relative risk of infection from bats may be more prominent.

179

180

Table 22-3 Postexposure Recommendations for Rabies Exposure of People in the United States^a

POTENTIAL SOURCE OF INFECTION	SITUATION	ANIMAL DISPOSITION	POSTEXPOSURE PROPHYLAXIS FOR PEOPLE
Dog, cat, or ferret ^b	All bites; healthy, owned	Confine; observe for at least 10 days, especially if unprovoked attack	None or consider, if unprovoked; yes, if CNS signs develop in animal
	All bites; healthy, stray (available or escaped)	If available, euthanize immediately; submit head for examination	Yes; stop if laboratory results negative, or continue if animal unavailable
	All bites; CNS signs or illness	Euthanize immediately; submit head for examination	Yes; if negative FA result, stop
Bat	Bite, scratch, mucous membrane exposure, or reasonable probability of close direct contact (e.g., in same room indoors)	Safely collect bat; submit for examination	Yes; if negative FA result, stop
Wild carnivore	All bites	If captured, euthanize immediately; submit head for examination	Yes, if positive or animal at large; if negative FA result, stop
Small rodents ^c	All bites	Usually not examined	None, but consult public health officials if circumstances of bite warrant
Inoculation of attenuated vaccine ^d	Any episode	Not applicable	No postexposure prophylaxis required
<p>Data, in part, from Human Rabies Prevention—United States, 1999. Recommendations of the Advisory Committee on Immunization Practices (ACIP), <i>MMWR</i> 48:RR-1.</p> <p>CNS, Central nervous system; FA, fluorescent antibodies.</p> <p>Bite: any penetration of skin by teeth; injuries by bats can be small and undetected. Nonbite: contamination of open wounds, abrasions, mucous membranes or scratches with saliva or neural tissue of a rabid animal.</p> <p>Nonexposure: petting, contact with blood, urine, or feces (e.g., guano) of rabid animal, especially if dry or exposed to sunlight, virus is inactivated.</p>			

a Other countries have different guidelines.

b Vaccination status of animal *should not* be used to make a decision on outcome for prophylaxis. An unprovoked attack by an animal is more likely than a provoked attack to indicate rabies. Bites from a healthy dog, cat, or ferret during feeding or handling should be considered as being provoked. Offspring of wild animals crossbred to domestic dogs and cats are considered wild carnivores and are handled in that category. In the United States, the likelihood of rabies transmission occurs by region. Dog rabies occurs predominantly along the Mexican border. Rabies in cats is more prevalent and is primarily associated with raccoon rabies in the eastern regions. In many developing countries,

Infectious Diseases of the Dog and Cat, 3rd Edition

dogs are the major vectors of rabies; thus an increased risk of transmission exists and prophylaxis would be more likely.

- c Squirrels, hamsters, guinea pigs, gerbils, chipmunks, rats, and mice. Lagomorphs are also included. Larger rodents such as woodchucks and beavers have been infected in areas where raccoon rabies is endemic and should be tested.
- d Accidental inoculation.

22.9.2 Postexposure Prophylaxis for People

The most common source of infection for people is untreated animal bites, although in areas in which bats are a source, the bite exposure may not be recognized. Once the infection develops, it is incurable; thus prompt postexposure management at the earliest indication is critical.¹¹⁰ Although less than five human cases of rabies occur each year in the United States, approximately 20,000 to 40,000 people annually are given antirabies PEP. In less developed countries, the cost of prophylaxis is prohibitive and so many cases are not prevented.

22.9.2.1 Wound Care

In cases of known bites, therapy of wounds should be aggressive because immediate, thorough washing of the wound has been shown to be effective in reducing the chance of rabies virus infection. Ethanol (43% or stronger) or commercial povidone-iodine solutions can be applied locally to open wounds. Bites should also be irrigated with large quantities of a 20% aqueous soap solution or quaternary ammonium compound (QUAT) under pressure. The optimal concentration of benzalkonium chloride, a QUAT, has been shown to be 1% to 4%; however, most commercial hospital disinfectants have a 0.13% concentration. Deep puncture wounds can be effectively cleaned by irrigation using a 15-ml syringe fitted with a blunted 19-gauge needle that is filled with a sterile saline solution. This provides 20 pounds per square inch of pressure, sufficient for cleaning but not so excessive as to cause further tissue damage.

22.9.2.2 Immunoglobulin

Specific prophylaxis in people has been most successful in reducing the number of deaths caused by rabies when active immunization is combined with human rabies immune globulin (H-RIG) (see [Table 22-2](#)). 180

H-RIG is preferable to unpurified γ -globulin because of its greater potency and lesser allergenicity. H-RIG is given one time, simultaneously with the initial dose of vaccine, or up to 7 days later. However, the dose is not repeated because it may interfere with the active immune response to subsequent vaccinations. If feasible, the H-RIG is infiltrated in the area around the wounds. Remaining volumes are given IM at a site away from the vaccination. Worldwide, H-RIG is in short supply and, in many countries, equine rabies immunoglobulin (E-RIG) is used.²³⁰ Unfortunately, the production of E-RIG has been discontinued in many countries. 181

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 22-4 General Guidelines for Importation of Dogs and Cats into “Rabies Free” Areas^a

1. Rabies certification and animal's health status
 - a. Owner name, address, telephone number
 - b. Identifying name of dog, cat, or ferret
 - c. Species, breed, sex, markings, age
 - d. Date of vaccination
 - e. Date of vaccination expiration
 - f. Rabies vaccination tag number
 - g. Vaccine producer and product name
 - h. Manufacturer's serial or lot number
 - i. Confirmation that animal found in good health
 - j. Veterinarian's signature
 - k. Veterinarian's address and license number
 - l. Owner retains original copy
 - m. Owner places tag securely on animal's collar
2. Identification
 - a. Electronic Microchip Implantation
 - b. Readable with ISO compatible reader (AVID®, Trovan®, Home Again®, or Destron®)
 - c. Implanted at time of blood serology
 - d. Microchip number must be on laboratory submission forms
3. Vaccination for Hawaii, United States of America^b
 - a. Previously unvaccinated: need 3 or more months between at least two vaccinations
 - b. Pups vaccinated at greater than 3 months of age for first vaccine
 - c. Kittens vaccinated at greater than 2 months (recombinant) or 3 months (inactivated) of age for first vaccine
 - d. Previously vaccinated: need a booster between 90 days and 12 months of arrival
 - e. The most recent vaccination is valid for 12 months to qualify for 30-day quarantine
 - f. No rabies vaccine within immediate 90 days before arrival

Infectious Diseases of the Dog and Cat, 3rd Edition

4. Blood testing

- a. Done by Office International des Epizooties (OIE) Standards
- b. FAVN test or RFFIT used
- c. Passing result is 0.5 IU/ml or greater
- d. Results are reported directly to veterinarians
- e. Collect blood at least 10 to 14 days after vaccination
- f. Cannot enter until at least 90 days have passed from the time laboratory receives sample

FAVN, Fluorescent antibody virus neutralization; RFFIT, rapid fluorescent-focus inhibition test.

For Hawaii: 30 days' quarantine if above qualifications are met; otherwise 120-day quarantine.

For United Kingdom: Quarantine period is 6 months with the following exceptions, whereby the quarantine is waived for commercially traded animals: (1) The animal must be born on a registered holding facility where it has remained with no contact to wild animals susceptible to rabies. (2) It has been vaccinated with a one unit (WHO standard) inactivated product when at least 6 months of age and at least 6 months before export. (3) It must have a certified blood test and veterinary health certificate, vaccination record, and implanted microchip as outlined above. (4) Agriculture Department, United Kingdom, must be notified of entry within 24 hours of arrival.

For Australia: The minimum quarantine is generally 30 to 60 days if the above guidelines are met and is variable depending on the country of origin and time interval between blood titer testing and arrival. A period of 180 days between the time of the titer and travel is maintained because this is the maximum incubation period for dogs and cats.¹⁴² Only a single vaccination is required, preferably within 6 to 12 months of entry. (1) Animals must be more than 6 months of age, not pregnant, or not of certain banned breeds. (2) If a first vaccination, it must be given at least 3 months of age and for boosters within 3 to 12 months of entry. (3) Animals must be accompanied by a health and rabies certificate, have an implanted microchip or unique tattoo and have an approved rabies viral neutralizing antibody test result as outlined above. In addition to some other parasite screenings, dogs must have seronegative test results to *Ehrlichia canis* and *Brucella canis* within 45 days and *Leptospira canicola* within 21 days of travel. If residing in Africa, dogs must be treated prophylactically for babesiosis.

- a Information from the World Health Organization and Office International des Epizooties and the regulating authorities of the various countries below.
- b Guidelines may vary and respective consulate for the country of interest should be contacted for the latest information. Some exceptions to the above guidelines are listed for the indicated geographic area.

22.9.2.3

Vaccination

Rabies human diploid cell vaccine (HDCV) is highly effective and safe for pre- and postexposure immunizations; however, it is too expensive for use in many developing countries. Two additional vaccines are rabies vaccine adsorbed (RVA), a fetal rhesus monkey lung cell culture rabies vaccine that is in very limited supply, and a purified chick embryo cell (PCEC) vaccine. These are the only commercial rabies vaccines currently available in the United States (see footnotes, [Table 22-2](#)). They are more immunogenic and less allergenic than previously available human rabies vaccines.²¹⁹ Five doses of 1.0 ml each are given IM. Postexposure therapy with HDCV, PCEC, or RVA and H-RIG must begin as soon as possible, preferably within 24 hours or less (see [Table 22-2](#), Postexposure, People). Postexposure failures have been noted when the vaccine has been given in the gluteal rather than the deltoid muscle. If previously immunized people are exposed to potentially rabid animals, IM boosters are administered on days 0 and 3. In some

181

182

Infectious Diseases of the Dog and Cat, 3rd Edition

regions, 0.1 ml ID booster doses have been substituted for some of the standard IM doses as a safe, convenient, and more economical solution, such as in developing countries.²⁰⁷ The ID route is not recommended for PEP in the United States. Veterinarians and other animal health care professionals should not receive boosters unless tests show no detectable titer. Based on serologic evidence from biennial testing, approximately 80% of vaccinated veterinarians will continue to sustain protective titers; they should be given boosters when an exposure is identified.

22.9.2.4

Exposure Incident

The decision to administer PEP in people is a medical urgency and is based on a large number of factors concerning the bite incident. The species of animal that inflicts the bite wound is important because dogs, cats, and especially wild carnivores and bats are more likely to transmit the virus. Many people might have been spared the concern and inconvenience of prophylactic therapy had cats been routinely vaccinated. Bites of rodents such as squirrels, chipmunks, rats, mice, and lagomorphs seldom if ever result in human PEP (see [Table 22-3](#), Rodents). Despite this fact, PEP has often been performed unnecessarily.

Table 22-5 Recommendations for Preexposure Rabies Prophylaxis in Researchers, Animal Health Professionals, and the Population at Large

EXPOSURE	POPULATION	NATURE OF EXPOSURE	ROUTE OF EXPOSURE	RECOMMENDED PROPHYLAXIS
Continuous	Rabies research laboratory staff, biologics production staff	High concentration of virus	Aerosol, mucosal, bite, etc.	Primary series; serologic test at 6-month intervals, booster when level not adequate
Frequent	Rabies diagnostic laboratory staff, spelunker, veterinarians and staff, wildlife workers, travelers visiting enzootic areas (over 30 days)	Episodic exposure, recognized source	Bite or nonbite	Primary series; serologic test every 2 years; consider booster when level not adequate; antibody titers are surrogate markers for continuing immunity
Infrequent	Veterinarians, animal control and wildlife workers in low rabies enzootic areas, veterinary students	Episodic, recognized source	Bite or nonbite	Primary series; no serologic testing or booster vaccination
Rare	U.S. population at large, including people in enzootic areas for rabies	Episodic	Bite with recognized source	No vaccination
Modified from: Human Rabies Prevention—United States, 1999, Recommendations of the Advisory Committee on Immunization Practices (ACIP). <i>MMWR</i> 1999;48 {No. RR-1} Minimum acceptable antibody titer complete neutralization at a 1:5 serum dilution with rapid fluorescent focus inhibition test.				

The type of exposure is important in determining if PEP should be used. Canids are the most important vector for rabies transmission to people of Asia, Africa, and Latin America. In other areas of the world, with more extensive canine vaccination programs, wild mammals, especially bats, predominate as vectors.

Exposure to rabies is via a bite, scratch, or other situation in which saliva or CNS tissue of a potentially rabid

Infectious Diseases of the Dog and Cat, 3rd Edition

animal enters an open or a fresh wound or comes in contact with mucous membrane of the eye, nose, or mouth. Nearly all cases of human rabies have been acquired by exposure to saliva in bite wounds or, very rarely, on abraded or scratched skin. Nonbite exposures rarely result in rabies virus infection. Indirect nonbite exposure has never resulted in a human infection. This situation might occur if a rabid animal had bitten a dog and the owner cleaned the wounds. Handling of blood or urine in carcasses of infected dogs did not appear to be of risk.²⁰⁰ Live rabies virus could not be isolated from blood or urine although viral RNA was found in the urine samples and urinary tissues, especially the urinary bladder. In many human infections with bat rabies variants, the type of exposure is often not evident¹⁶⁴ but is believed to be caused by an unrecognized bite. The lack of a demonstrable bite or scratch, and therefore clinical suspicion, often delays a diagnosis and potential early prophylaxis. Therefore a new recommendation, although often controversial and expensive to implement, has been to consider PEP if a reasonable chance of exposure exists when bats are involved.^{11,87} Unfortunately, the tendency to err on the side of caution means that PEP is often administered without confirmation.^{164,235} PEP is always indicated in people with compromised immune systems such as those with AIDS.¹ The use of PEP may be associated with potential adverse effects such as local swelling, myalgia, pyrexia, vomiting, or systemic allergic reactions.

The epidemiology of the biting incident is also important in determining the need to initiate prophylaxis before laboratory confirmation (see [Table 22-3](#)). Bites from rabies-infected animals usually occur without provocation. Animals that show neurologic signs at the time of the bite or soon after should be considered rabid. Bite exposures are much more likely to result in rabies infection than scratches, unless the scratches were contaminated by the animal's saliva. The prevalence of rabies in the geographic area is also important. People accidentally injected with inactivated animal rabies vaccines do not require PEP. For additional information on rabies in exposed people, consult the CDC rabies web page (<http://www.cdc.gov/ncidod/dvrd/rabies>).

182

183

22.9.3 Preexposure Prophylaxis for People

Preexposure prophylaxis is warranted in people with a high vocational or recreational risk of contacting rabid animals (see [Table 22-2](#) and [Table 22-5](#)). An initial three-dose series (days 0, 7, and 21 or 28) has provided superior protection, when followed for 10 years, as compared with the two-dose (days 0 and 28) primary immunization sequence.²⁰⁵ Veterinarians, animal health technicians and caretakers, animal control officers, wildlife biologists, bat handlers, laboratory workers, and spelunkers in rabies-endemic and epidemic areas should receive preexposure vaccination. Disaster response personnel should also consider preexposure vaccination because of packs of dogs that create risk under these circumstances.⁹³ Despite CDC recommendations for vaccination of animal health workers, a large proportion of at-risk staff in these areas have not received vaccination.²¹⁵ Cost or short-term employment may be barriers to uniform compliance. Unfortunately, many rabies endemic countries do not have the means to administer rabies vaccines for people in the quantities desired.

Substitution of 0.1 ml dose of ID HDCV is also effective for primary immunization and is cost-effective alternative in underdeveloped countries to the less costly but often used nervous tissue–derived vaccines.²⁰⁷ More frequent boosters are needed with ID as compared with IM use because of a shorter duration of immunity.¹⁷ Concerns have surfaced about the consistency of the vaccines used for ID procedure and immune response that results.²²⁵ The use of ID rabies vaccine has been discontinued in the United States as a business decision but not for public health reasons. Hypersensitivity reactions have been the main side effects noted in approximately 6% of those receiving booster vaccinations with HDCV after having received the primary series.

Infectious Diseases of the Dog and Cat, 3rd Edition

Local and systemic immune complex-mediated allergic reaction have developed with the use of HDCV, although the reactions are less than those with previously available products. Hives, urticaria, arthralgia, fever, nausea, and vomiting can develop within 1 week of booster vaccinations.

The risk of veterinarians being exposed to rabid animals is more than 300 times greater than that of the general population.⁷⁸ In one study, most (230) of the 380 exposures occurred to veterinarians during nonbite contact while they examined rabid animals. Seventy-nine exposures were the result of an animal bite.⁷⁸ Seventeen were the result of exposures at necropsy. Many of these potential exposures resulted from contact with infected cattle, although a summary claimed only 13 known confirmed instances of rabies transmission from cattle to people worldwide. No human rabies has been documented after preexposure vaccine administration by the IM route.

23 CHAPTER 23 Pseudorabies

Marc Vandeveld

23.1 ETIOLOGY

Pseudorabies virus (PRV) is an enveloped DNA virus and an alpha-herpesvirus. As with other herpesviruses, PRV can cause latent infection, with viral DNA being incorporated into the host cell genome. The virus is relatively resistant to environmental factors and can survive outside the host for several months under favorable climatic conditions. Survival of PRV depends on temperature (10 days at 37° C, 40 days at 25° C) and pH (optimum, 7), and it is quickly inactivated by drying and exposure to ultraviolet light.⁴ The genes of PRV have been cloned and sequenced, and its genetic relationship to other animal herpesviruses has been studied.

23.2 EPIDEMIOLOGY

PRV infection (known as *Aujeszky's disease*, *mad itch*, and *infectious bulbar paralysis*) occurs in most countries of the world with the exception of Australia and has been responsible for massive economic losses. Although many mammalian species are susceptible to infection with PRV, it is predominantly a problem in pigs, the main reservoir of the virus. However, cattle, fur-bearing animals, dogs, and cats are sporadically affected.^{15,20} It does not appear to affect humans; most reports have been circumstantial and have not been documented. Infection frequently is subclinical in pigs because they have become well adapted to the virus. The disease is spread by commercial movement of infected pigs or contaminated pork products. Venereal transmission occurs when infected boars shed PRV in semen. Although wild animals such as raccoons, panthers,¹⁰ and rats may act as transient reservoirs, they are not important in maintaining the disease in nature. Their role is limited to temporary local spread of virus within enzootic areas. Similarly, PRV infection in dogs and cats only occurs in areas where the disease is enzootic in pigs. Such epidemiologic interaction among species has been documented by molecular biological studies on viral isolates.¹¹ In fact, the occurrence of typical pseudorabies signs in pets can be the first indication that the disease is enzootic in the local pig population. Pets almost invariably are infected as a result of consuming contaminated raw pork. Dogs also have developed pseudorabies after having bitten infected pigs. Direct spread from dog to dog has not been shown to occur.²⁷

184

23.3 PATHOGENESIS

Naturally acquired infection in dogs and cats occurs after ingestion of the virus, although a similar sequence of events occurs after parenteral inoculation of virus. PRV enters the nerve endings at the inoculation site and travels in retrograde fashion via the axoplasm of the nerve fibers to the brain.⁷ The incubation time in dogs and cats, regardless of inoculation sites, is 3 to 6 days. Experimental studies in orally infected cats have shown that PRV replicates in the tonsils and travels from the oral mucosa via the sensory branches of the ninth and tenth cranial nerves to the nucleus, tractus solitarius, and area postrema in the medulla oblongata.¹⁴ The fifth cranial nerve has been less frequently involved. Experimental infections in rats have shown that PRV spreads in a highly specific manner through synaptic connections.^{3,7} Apart from visible damage to the brain tissue associated with inflammatory changes, the virus can cause considerable functional alterations of the nerve cells.⁵

Infectious Diseases of the Dog and Cat, 3rd Edition

23.4 CLINICAL FINDINGS

The majority of dogs and cats that become infected develop severe clinical signs. The onset of clinical illness is hyperacute, and signs progress rapidly until death occurs; the total course rarely lasts longer than 48 hours. With very few exceptions, pseudorabies is always fatal in dogs. Cats may be somewhat more resistant but have rarely recovered from the disease.

The initial sign often noted by the owner is a change in behavior, such as inactivity, lethargy, and indifference, although some animals become aggressive or restless. Dyspnea, diarrhea, and vomiting are occasionally seen. The dyspnea is often caused by severe pulmonary edema. Body temperature may be normal or abnormal, and hypersalivation is common. However, the most characteristic sign is intense pruritus, which usually occurs in the head region and rarely occurs in other areas such as the neck and shoulders. The animals violently scratch their faces and ears and rub their heads against the floor or walls. One side of the head and neck may become swollen. Self-mutilation results in erythema, excoriation, and ulceration of the skin and underlying tissues (Fig. 23-1). The scratching becomes increasingly more frantic and may end in generalized convulsions. Most of the other neurologic signs that are observed in PRV infection refer to lesions in the lower brainstem and consist of one or several deficits in cranial nerve function. These deficits are usually unilateral and include anisocoria, mydriasis, lack of direct or consensual pupillary light reflexes, trismus, paresis and paralysis of the facial muscles, head tilt, inability to swallow, and vocal changes. Anisocoria and a hoarse voice are considered to be highly consistent signs in the cat.²⁴ Less commonly observed neurologic signs include behavioral abnormalities such as aggressiveness, generalized hyperesthesia, head pressing, and generalized convulsions. The latter often occur as sequelae to frantic scratching. Paresis and paralysis of the limbs are sometimes noted shortly before death. Although less common, in some cats death has been preceded predominantly by acute GI signs.³⁵ Arrhythmias may manifest by an irregular pulse and dropped beats as a result of myocarditis.³²

Fig 23-1 Dog with pseudorabies and self-mutilation injuries. (Courtesy Daniel Harrington, Purdue University, West Lafayette, Ind.)

Infectious Diseases of the Dog and Cat, 3rd Edition

An atypical course of the disease has also been observed in cats that died suddenly without developing neurologic signs.¹⁸ Pruritus has been absent in some cases of spontaneous PRV infection in dogs³⁷ and in experimental oral infection in cats.¹⁴ gastrointestinal signs have been the predominant feature of some infected dogs.⁹

23.5 DIAGNOSIS

Hematologic or biochemical abnormalities are not found in pseudorabies. Cerebrospinal fluid may show increased protein concentration and mononuclear pleocytosis. This finding is strongly indicative of viral encephalitis but is not specific for pseudorabies. Electrocardiographic findings may include cardiac arrhythmias.^{23,32}

Traditionally, the diagnosis of pseudorabies consisted of cutaneous inoculation of infected tissue (usually brain) into a rabbit. Scratching and automutilation of the inoculation site occurred after an incubation of 5 to 6 days, followed by the rapid death of the animal. Virus can also be propagated in the brains of mice after intracranial inoculation.³¹ Pruritus can occur in some mice at the site of inoculation. Newer diagnostic methods such as direct fluorescent antibody examination for virus have made animal inoculation studies obsolete. This procedure can detect virus in smears or frozen sections of various tissues. The brain and tonsils are the tissues of choice in such studies. Polymerase chain reaction (PCR) has been used to detect PRV.³⁰ PCR has been used successfully to detect the virus in a cat in Japan.¹⁶

184

185

Virus can be isolated in tissue culture from lung and spleen and especially from brain and tonsils of animals with pseudorabies. Although many cell lines have been used, most laboratories use pig kidney epithelial cells. A definite cytopathic effect consisting of syncytial formation is visible after 12 to 24 hours. Virus isolation is not always easy in dogs, even in well-substantiated cases.² Pharyngeal washings, tonsillar swabs, and saliva are unsuitable for viral isolation in dogs.¹⁹

Virus neutralization, immunodiffusion, and enzyme-linked immunosorbent assay (ELISA) methods commonly are used to detect serum antibody to PRV in pigs. Serologic studies have been valuable in determining the incidence of disease in pig populations from an epizootiologic and a disease prevention point of view. PCR has been able to detect latency in the porcine population.³⁰ Virus neutralizing antibodies have not been found in sera from dogs tested during an outbreak of PRV infection.¹⁹

23.6 PATHOLOGIC FINDINGS

No gross lesions are diagnostic of pseudorabies, with the exception of the skin lesions that result from intense pruritus. In some cases, abnormal stomach contents have been noted because of pica. Pulmonary edema and congestion have been consistent findings. Focal myocarditis has been found in dogs and cats. Lesions in the central nervous system are almost exclusively located in the brainstem and primarily involve cranial nerve nuclei.⁸ They may be unilateral and consist of perivascular cuffing with mononuclear cells and pronounced proliferation of astrocytes and microglial cells (Fig. 23-2, A). The areas of focal gliosis often show degeneration (karyorrhexis) in the center and may progress to the formation of microabscesses (Fig. 23-2, B and C). Severe changes occur in neurons, with chromatolysis and disintegration of the nucleus. The most significant finding is the presence of weak eosinophilic viral inclusion bodies in the nuclei of astrocytes and neurons (Fig. 23-2, D). Viral antigen can be specifically demonstrated in formalin-fixed, paraffin-embedded tissues with immunocytochemical methods⁶ or in situ hybridization.^{28,34} Inflammatory changes can also be found in the nerves and ganglia associated with the

Infectious Diseases of the Dog and Cat, 3rd Edition

site of viral entry. Severe inflammation of the myenteric plexus in the alimentary canal of dogs naturally infected with PRV has also been reported.^{9,13} Experimentally infected dogs had ganglioneuritis of autonomic nerves of the heart.²³

Fig 23-2 Histologic findings of pseudorabies encephalitis. **A**, Disseminated perivascular cuffing and gliosis in the medulla oblongata (H and E stain, x100). **B**, Neuronal degeneration (*arrow*) with nodular gliosis (H and E stain, x250). **C**, Microabscess (H and E stain, x250). **D**, PRV inclusion body in glial cell nucleus (H and E stain, x400).

23.7 THERAPY

Treatment of pseudorabies is generally futile because the disease is almost always fatal. Heavy sedation and anesthesia may lessen or relieve the itching and convulsions; however, nothing can alter the outcome of the disease. Treatment with anti-PRV serum did not improve the condition of a dog with Aujeszky's disease²⁹ and is considered to be ineffective in the prevention of infection.²⁷

185

186

23.8 PREVENTION

Prevention is the most important means of control of PRV infection in dogs and cats. Contact with pigs and especially the use of raw pork from endemic areas as animal food should be avoided. It is possible to vaccinate small animals against PRV, although this is indicated only in endemic areas, where exposure to infected pigs may

Infectious Diseases of the Dog and Cat, 3rd Edition

occur. Natural infection with PRV has not been observed in vaccinated dogs and cats.¹ However, experimental vaccination challenge studies showed that it may be difficult to protect dogs with an inactivated vaccine, although most animals develop serum neutralizing antibodies to PRV.²⁷ Attenuated PRV vaccines may cause postvaccinal reactions that may be as lethal as the natural infection. PRV deletion mutants have been developed for vaccination of pigs.^{21,22,25} Such vaccines are safe and very useful for controlling the disease because serologic surveys can distinguish between vaccine-induced and natural anti-PRV antibodies. Deletion vaccines have been tested in raccoons, albeit with limited success.³⁶ DNA vaccines have also been developed.¹⁷ Human adenoviruses have been used as vectors for experimental immunization of cats against PRV antigens.¹² To the author's knowledge, none of these modern vaccines have been systematically tested or applied in dogs and cats. In recent years, considerable progress has been made in the eradication of PRV infection in swine in many areas of the world.²⁶ As a result, Aujeszky's disease is becoming a very rare condition in dogs and cats, and the development and application of PRV vaccines in small animals have remained insignificant.

24 CHAPTER 24 Enterovirus Infections

Craig E. Greene

Picornaviridae, the family of the smallest RNA viruses, contains the genus *Enterovirus*. Species in this genus commonly infect humans and have classically been separated into polioviruses, coxsackieviruses, enteric cytopathogenic human orphan (echo) viruses, and as yet unclassified enteroviruses. Newer members of the genus are called enteroviruses and are designated by a sequential numbering system. Enteroviruses are environmentally resistant and infect people primarily via the fecal-oral route. After replication in submucosal lymphatic tissues, the viruses may spread systemically to various other tissues.

Dogs have been tested to determine whether they harbor a variety of human enteroviruses because of the possible zoonotic potential (Table 24-1). Similar information is not available for cats. Dogs have been shown to be exposed to and to chronically shed human enteroviruses; however, serologic evidence of infection does not always correlate with shedding of the viruses. Although dogs appear to become infected with these viruses, clinical signs have not been apparent. The viruses can be found in the stools for a period of months, but whether the extended shedding represents reexposure is uncertain. Enteroviruses recovered from nasopharyngeal or fecal cultures of dogs have been grown and cause cytopathogenic effects, primarily in monkey kidney but not canine cell lines, supporting the fact that they are human viruses. Furthermore, neutralization tests have shown them to be indistinguishable from the human isolates.^{8,9}

In some instances, enteroviruses were found in canine feces that were “just passing through,” not causing infection. These viruses may have been obtained from sources contaminated by human feces. Alternatively, they may be enteroviruses antigenically related to human enteroviruses or other viruses neutralized by nonspecific substances in the testing sera. Newer techniques to determine viral homogeneity by genetic analysis must be performed on isolates to resolve this issue.

187

Table 24-1 Human Enteroviruses Recovered from Asymptomatic Dogs

VIRUS	SPECIMEN SOURCE	GEOGRAPHIC LOCATION
Poliovirus 1	Feces	West Bengal ²
	Feces	Costa Rica ⁵
Echovirus 6	Feces	California ¹
	Nasopharynx, feces	New Mexico ^{1,6,10}
Echovirus 7	Feces	West Bengal ²
Coxsackievirus A9, A20	Feces	Costa Rica ⁵
Coxsackievirus B ₁	Nasopharynx, feces	Texas, New Mexico ^{1,6}
Coxsackievirus B ₃	Nasopharynx, feces	New Mexico ⁶
Coxsackievirus B ₅	Nasopharynx, feces	New Mexico ⁶
Unclassified enteroviruses	Feces	Philippines ¹²

Feeding of echovirus 6 or coxsackievirus B1 to dogs produced minimal signs suggestive of enteric disease. Although the virus could be isolated from the feces, seroconversion could not be demonstrated.^{7,11} Infection seems to be limited to the alimentary tract of dogs and does not spread systemically as such infections do in people. Although dogs shed these viruses in low amounts, viral spread to susceptible dogs has resulted in infection.¹¹ Whether infected dogs can be a source of human infection is uncertain.

²⁵ CHAPTER 25 Mumps and Influenza Virus Infections

Craig E. Greene

^{25.1} MUMPS

Mumps virus is a member of the family *Paramyxoviridae* and genus *Paramyxovirus*. The virus causes illness in humans—its primary natural hosts; however, nonhuman primates and other laboratory animals have been experimentally infected. Clinical signs in affected humans include fever, anorexia, and progressive, independent enlargement of the parotid salivary glands. Meningitis, the main complication of infection that sometimes develops, results in headache and nuchal rigidity. Encephalitis, polyarthritis, and pancreatitis may develop, although they are uncommon. Vaccination programs have greatly reduced the prevalence and severity of this infectious disease throughout the world.

Mumps viral antibodies have been identified in the sera of healthy dogs; however, dogs can be infected with canine parainfluenza viruses (similar to but distinct from simian virus 5 of nonhuman primates; see [Chapters 6 and 7](#)), which may cross-react with some mumps viral antigens. Interpretation of prior serologic studies may be misleading for this reason. Nevertheless, reports have been made of parotid salivary gland enlargement in dogs from households in which children in the family have had concurrent or recent mumpslike infections.^{1,9,13}

Antibody to mumps viral antigen was detected in the serum of some affected dogs.^{9,13} A virus that had been neutralized by mumps viral antisera was found in one dog.⁹ Early experimental attempts to produce mumps in dogs or cats by inoculation of virus directly in the gland were inconclusive.⁹ Although in vivo transmission studies are inconclusive, mumps virus does grow well in primary dog kidney cell culture and has been a source of attenuated vaccine for human use.^{8,14} Veterinarians in practice should be aware of the possible association between mumps in children and pets, although definitive evidence for animal infection is lacking.

^{25.2} INFLUENZA

Influenza viruses are in the family *Orthomyxoviridae*. Almost every winter, two genera—types A and B—produce episodic outbreaks of an acute self-limiting febrile illness in susceptible humans. Type C influenza viruses are less closely related but produce a similar disease. Fever, myalgia, and signs of upper or lower respiratory tract infections are the most common manifestations. Mortality is the result of pulmonary complications. Pandemic spread of influenza may result periodically when genetic alterations of surface glycoproteins results in a new viral strain to which the world population has no immunity.

Influenza virus spreads through the transfer of virus-containing respiratory secretions from an infected to a susceptible human. Transfer through small (<10 µm) aerosols is the primary mode of spread.

Because of the close association of pets with humans, concern has been raised that dogs and cats may be important in the spread or maintenance of influenza infection. Many reports exist of serologic evidence of infection of dogs and cats with influenza virus. Experimental intranasal or intravenous infection of dogs^{7,11,12,15} and cats^{11,12} with influenza virus A strains, of dogs¹⁵ and cats¹¹ with type B strains, and of dogs¹⁰ with type C strains has provided convincing evidence that they are susceptible to these infections. Clinical signs in infected animals either were absent or consisted of a mild conjunctivitis, serous nasal discharge, and variable fever. Serologic responses have

Infectious Diseases of the Dog and Cat, 3rd Edition

been inconsistent, although viruses could be recovered from the respiratory secretions. Cats and dogs were also infected in some instances by contact with animals that were infected.

Spontaneous influenza viral infections of dogs and cats have been associated with human populations that are experiencing epidemics of the disease.^{2,12} No evidence suggests that the virus spreads from infected pets back to humans. This finding is in contrast to the situation in which the virus spreads between species, from humans and birds and back (“mixing vessel hypothesis”) probably occurs, with genetic recombination and evolution of new viral strains.¹⁸ Pigs have played an important role in the emergence of pandemic human influenza viral strains in the past.

188

In the avian influenza virus outbreak of 2004 caused by A H5N1 strain, a household of cats and some captive exotic cats in Thailand died in association with the death of some chickens. The possibility that this was caused by influenza virus has not yet been substantiated.¹⁹ Numerous other mammalian species such as seals, whales, mink, and ferrets are also susceptible to avian influenza viruses; however, viral replication in most of these animals, as it is in cats, is self-limiting. Only the pig appears important in the amplification of the virus between chickens and humans.

In Florida, a strain of equine influenza virus that had been isolated in Wisconsin in 2003 jumped the species barrier and infected racing greyhounds.¹⁶ It is likely the strain that is spreading through the horse population. Virus isolation and serum antibody titers were used to confirm the viral cause. Past outbreaks of fatal respiratory disease in greyhounds have been attributed to streptococcal infections (see [Chapter 35](#)); however, this may have been responsible in the past.

Infectious Diseases of the Dog and Cat, 3rd Edition

26 CHAPTER 26 Arthropod-Borne Viral Infections

All arthropod-borne (Arbo-) viruses known to infect dogs and cats belong to the families *Togaviridae*, *Flaviviridae*, *Bunyaviridae*, or *Reoviridae* (Table 26-1). These RNA viruses are usually maintained in nature by a sylvan cycle involving an arthropod vector and a vertebrate reservoir host (Fig. 26-1). The worldwide distribution of the mosquito-borne infections is presented in Fig. 26-2. Arboviruses usually replicate within their insect vectors, causing minimal or no cell injury. In contrast, vertebrate hosts' cells are often damaged by cytolysis. Although domesticated animals are usually incidental hosts for these infections, in some cases, they serve as reservoirs. As unnatural hosts, domesticated animals may be subclinically affected or show signs of disease (usually nonsuppurative, neurotropic encephalitis, abortion, or teratology). The clinical susceptibility of people, dogs, and cats for each disease also varies. Results of serologic testing indicate that a large number of dogs and cats may be exposed to these viruses; however, clinical illness is uncommon. Because serologic cross-reactivity between certain viruses can occur, and because dogs and cats can be subclinically infected, the following discussion emphasizes instances in which virus isolation and consistent pathologic findings have been present or experimental inoculation of dogs or cats has been performed.

Classical methods of diagnosing arboviral infections have included isolation and replication of virus, production of antigen extracts, and preparation of polyclonal or monoclonal antisera. Newer techniques, which involve RNA fingerprinting, immunohistochemistry, nucleic acid hybridization, polymerase chain reaction (PCR), and nucleic acid sequencing, have replaced some of the classical testing. These latter genetic techniques have now replaced viral isolation and serotyping as the initial screening procedures. Genotypic and phenotypic information should be complementary; however, in most cases, deducing the phenotype of these viruses from the known genomic sequences is not yet possible. Although genomics have been epidemiologically used to track virus strains, pathogenicity and cross-protectivity are difficult to assess without isolates.

26.1 Mosquito and Gnat-Borne Infections

Craig E. Greene

Charles A. Baldwin

26.1.1 Togaviridae

Alphaviruses in this family are grouped into seven antigenic complexes, and three of these (see Table 26-1) occur in the New World, causing sporadic equine, human, canine, and feline infections. Natural and experimental susceptibility of dogs to Venezuelan equine encephalitis (VEE) virus has been well described.⁵⁰ In both natural and experimental infections involving mosquitoes, viremia and seroconversion occur without clinical illness. For this reason, dogs have been considered good sentinel hosts for human VEE infection. Dogs also have been used to monitor the spread of infection into geographic areas. Parenteral inoculation of VEE in dogs has produced fever, leukopenia, and neurologic deficits at the peak of the febrile response. Cerebrovascular hemorrhage and infarction were detected. Naturally occurring VEE was also suspected as causing encephalitis in a puppy.⁵⁰ Eastern equine encephalitis (EEE) has been diagnosed in naturally infected dogs from south-central Georgia.¹⁰ All of these pups were younger than 6 weeks, with signs of diffuse encephalitis exhibited by ataxia, tremor, excessive salivation, and seizure.

Petechial hemorrhages have been grossly evident on the surface of the brain at necropsy. Histologic lesions in the brain were inflammation with macrophage infiltration and perivascular cuffing, edema, gliosis, hemorrhage,

189

Infectious Diseases of the Dog and Cat, 3rd Edition

and multifocal necrosis (Fig. 26-3). Mononuclear and neutrophilic infiltrates have been present in the meninges. Foci of myocardial degeneration and necrosis with mononuclear infiltration have been found in the heart. The viral association has been confirmed by use of an oligonucleotide probe and viral isolation. EEE has also been isolated from the central nervous system (CNS) of a litter of dying 6-week-old puppies in which no microscopic lesions could be demonstrated.¹¹ The infection may have been coincidental. Experimentally, dogs have developed diffuse encephalitis after intracerebral or parenteral inoculation of western equine encephalitis virus.⁵⁰

Fig 26-1 Arthropod-borne viral infections have a sylvan cycle involving arthropod vectors that feed on reservoir hosts. Domestic animals and people are usually incidental hosts, but they may serve as reservoirs in some instances (see Table 26-1). (Courtesy University of Georgia, Athens, Ga.)

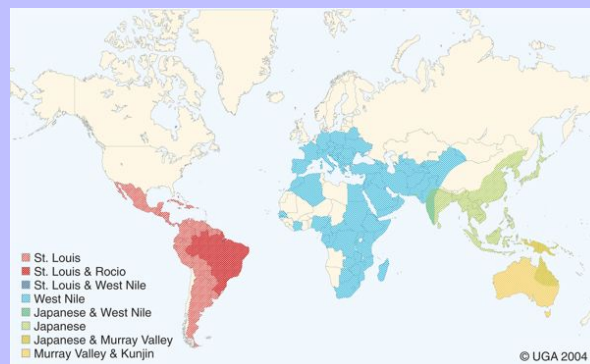

Fig 26-2 Worldwide distribution of arboviral infections from the World Health Organization. (Map drawn courtesy University of Georgia, Athens, Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Ross River and Barmah Forest viruses are endemic in Australia, primarily with kangaroos and wallabies (family Macropodidae) acting as major mammalian reservoirs. Serum neutralizing antibodies are widespread in human and mammalian populations, and some dogs and cats have neutralizing antibodies to these viruses. Dogs and cats experimentally infected by feeding mosquitoes were relatively resistant to both viral infections.²⁰ Only a few animals seroconverted, and none developed viremia or clinical signs. Although these animals are naturally exposed, they are not likely to be important reservoirs of these viruses.

26.1.2 Bunyaviridae

Tenshaw virus inoculated into dogs and cats produced asymptomatic viremia.⁵⁰ Mosquito transmission from infected dogs was also demonstrated. Rift Valley fever virus (RVFV) has produced viremia, severe hepatic necrosis, myocarditis, splenic congestion, meningitis, diffuse petechiae, and death in puppies and kittens younger than 3 weeks.⁵⁰ Virus can also be transmitted from puppies to their mother and to other puppies. Older puppies do not succumb to infection but do develop viremias. The virus can cause abortions and stillbirths in pregnant bitches. Inhalation or ingestion of the virus from infected carcasses may occur under natural circumstances. (For a complete discussion of RVFV infection, see below.) La Crosse virus infection is remarkable in adaptation to at least one of its vectors, *Aedes triseriatus*. Vector infection is life long, and the virus is transmitted transovarially to subsequent generations of mosquitoes. It is the primary cause of arboviral encephalitis in the United States. Two litters of puppies younger than 3 weeks developed a sudden onset of seizures and neurologic dysfunction after infection with La Crosse virus.¹⁷ An adult dog from Florida developed CNS signs of forebrain disease that responded to simultaneous treatment with antibacterials and glucocorticoids; however, it then developed seizures.¹¹² Severe diffuse necrotizing to granulomatous meningoencephalitis (GME) affecting primarily the cerebral cortex was noted in the affected dogs described previously (Figs. 26-4 and 26-5). Immunohistochemical testing demonstrated La Crosse virus within the affected brain tissue. Whether La Crosse virus is cause of idiopathic GME in dogs is uncertain (see Chapter 84, Neurologic Diseases of Uncertain Causes).

26.1.2.1

Rift Valley Fever

RVFV, a *Phlebovirus* infection of Africa and the Middle East, is capable of being transmitted by many species of mosquitoes. Among domestic species, RVFV affects predominantly sheep, cattle, and goats, and occasionally human beings. In people, the disease is characterized by hepatocellular failure, acute renal failure, and hemorrhagic manifestations.² Sera from wild and domestic dogs and cats in endemic regions have had positive test results. However, in a study using the more specific plaque reduction neutralization test, only lions from areas of three prior outbreaks had positive test results.⁵⁵ The mammalian reservoir for infection may exist in exotic carnivores such as the lion; however, domestic dogs and cats can be experimentally infected and maintain a viremia sufficient to infect mosquitoes.

Clinical illness in inoculated dogs is seen only in the first few weeks of life.¹²³ Some pups became hyperthermic during infection, while all died in a terminal hypothermic state. Some of the animals showed signs of CNS dysfunction near death. In older animals, 50% develop viremia and a corresponding increase in serum neutralization titer. Clinical signs in older animals were unapparent; however, transmission of infection from pup to mother and from pup to pup was demonstrated.

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 26-5 Perivascular necrosis in the brain from a pup with La Crosse virus infection (H and E stain, x40). (Courtesy Charles A. Baldwin, University of Georgia, Athens, Ga.)

High mortality has been observed when kittens less than 3 weeks of age were inoculated with virus.¹²⁴ Certain strains of feline panleukopenia virus vaccine used in the challenged kittens may have partially protected them against challenge with RVFV. A transient febrile response was followed by terminal hypothermia. Neurologic signs were ataxia followed by recumbency and paddling movements within 24 hours before death. As with pups, evidence indicated that the virus spread to other kittens and adults.

On gross necropsy of dying pups and kittens, the liver and spleen were enlarged and soft in consistency.⁸⁶ In the liver, faint gray to yellow foci, 1 mm in diameter, are surrounded by thin hyperemic borders. Petechial and ecchymotic hemorrhages were found on the serosal surfaces of the heart, abdominal lymph nodes, and mucosal surfaces of the gastrointestinal tract. Histologically, hepatocellular necrosis has been the most consistent finding. In less severe areas, foci of necrosis are evident, whereas in the most severe cases, the entire liver is necrotic with little normal parenchyma. Multifocal inflammation and necrosis have been evident in the myocardium. Perivascular nonsuppurative meningoencephalitis, characteristic of other arboviral infections, was found in the CNS. Lesions in experimentally infected dogs and cats did not show characteristic eosinophilic intranuclear inclusions or Councilman-like bodies observed in other hosts.⁸⁶

26.1.3 Reoviridae

Orbiviruses are one of nine genera in the family *Reoviridae*. Dogs, which can be infected subclinically with African horse sickness virus, develop a serologic response and a viremia enabling them to transmit the infection.⁵⁰ They are thought to acquire infection naturally and suffer illness and death from eating infected horse meat or from the tick *Rhipicephalus sanguineus*.⁵⁶ Abortion in pregnant bitches and their subsequent

Infectious Diseases of the Dog and Cat, 3rd Edition

death have occurred 7 to 9 days after vaccination with a bluetongue virus–contaminated, modified live virus combination canine vaccine.^{1,39,133} Lesions in the dam consisted of interstitial pneumonia, myocardial degeneration, hepatic vasculitis, and renal glomerulitis.³⁹ Natural disease with this virus in dogs is unlikely based on the observed low seropositivity of dogs tested in endemic areas.⁵⁷

191

192

26.1.4 Flaviviridae

Flaviviruses are small, icosahedral, enveloped virions (45 to 60 nm diameter; 45 nm for West Nile virus [WNV]) with a single-stranded, positive-sense RNA genome.⁸⁹ The genus type species is the yellow fever virus (*flavi*, Latin for yellow); the genus also includes the St. Louis encephalitis (SLE) virus, which serologically cross-reacts with WNV.

SLE, Murray Valley encephalitis, and Kunjin viruses, along with other closely related viruses, belong to the Japanese encephalitis serocomplex. Infections caused by these viruses are maintained in nature by cycles involving birds as vertebrate hosts and predominantly *Culex* mosquitoes as vectors. Although dogs have been more resistant to SLE, serosurveys have demonstrated that they develop titers during human epidemics. Parenteral inoculation of Japanese encephalitis virus has resulted in subclinical infection, but intracranial inoculation resulted in encephalitis with corresponding neurologic deficits.⁵⁰ Louping-ill is described in a separate section of this chapter. Dogs have developed fever, viremia, and serologic response to Powassan virus.⁵⁰ Wesselsbron virus was isolated from the CNS of a dog with encephalitis.⁵⁰ Inoculation of brain tissue from this animal into naïve dogs produced seroconversion, viremia, and transient paralysis in one dog. Yellow fever virus has produced a transient viremia in cats after inoculation; however, puppies, even when splenectomized, could not be infected. European tick-borne encephalitis and louping-ill—two tick-transmitted flavivirus infections that can infect dogs—are discussed later in this chapter.

Cats have been reported to be refractory to SLE virus because they do not develop a humoral immune response after experimental infection and have not shown measurable antibody levels in field serosurveys.⁶⁹ Cats do develop antibodies to Powassan virus.⁶⁹

26.2 West Nile Virus Infection

Carol A. Lichtensteiger

Craig E. Greene

26.2.1 Etiology

WNV is a mosquito-borne arbovirus of the family *Flaviviridae*, genus *Flavivirus*, and serocomplex group of Japanese encephalitis virus. WNV was originally isolated in 1937 from a febrile woman in the West Nile area of Uganda, Africa (see Reviews).^{*} The virus has two lineages; only lineage 1 has been associated with disease in mammals.^{16,23} Based on genome sequence, the WNV isolate circulating in the novel outbreak in the United States is relatively stable and is most closely related to an isolate from a goose from a 1998 outbreak in Israel.[†]

* References 42, 52, 66, 97, 103.

† References 5, 13, 16, 66, 74.

Infectious Diseases of the Dog and Cat, 3rd Edition

26.2.2 Epidemiology

Historically, WNV has had a bird-mosquito-bird sylvatic cycle in Africa (endemic), parts of Asia, Australia (Kunjin variant), and Southern Europe, with only occasional small outbreaks of mild febrile illness in people and rare human or equine neurologic disease.[‡] In the 1990s, several outbreaks with neurologic disease in people and horses occurred in Europe and the Middle East, and a 1998 outbreak in Israel was the first reported outbreak with avian mortality.[§] WNV was not recognized in the Western Hemisphere before its emergence in New York City in 1999.⁷⁴ In the following 3 years, viral activity and disease spread nationwide in the United States (Table 26-2).^{*}

Table 26-2 Spread of West Nile Virus Activity Across the United States

YEAR	STATES ^a	PEOPLE ^b		EQUINE CASES	CANINE CASES
		CASES	DEATHS		
1999	4 ^c	63	7	25	—
2000	7	21	4	65	—
2001	27	66	9	733	—
2002	44	4156	284	14,539	7
2003	46 ^d	9122	223	~4105 ^e	27 ^e

- a Number of states with activity; the activity remained in affected states with new states added each year. Human disease usually occurred in a few less states than viral activity in birds, mosquitoes, and horses; activity in birds can be a harbinger of human disease.⁴⁹ In addition to the states listed, starting in 2000, Washington, D.C. has also had viral activity.
- b Recognized humans cases in the first 3 years were essentially all neurologic disease. In 2003, many of the reported patients were febrile, not neurologic. Recognition of the milder disease likely explains the decreased fatality rate.
- c New York, New Jersey, Maryland, and Connecticut.
- d States spared are Oregon, Nevada, Alaska, and Hawaii.
- e As of November 20, 2003.

Before the United States outbreak, one dog and no cats had been reported ill with WNV. The affected dog died over 35 years ago in Botswana, Africa, after being diagnosed with a neurologic disease; the isolated virus was originally identified as Wesselbron; however, with subsequent sequence data, it was identified as WNV.^{23,107} Serologic surveys for prevalence indicated dogs seroconvert without clinical disease in areas with WNV activity: 37% in Africa in 1988; 24% in India in early 1990s; 5% in New York City in 1999; and 2.4% in Missouri in 2002.^{18,21,68,79}

The WNV outbreak in the United States has been the largest ever recorded arbovirus epidemic. It deviated from historic outbreaks by its marked avian mortality and increased diversity of affected host species. Mortality in crows (crows and blue jays) was especially high. Deaths associated with WNV have been reported (including nonrefereed reports) in over 150 avian species.[†] Birds were a direct source of virus spread, as virus is shed in saliva and cloacal excretions, and carnivores may ingest carcasses.^{8,12,67} In the United States outbreak, in

Infectious Diseases of the Dog and Cat, 3rd Edition

addition to widespread disease in birds, people, and horses, published reports document WNV disease in squirrels, two dogs, a wolf, two sheep, an alpaca, and several hundred farmed alligators.[‡] Other animals reported as infected in a surveillance survey included three cats, 27 dogs, a skunk, and a few bats, raccoons, and rabbits (ArboNET, CDC Reporting Service www.cdc.gov/mmwr/preview/mmwrhtml/mm5322a9.htm).^{5,26,52,70}

Mosquitoes are the major transmission vectors of WNV, although other ectoparasites such ticks can be viable vectors,⁵⁸ and birds are the major vertebrate reservoir host. Although most of the natural transmission in the United States has been associated with two *Culex* subspecies, WNV has been isolated from at least 37 mosquito species. Most WNV disease is associated with the mosquito season, and disease usually peaks in late summer. However, the means by which the virus overwinters has not been established, and disease can occur in mid winter.¹²

In general, mammals are considered incidental or dead end hosts. The viremia is thought to be too low for transmission to mosquitoes; at most, rare inefficient transmission might occur.^{8,18,22,66} In experimental infections in cats and dogs, cats developed higher virus serum titers (10^3 to 10^4 pfu/ml, 0.5 to 8 days postinoculation) than did dogs ($10^{1.6}$ to $10^{2.2}$ pfu/ml between 0.5 and 3.5 days postinoculation).⁸ However, the titers in the cats were still low and transient compared with those found in birds; therefore even cats are unlikely to be efficient reservoirs for mosquito infection. The viral titer needed for transmission varies with mosquito species and is not precisely defined; however, transmission to mosquitoes can occur with titers in the range of at least 10^2 Vero cell pfu/ml of blood.

With the WNV outbreak in the United States, new natural routes of infection were suspected: ingestion (predation, milk consumption by nursing), blood transfusion, organ transplantation, and transplacental transfer.^{28,31} Rare laboratory transmission to people occurred via local trauma while working with carcasses of infected birds and rodents.^{27,103} Oral transmission was documented experimentally in cats and is the likely route of a large outbreak in farmed alligators fed tissues from infected horses.^{8,85} Summer of 2002 was the first time that WNV disease was recognized in canids in the United States outbreak; details have been reported on three occasions (two adult dogs and a juvenile captive wolf). Thirty-one other dogs and three cats have been reported to surveillance databases as possible affected.

26.2.3 Pathogenesis

WNV causes high viremia in birds and low viremia in other vertebrate hosts. The virus infects parenchymal cells of multiple organs and causes cell necrosis. From studies in mice, both the B-cell and T-cell components of the immune system control WNV infection.^{35,126} The generation of IgM is critical for host protection.³⁶ However, the T-cell limb may also be immunopathogenic in the CNS.¹²⁶

Infectious Diseases of the Dog and Cat, 3rd Edition

26.2.4 Clinical Findings

26.2.4.1 Dogs

When experimentally infected by mosquito, dogs have remained clinically healthy.⁸ They developed a viremia of low magnitude and short duration and showed no clinical manifestations of illness except for transient pyrexia in one dog. Virus was not detected in the saliva of any dogs during the course of their infections.

Natural infections do occur. Based on the four published canid cases (two adult dogs and a captive juvenile wolf), fever, central neurologic disease (especially ataxia), and possibly heart disease are expected.^{21,76,98a} In addition, one dog had unspecified renal disease and marked granulomatous inflammation (possibly a preexisting disease).²¹ Another dog had pulmonary edema and arrhythmias from heart disease. This patient also had immune-mediated thrombocytopenia and hemolytic anemia, also likely a preexisting condition. Common neurologic findings in the canids include lethargy, weakness, and ataxia; some also had conscious proprioceptive defects, head tilt, head bobbing, stupor, and blindness. Dogs can seroconvert with no clinical signs.* No reports have been published of canids surviving natural WNV disease. All the reported dogs had encephalitis, myelitis, and myocarditis.^{21,76} In canids, virus is found in multiple organs and is not restricted to inflamed organs.

* References 8, 18, 21, 68, 79.

26.2.4.2 Cats

Experimentally infected cats remained clinically healthy when they were infected via consumption of infected mice.⁸ However, the cats that were experimentally inoculated by mosquito feeding develop mild transient fever, inappetence, and lethargy. As with dogs, virus was not detected in saliva of the cats; however, viremia was greater and more sustained than that of correspondingly infected dogs. The three cats reported to surveillance databases, and the experimentally infected dogs and cats lack histopathology data.^{8,18}

26.2.4.3 People

The incubation period in human infections is 2 to 15 days (usually 2 to 6 days).¹⁰³ Of the people infected in the United States outbreak, the infection was asymptomatic in approximately 80% and a mild febrile illness in approximately 20% of infected people. In people who become ill, approximately 1 in 150 develop neurologic disease.⁸⁷ Most of the neurologically affected patients had meningoencephalitis, although a few developed severe myelitis and flaccid paralysis.⁶³ Mortality was up to 10%, and approximately 35% of recovered patients had residual neurologic deficits.⁹⁷ The disease is not age restricted; however, older people are more susceptible, likely caused by waning immune competence. Besides the fever and meningoencephalomyelitis in people, pancreatitis (one United States patient), rare myocarditis, and, in endemic Africa, hepatitis has been associated with WNV disease.

Infectious Diseases of the Dog and Cat, 3rd Edition

26.2.4.4 Other Animals

Similar to people, encephalomyelitis is the major disease in horses.^{25,95,98,129} Mortality in neurologically affected horses is approximately 40%.^{98,129} Many birds, especially crows, develop copious antigen in multiple organs and die without histopathologic changes, apparently resulting from rapidity of death. In birds, viral antigen is most abundant in the heart and kidney and is often also detectable in the spleen and brain. Other birds, especially raptors, tend to have an encephalitis and myocarditis at the time of death.^{41,110} Similar to dogs, horses and squirrels have encephalitis and myelitis, and squirrels have myocarditis.*

* References 25, 53, 64, 95, 98, 129.

26.2.5 Diagnosis

Detection of virus specific antibodies in serum confirms exposure to WNV. Options for serologic testing include serum neutralization (plaque reduction neutralization), IgG–enzyme-linked immunosorbent assay (IgG-ELISA), and capture assays for IgG or IgM.^{21,22,67,95} Compared with antiviral IgG, IgM has minimal cross-reactivity with other arboviruses.⁷⁸ The duration of antibody titers is undocumented; IgM titers are thought to be short lived.⁹⁵ However, serum IgM titers persist in people up to 500 days and therefore may not be a specific marker for acute active infection.¹⁰³ Antiviral IgM in the cerebrospinal fluid (CSF) does indicate intrathecal production. A fourfold or greater rise in plaque reduction neutralization titer is evidence of an active infection.⁹⁵

At necropsy, diagnosis is based on lesions (encephalitis, myelitis, and myocarditis) and documentation of virus in tissues: viral antigen by immunohistochemistry, viral genome by reverse transcriptase polymerase chain reaction (RT-PCR), or viable virions by virus isolation.[†]

193

For immunohistochemistry, both polyclonal rabbit antibody and polyclonal and monoclonal mouse antibody preparations have been used to label WNV antigen in fixed tissues. However, the labeling by different antibodies is not necessarily congruent.²¹ In the three published canid cases, viral antigen has been documented (number positive/number tested) in brain (1/3), heart (3/3), kidney (2/3), and adrenal glands (2/2).^{21,76} The two spleens that were tested did not show any presence of antigen.

194

Viral genome is detected by RT-PCR with amplicon detection by resolution in a gel or by 5' nuclease fluorogenic real time PCR.^{21,76} The published cases of diseased canids are too few to validate the optimal tissue collection. Viral genome has been documented (number positive/number tested) in brain (2/2), kidney (2/2), liver (1/2), and the heart, lung, and spleen (each 1/1).^{21,76} Although the published canid PCR studies used fresh or cryopreserved tissues, formalin-fixed tissue should also be adequate.⁶⁴

WNV is usually isolated using Vero cells, a cell line that develops a cytopathic effect 3 to 5 days following inoculation.^{8,22,108} Virus identification can be confirmed by serum neutralization or PCR assays. However, virus isolation is not readily available because a biosafety level-3 laboratory is required. In addition, virus isolation is not a sensitive method to document presence of virus in infected mammals, likely because of the low transient viral titer.^{60,98,103}

Infectious Diseases of the Dog and Cat, 3rd Edition

26.2.6 Pathologic Findings

Three cases of natural disease in canids and two cases of experimental infections in dogs and one in cats have been published, although the experimental studies lack histopathologic data.^{8,18,21,76} No specific changes are seen in serum chemistry or on complete blood counts, and generally no gross necropsy findings are produced, although the myocarditis may be grossly visible. Histologically, both encephalomyelitis and myocarditis are expected.

The encephalomyelitis is of variable intensity and characterized by gliosis, lymphocytic infiltrate, and neuronal necrosis (Fig. 26-6). The inflammation affects the gray matter more intensely than it does the white matter and includes glial nodules and mild vascular cuffing. To date, meningitis has not been recognized as a disease component in canids. The intensity of the myocarditis among canine patients varies from minimal to severe. In areas of myocarditis, myocytes are degenerative and necrotic, and lymphocytes predominate in the infiltrate with a few contributing neutrophils (Fig. 26-7). Two of the three published canid cases had scattered small foci of necrosis and lymphoid infiltrate in the adrenal gland cortex, these foci correspond to areas of immunolabeling for virus (Fig. 26-8, A and B). Viral antigen has been identified by immunohistochemistry in neurons (the wolf pup), myocytes (Fig. 26-9), renal tubular cells, and adrenal glands (see Fig. 26-8, B). One dog had unspecified clinical renal disease and a granulomatous nephritis with viral antigen. Although the kidney of this dog had a 1000-fold more viral genome than the heart, brain, or spleen,²¹ the nephritis may have been a preexisting renal disease given the nature of the inflammation and the fact that canids and other host species have West Nile antigen in the kidney without lesions. However, in Africa, rare unspecified renal disease has been associated with human cases.⁶² Dogs and cats experimentally infected with the NY99 West Nile isolate had no gross lesions, and the published studies did not include histopathologic data.⁸

Fig 26-6 West Nile virus encephalitis in the brain stem of a dog. Glial cells and a few lymphocytes form the infiltrate. *Arrow*, necrotic neuron. Of the three reported canids, the wolf had more marked encephalitis and was the only brain to label with immunohistochemistry for viral antigen (H and E stain, bars, 20 microns). (Courtesy Veterinary Pathology, University of Illinois, Urbana, Ill.)

Infectious Diseases of the Dog and Cat, 3rd Edition

26.2.7 Therapy

No specific therapy is available for affected dogs or cats; treatment is limited to supportive care for the patient and treatment of any underlying immunosuppressive disease. Some immunosuppressed human patients have improved following treatment with specific immune globulin transfusions.¹⁰⁶ Experimentally infected animals have been treated with pentoxifylline, gentamicin, or glucorticoids.⁶⁶ The efficacy of the antiviral drugs and glucocorticoid therapy used in humans or horses is unknown.⁹¹

26.2.8 Prevention

No vaccine is available for any species other than horses. Two experimental vaccines for people are in early first-phase clinical trials.⁹¹ In dogs and cats, as in people, the main means of prevention is protection from mosquitoes.

Because transmission in people has occurred via blood transfusions,³¹ blood donor dogs should be protected from mosquito exposure. Although its role in the natural epidemiology is undefined, oral transmission can occur; hence preventing predation or carcass consumption, especially of squirrels, horses, and birds may be warranted.⁸

Infectious Diseases of the Dog and Cat, 3rd Edition

26.3 TICK-BORNE INFECTIONS

26.3.1 CENTRAL EUROPEAN TICK-BORNE ENCEPHALITIS

Andrea Tipold

Marc Vandeveld

26.3.1.1 Etiology

Central European tick-borne encephalitis is caused by a flavivirus and transmitted by ticks (*Ixodes ricinus*).⁴⁶ The disease has been described in people, dogs, horses, monkeys, and wild ruminants, but not in cats. The disease has been observed in dogs, in central Europe (Switzerland, Austria, Germany, the Czech Republic), and in Sweden, Norway, Italy, and Greece; it tends to be endemic in focal areas.^{34a,114} The central disease is in the overlap region between the eastern and western forms of the disease, which follows the distribution of the respective vectors, *I. ricinus* and *I. persulcatus* (Fig. 26-10, A and B).

26.3.1.2 Clinical Findings

In the dog, three different courses of the disease are observed.^{65,102,115} Dogs may be asymptomatic^{40,65} or develop severe encephalitis^{46,115} from which they either recover or die. Severe cases exhibit fever (over 39° C [102.5° F]) and multifocal neurologic signs consisting of myoclonus, convulsions, hemiparesis to tetraparesis, stupor, hyperesthesia, and multiple deficits of the cranial nerves. Spinal reflexes may be reduced (polioencephalomyelitis).¹¹⁵ Rottweilers are overrepresented in the literature (8 Rottweilers from 22 described cases).¹¹⁴ The signs are usually progressive and dogs die within 4 to 7 days or are euthanized. Some dogs may recover showing a rising antibody titer.⁶⁵

26.3.1.3 Diagnosis

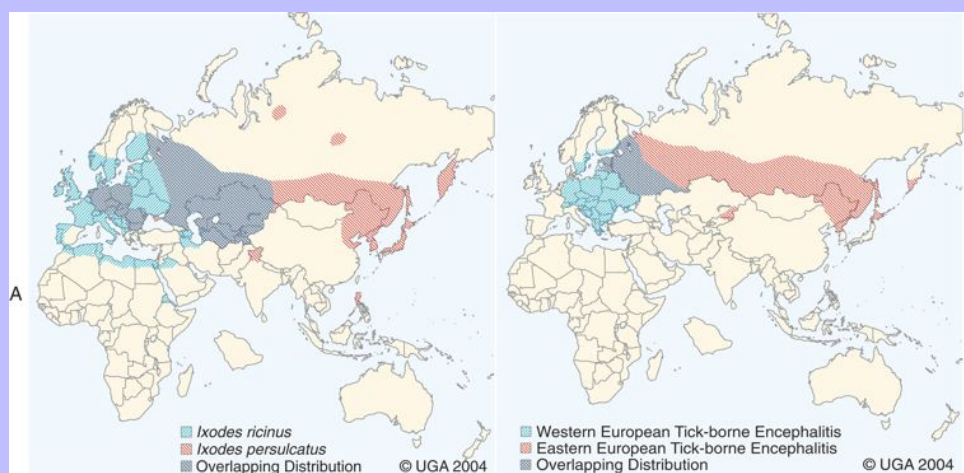

As in other viral infections of the CNS, mononuclear pleocytosis is found in CSF.¹¹⁵ Antibodies against the virus can be measured in serum and CSF.^{40,65} However, because of a high seroprevalence in endemic areas, clinically healthy dogs, as well as dogs with other CNS diseases, may also exhibit significant antibody titers.^{34a,40} Therefore a firm clinical diagnosis remains difficult. Only rising antibody titers can confirm the diagnosis. In view of the rapid progression of the disease in many cases, only postmortem histopathology will allow a definitive diagnosis.

26.3.1.4 Pathologic Findings

A nonsuppurative meningoencephalomyelitis with predominant lesions in the gray matter of the brain stem and cerebellum is found.^{82,115,129,130} Immunohistochemical staining revealed central European tick-borne encephalitis virus in Purkinje cells, neurons of brain stem nuclei, neuronal cell processes, and cytoplasm of macrophages.¹³⁰ Rapid clearance of the virus apparently occurs given that viral antigen is not easily found in advanced cases.

195

Fig 26-10 A, Map of distribution of *Ixodes ricinus* and *Ixodes persulcatus* ticks in the Western Hemisphere. B, Map of distribution of Western and Eastern tick-borne encephalitis virus infection in people showing corresponding distribution and overlap. (Courtesy University of Georgia, Athens, Ga.)

26.3.1.5 Therapy and Prevention

Treatment can only be supportive; glucocorticoids may worsen the disease process. Neither specific vaccines nor vaccination schedules exist for the dog; although human vaccines have been used in dogs in endemic areas. Antibody production may be shown in such dogs; however, until recently, no proof has been found for the efficacy of such vaccines in animals. In some endemic areas, the measurement of serum antibody titers against the central European tick-borne encephalitis virus is used to examine the spread of infected ticks.⁶⁵

26.3.2 LOUPING-ILL

Hugh W. Reid

26.3.2.1 Etiology

Louping-ill is an acute viral encephalomyelitis transmitted by the sheep tick *Ixodes ricinus*. Although louping-ill occurs most frequently in sheep, it has been reported in people, horses, pigs, cattle, goats, farm-raised deer, and dogs but not in cats.^{54,77}

The causal virus is a member of an antigenically closely related complex of arthropod transmitted viruses (family *Flaviviridae*) known as the tick-borne encephalitides (TBE) as described in the previous section. These viruses, present throughout the northern temperate latitudes, are primarily associated with disease in people. Infection in domestic animals has been recognized on a regular basis only in the British Isles in areas of rough pastures where sheep ticks are prevalent. However, encephalomyelitis in sheep resulting from

Infectious Diseases of the Dog and Cat, 3rd Edition

infection by either louping-ill virus or closely related viruses has occurred also in Bulgaria, Turkey, Spain, and Norway, suggesting that the disease may be more widespread.⁹⁹

In addition, meningoencephalitis caused by TBE viruses affecting dogs has been reported from Austria, Germany, and Switzerland,^{101,132} suggesting that disease in dogs caused by this complex of viruses has a wide distribution in Europe.

Risk of infection is generally restricted to the periods of tick activity, mainly in the spring and early summer, with a recrudescence in some areas in the fall. However, the precise periods of tick activity vary with latitude and altitude. In dogs, infection has been diagnosed most frequently in working sheepdogs and gun dogs, but any animal visiting enzootic areas during periods of tick activity may become infected.

Infection is assumed to be via the bite of the tick. Alternative routes of transmission should not be overlooked because disease in people is encountered in abattoir workers. Young goats and pigs can become infected by the ingestion of virus-infected milk and carcasses, respectively.

26.3.2.2

Clinical Findings

The initial systemic phase after infection generally is not associated with clinical signs, but during this period, the animal is viremic. The virus invades the CNS, and the subsequent course of disease is variable. Many infections are not recognized clinically because virus is eliminated by the immune response that subsequently maintains protection and detectable serum antibody titers, probably for the life of the animals. In animals that do develop clinical disease, initial signs, which are primarily caused by cerebellar dysfunction, include mild paresis, ataxia, and tremors that are sometimes associated with difficulty in eating. Within 24 hours, severe incoordination develops. The affected animal is usually in lateral recumbency, paddling its limbs, but this may progress to complete tetraplegia or opisthotonos.

Death may occur at any time, but in dogs that survive, recovery is slow, and locomotor dysfunction may persist for months. On recovery, temperamental and physical changes may be present, the animal being nervous, exercise intolerant, and less tractable.

196

197

Infectious Diseases of the Dog and Cat, 3rd Edition

26.3.2.3 Diagnosis

Diagnosis relies on the detection of a rising serum antibody response to louping-ill virus during the course of the infection. In fatal cases, histologic examination of the brain accompanied by virus isolation can confirm the disease. Histologic changes include neuronal necrosis and perivascular lymphoid cell accumulations that are particularly prominent in the spinal cord and cerebellum (Fig. 26-11). Immunohistochemical staining for virus in tissue specimens has been used but may give false negative results in the more protracted cases.⁷² Virus may be isolated from a homogenate of brain tissue by intracerebral inoculation of 3-week-old mice or in tissue culture cells.

26.3.2.4 Therapy and Prevention

Supportive therapy during the acute phase is beneficial, but no specific therapy is available. An inactivated, tissue culture–propagated vaccine incorporated in an oil adjuvant is available for protection of cattle, sheep, and goats and has been used in dogs. However, dogs appear to require at least two injections to elicit a detectable serum antibody response, and a proportion of them develop painless, fluid-filled swellings at the site of injection that may require surgical drainage.¹¹³

The ecology of louping-ill virus depends largely on a sheep-tick cycle, with little involvement of the native fauna. Systematic vaccination of sheep may reduce the prevalence of virus and may therefore reduce the risk of infecting other incidental hosts such as dogs. In continental Europe the virus is mainly maintained in a cycle involving ticks and woodland rodents and control is largely limited to vaccination of people.

27 CHAPTER 27 Salmon Poisoning Disease

John R. Gorham

William J. Foreyt

27.1 ETIOLOGY

Salmon poisoning disease (SPD), or salmon disease, is a highly fatal, helminth-transmitted rickettsial disease of domestic and wild Canidae that occurs on the western slopes of the Cascade Mountains from northern California to central Washington (Fig. 27-1). Occasionally, cases of SPD occur outside the indigenous range of the disease in areas where infected fish migrate or are transported. The presence of cases in British Columbia may indicate that the indigenous range of the disease is greater than previously reported.¹ A similar disease has been reported in Brazil.^{18a}

27.1.1 Salmon Disease Agent

The etiologic agent of SPD is *Neorickettsia helminthoeca*, a coccoid or coccobacillary rickettsia that is approximately 0.3 μm .^{4,22} Pleomorphic rods up to 2 μm long, sometimes bent in rings or crescents, have been observed. The gram-negative rickettsial organisms appear purple with Giemsa stain, red with Macchiavello's stain, black or dark brown with Levaditi's method, and pale blue with hematoxylin and eosin stain. The rickettsiae almost fill the cytoplasm of cells of the mononuclear phagocyte system (MPS) that they primarily infect (Fig. 27-2). The rickettsiae have been grown in canine monocytes,¹² canine leukocytes and sarcoma cells, mouse lymphoblasts, and a macrophage cell line.^{21,24} Antigenically and genetically, *N. helminthoeca* is closely related to *Ehrlichia* spp. Based on 16SrRNA gene sequences, *N. helminthoeca* is most closely related to *Neorickettsia (Ehrlichia) risticii*, the agent of Potomac horse fever, and *Neorickettsia (Ehrlichia) sennetsu*, the agent of human sennetsu fever in Japan (see Table 28-1).⁵

In dead fish, rickettsiae in metacercariae (encysted trematode larvae) of *Nanophyetus salmincola* do not survive 30 days at 4° C.¹¹ In lymph nodes, organisms resist freezing at -20° C for 31 to 158 days;²³ they remain viable in leukocytes at 4.5° C and 52.5° C for 48 hours and 2 minutes, respectively, but not at 60° C for 5 minutes.²⁷ At -80° C the agent can be maintained in cell culture fluid for up to 3 months.³

27.1.2 Elokomin Fluke Fever Agent

It is highly likely that the Elokomin fluke fever (EFF) agent⁶ is another strain of *N. helminthoeca*.^{12,13} The disease in dogs associated with the EFF agent results in high morbidity but a lower mortality than SPD. It appears that metacercariae can harbor EFF and SPD agents simultaneously. EFF is rarely recognized as a distinct entity in naturally occurring disease. Histologically, EFF infections in dogs are similar to but less severe than those seen with SPD. In a survey of 331 practitioners in endemic areas, 35% reported that they had diagnosed SPD in dogs that had been treated previously for SPD.¹⁴ Although it has been generally accepted that dogs surviving SPD infection had a solid immunity, the data now suggest that other strains such as EFF may be pathogenic under field conditions,¹ or the initial SPD infection failed to evoke a durable immunity.²

Infectious Diseases of the Dog and Cat, 3rd Edition

27.2 EPIDEMIOLOGY

The vector of SPD is a trematode, *N. salmincola*, which harbors the rickettsiae throughout its life cycle stages from egg to adult.¹⁹ Three different hosts are required for the completion of the trematode life cycle—snails, fish, and mammals or birds (Fig. 27-3). Lists of intermediate and definitive hosts of the fluke can be found elsewhere.¹⁹ The snail intermediate host, *Oxytrema silicula*, is a pleurocerid that inhabits fresh or brackish stream water in coastal areas of Washington, Oregon, and northern California. Areas of trematode infection therefore depend on the distribution of *O. silicula*. Cercariae (free-swimming trematode larvae) leave the snail and penetrate the second intermediate host, which is usually a salmonid fish, certain species of nonsalmonid fish, or the Pacific giant salamander (*Dicamptodon ensatus*). The metacercariae usually localize in the kidneys of fish (Fig. 27-4) but can be found in any tissue, as well as slime on the skin of the fish. Fish are infected in freshwater and retain the trematode and the rickettsial infection throughout their ocean migration before returning to fresh water up to 3 years later.²⁸

Adult trematodes develop in the intestine approximately 6 days after the ingestion of metacercariae-infected fish by dogs and certain other fish-eating mammals that serve as definitive hosts, such as bears and raccoons, and certain birds. Clinical signs of rickettsial disease occur in Canidae, primarily dogs, foxes, and coyotes. However, two captive polar bears receiving long-term glucocorticoid therapy for skin conditions succumbed to an SPD-like disease after eating inadequately frozen salmon.²⁶ Cats are not susceptible to SPD, but trematodes develop when infected fish are ingested.¹⁹

SPD also has been transmitted by parenteral injection of infected blood, spleen and lymph suspensions, adult flukes, helminth-infected snail livers, and helminth eggs. Partial transmission success was obtained by allowing ticks (*Haemaphysalis leachi* and *Rhipicephalus sanguineus*) that had fed on infected dogs to subsequently feed on susceptible dogs and by parenteral injection of suspensions of *R. sanguineus* into dogs.²² Susceptible dogs also have been experimentally infected with cell-cultured *Neorickettsia* organisms²⁴ and aerosolized lymph node suspensions from infected dogs; on rare occasions, direct transmission of infection between dogs has been suspected.²

27.3 PATHOGENESIS

After ingestion of raw, metacercariae-infected salmonid fish by a susceptible dog, the fluke matures, and the adult stage attaches to the mucosa of the intestine and by some unknown mechanism inoculates the rickettsiae (Fig. 27-5). Initial replication of rickettsiae probably takes place in the epithelial cells of the villi or the intestinal lymphoid tissue. Inflammation of the solitary lymphoid follicles and Peyer's patches along the intestinal tract contributes to enteritis. Mild enteritis may be observed in dogs infected only with the flukes but without rickettsiae.

Fig 27-6 Clinical course of salmon poisoning disease in a dog. (University of Georgia, Athens, Ga.)

Rickettsiae enter the blood early in the course of the disease and spread to the lymph nodes, spleen, tonsils, thymus, liver, lungs, and brain.¹³ Although secondary bacterial infections often occur, the exact cause of death in SPD is unknown. Investigations to demonstrate a toxin have been limited.

Infectious Diseases of the Dog and Cat, 3rd Edition

27.4 CLINICAL FINDINGS

27.4.1 Salmon Poisoning Disease

The signs of SPD are consistent in all Canidae. The usual incubation period after the ingestion of parasitized fish is 5 to 7 days, although some dogs have incubation periods as long as 19 to 33 days. The first sign usually is a sudden febrile response, which typically reaches a peak of 40° C to 42° C (104° F to 107.6° F; [Fig. 27-6](#)). The temperature gradually decreases to normal or below normal over the next 4 to 8 days. Dogs are frequently hypothermic when death occurs 7 to 10 days after the initial clinical evidence of infection. Some animals show only a slight increase in temperature or a shortened febrile period; however, they may still die if left untreated.

Fig 27-7 Egg of *N. salmincola* (x480).

Anorexia frequently accompanies or follows the onset of fever and may be marked and complete. Affected animals often continue to have inappetence throughout the course of the disease. Marked weight loss, weakness, and depression usually follow. Within 14 days of eating infected fish, coyotes on a controlled experiment lost approximately 58% of their body weight when compared with uninfected coyotes.¹¹ Diarrhea and vomiting may occur, with the diarrhea becoming progressively worse and often consisting primarily of blood at the time of death. The animal occasionally exhibits extreme thirst and drinks copious quantities of water. A serous nasal discharge may develop early in the febrile period. Later, a mucopurulent conjunctival

Infectious Diseases of the Dog and Cat, 3rd Edition

exudate may be seen. Enlarged cervical and prescapular lymph nodes can be palpated as early as 5 days after infection.

SPD-infected dogs may show severe gastrointestinal signs, which are often clinically indistinguishable from canine parvoviral enteritis (see [Chapter 8](#)). Distemper and SPD can also occur concurrently, and appropriate laboratory tests can be conducted to determine which agent is involved in a particular animal (see [Appendix 5](#), Laboratory Testing for Infectious Diseases of Dogs and Cats).

27.4.2 Elokomin Fluke Fever

The incubation period for EFF is generally 5 to 12 days. The febrile period, which differs from that of SPD, is marked by an elevated temperature plateau lasting 4 to 7 days, followed by a decline, usually to a subnormal temperature.⁶ Other signs are similar to those of SPD.

27.5 DIAGNOSIS

Operculated trematode eggs appear in dog feces 5 to 8 days after the ingestion of infected fish. The light brown eggs are approximately 87 to 97 μm long and 35 to 55 μm wide, with a small, blunt point on the end opposite the indistinct operculum ([Fig. 27-7](#)). Eggs can be detected on direct smears or by a washing-sedimentation technique.⁷ In addition, the authors of this chapter have routinely recovered *N. salmincola* eggs with the standard sugar flotation technique (specific gravity, 1.27). Eggs recovered by this method are somewhat deformed but easily recognizable.⁹ Diagnosis of the rickettsial disease cannot be made entirely on the presence of trematode eggs in feces, because trematode infection does not necessarily indicate rickettsial infection. In addition, animals that have recovered from the rickettsial disease may continue to shed eggs in feces or can be reinfected with the trematode. The trematode infection can remain patent for 60 to 250 days.¹¹

Fluid aspirated from enlarged lymph nodes can be air dried on a microscope slide, fixed, defatted for 1 minute with a mixture of equal parts of ether and absolute alcohol, and then stained by Giemsa or Macchiavello's stain. In addition, a rapid-staining Giemsa technique can be used that involves staining the fixed smears for 2 minutes with equal parts of stock Giemsa and buffered water at pH 7.2 and then flushing the slides with tap water.⁷ Typical intracytoplasmic rickettsial bodies are characteristically seen in MPS cells (see Fig. 27-2). Extracellular organisms are not easily separated from artifacts and should not be considered diagnostic for SPD.

201

Table 27-2 Drug Therapy for Salmon Poisoning Disease

DRUG ^a	DOSE ^b (mg/kg)	ROUTE	INTERVAL (HOURS)	DURATION (DAYS)
Oxytetracycline ^c	7	IV ^d	8	3–5
Doxycycline ^c	10	IV ^d	12	7
Tetracycline ^c	22	PO	8	3–5
Praziquantel ^e	10–30	PO, SC	Once	3–5

IV, Intravenous; PO, by mouth; SC, subcutaneous.

- a See [Appendix 8](#), Drug Formulary, for additional information.
- b Dose per administration at specified interval.
- c For rickettsial infection.
- d Parenteral therapy preferred because of gastrointestinal signs.
- e For fluke infection.

Hematologic and biochemical findings of SPD-infected domestic dogs are often nonspecific, and total leukocyte counts have ranged from leukopenia to leukocytosis.²⁵ Laboratory results of 45 dogs representing 17 breeds and various mixed breeds that were naturally infected with SPD are listed in [Table 27-1](#).²⁰ Thrombocytopenia in 88% of the dogs tested, lymphopenia (77%) eosinophilia (77%), increased alkaline phosphatase (ALP) values (64%), and reduced serum albumin values (49%) were the consistent findings.²⁰ In experimentally infected coyotes, significantly higher numbers of band cells, lower numbers of eosinophils, and lower concentrations of creatinine, glucose, calcium, inorganic phosphorus, albumin, and ALP were detected when compared with uninfected coyotes.¹¹

27.6 PATHOLOGIC FINDINGS

The principal gross findings at necropsy are changes in lymphoid tissues. The tonsils, thymus, and visceral and somatic nodes are markedly enlarged. The most pronounced swelling occurs in the ileocecal, colic, mesenteric, portal, and lumbar nodes. The nodes are usually yellowish, with prominent white foci representing the cortical follicles. Occasionally, nodes show diffuse petechiae, and edema is often observed.

The spleen frequently ranges from slightly swollen to nearly twice the normal size. Splenic follicles, which often appear as grayish-white nodules in foxes, are unaffected in dogs. The spleens of animals that die of SPD are typically a dark bluish red, smooth, soft, and blood filled. Livers of dogs are usually normal, although those of foxes are usually soft and a pale yellowish brown. Hemorrhages may appear in the gallbladder wall. Petechiae may be the only change in the pancreas. The kidneys of dogs are grossly normal, whereas those of foxes may have a slight color change and become a pale yellowish brown. The mucosa of the urinary bladder may show petechiae.

Along the intestinal tract, petechiae may be apparent in the mucosae of the lower esophagus, large intestine, ileocolic valve, distal colon, rectum, and gastric serosa. Bleeding ulcers may be found in the pylorus. Intussusception of the ileum in the colon may also occur. The intestinal contents frequently contain free blood. Some blood may also appear in the colon and rectum. The intestines are typically empty except for some bile-stained mucus. Flukes in the intestinal tissue, primarily found in the duodenum, cause some tissue damage but are usually not pathogenic.

Infectious Diseases of the Dog and Cat, 3rd Edition

Microscopically, a characteristic pattern is observed in lymphocytic tissues. The lymph nodes show a marked and consistent depletion in the number of mature lymphocytes, with hyperplasia of the MPS cells in the cortex and medulla. Most foxes and dogs have foci of necrosis in the MPS cells. The central nervous system is usually involved with nonsuppurative meningitis or meningoencephalitis.¹⁸

27.7 THERAPY

All patients should be hospitalized so that they receive adequate monitoring and nursing care. Control of the infectious agent, *N. helminthoeca*, can be achieved with oral or parenteral sulfonamides, penicillin, chlortetracycline, chloramphenicol, doxycycline, or oxytetracycline. Aminoglycosides are ineffective. The preferred treatment schedule is oxytetracycline given for at least 3 days (Table 27-2). Oral tetracycline therapy, used for most rickettsial disease, may be difficult and may not be indicated because of the severe vomiting and diarrhea that is usually present.

Relief of dehydration, emesis, and diarrhea is also important. Fluid therapy with appropriate electrolytes should be administered intravenously. In cases of hemorrhagic diarrhea, transfusion of whole blood may be necessary. Other antidiarrheal treatments include fasting followed by gradual introduction of a bland, high-calorie diet. In addition, the most supportive treatment consists of keeping the dog dry, clean, and warm.

Praziquantel, when given as one dose at appropriate dosages (see Table 27-2), is highly effective against *N. salmincola* in coyotes and dogs.¹⁰ Elimination of *N. salmincola* from infected animals minimizes the diarrhea associated with fluke infections alone and minimizes or eliminates fluke eggs from feces.

27.8 PREVENTION

Vaccines have not been developed against SPD, therefore keeping dogs from feeding on infected fish is the best means of preventing infection. Because metacercariae can remain viable for months in rotting fish carcasses, dogs become infected with the fluke if they eat decomposed fish; however, they may not develop SPD. In addition, in many areas, metacercariae apparently contain nonpathogenic rickettsiae.¹⁷ Freezing fish at -20°C for 24 hours or thoroughly cooking infected fish kills the metacercariae and rickettsiae.⁸ Supplemental prevention methods include isolation of dogs with SPD and sterilization of equipment used around infected dogs.

Infection of fish in hatcheries can be prevented by using water that is not inhabited by snails. However, this is not possible in most hatcheries other than those that use drilled well water rather than stream water. Other control techniques such as snail elimination are impractical.

28 CHAPTER 28 Ehrlichiosis, Neorickettsiosis, Anaplasmosis, and *Wolbachia* Infection

Bacteria within the families *Rickettsiaceae* and *Anaplasmataceae* of the order *Rickettsiales* underwent reclassification in 2001. Reclassification was indicated after the molecular analyses of bacterial 16S rRNA and groESL gene sequences were elucidated.¹⁴⁶ The genera *Ehrlichia* and *Wolbachia* were moved from the family *Rickettsiaceae* and are now in the family *Anaplasmataceae*. The genera *Rickettsia* and *Orientia* remain in the family *Rickettsiaceae*. In addition, species within the genus *Ehrlichia* were reorganized: *E. phagocytophila*, *E. equi*, and *E. platys* now reside in the genus *Anaplasma*, and *E. risticii* and *E. sennetsu* are now in the genus *Neorickettsia*. The diseases caused by all of these organisms, despite their new genetic groupings, are intracellular parasitisms of mammalian leukocytes and are characterized as being monocytotropic (organisms predominantly residing in monocytes and macrophages), granulocytotropic (organisms predominantly in neutrophils and eosinophils), or thrombocytotropic (Table 28-1).

The genus *Ehrlichia* consists of tick-transmitted gram-negative obligate intracellular bacteria that infect primarily leukocytes (monocytes, macrophages, granulocytes). These acid-sensitive, pleomorphic coccobacilli of approximately 0.5 μm diameter are aerobes that lack a glycolytic pathway.⁴⁰⁶ *E. canis*, *E. chaffeensis*, *E. ewingii*, and *E. muris* remain members of the genus *Ehrlichia*. *E. (Cowdria) ruminantium*, the cause of heartwater of cattle in Africa, has been added to this genus.

N. sennetsu and *N. risticii* were reclassified because of their close relationship with *N. helminthoeca*, the cause of salmon poisoning disease (see Chapter 27). These agents are transmitted by invertebrate intermediate hosts, rather than tick vectors. *N. risticii* has been determined to be acquired by ingestion of infected snails. The vector of *N. sennetsu* has not been determined, but as with *N. helminthoeca*, transmission may involve the ingestion of raw fish that contains the pathogenic organism that was acquired by the fish from the snail.

The family *Anaplasmataceae* is composed of obligatory gram-negative intracellular organisms that parasitize leukocytes, erythrocytes, endothelial cells, or platelets. These agents are naturally transmitted to people and domestic animals from specific ticks that acquire their infections by feeding on mammalian wildlife reservoirs. The designation of *Anaplasma phagocytophilum* as a species group now comprises all strains of human granulocytotropic *Ehrlichia* (HGE) described worldwide; *E. equi* in the Western United States; and the European agent infecting ruminants, *E. phagocytophila*. They appear genetically and biologically indistinguishable, except for geographic, host, and pathogenic adaptations. *A. (E.) bovis*, *A. (E.) platys*, and *A. phagocytophilum* have all been classified within the genus *Anaplasma* because of their close genetic relationship to *A. marginale*. This chapter will discuss canine and feline diseases caused by these organisms that preferentially infect monocytic cell, granulocytic cell, or thrombocytic cells.

Wolbachia, and its sole species *W. pipientis*, is an obligate intracellular bacterium residing in the cytoplasmic vacuoles of the ovaries and other tissues of arthropods and helminths.¹⁴⁶ This genus is genetically intermediate to organisms in the two tick-transmitted genera of *Ehrlichia* and *Anaplasma*. However, it had not generally been considered a vertebrate pathogen until isolations were made from people and dogs (see later discussion of *Wolbachia* infection).

28.1 CANINE MONOCYTOTROPIC EHRLICHIOSIS AND NEORICKETTSIOSIS (*E. CANIS*, *E. CHAFFEENSIS*, *E. RUMINATIUM*, *N. SENNETSU*, AND *N. RISTICII* INFECTIONS)

T. Mark Neer

Infectious Diseases of the Dog and Cat, 3rd Edition

Shimon Harrus

28.1.1 Etiology and Epidemiology

Canine monocytic ehrlichiosis and neorickettsiosis are caused by obligate intracellular parasites of the genera *Ehrlichia* and *Neorickettsia*, respectively.¹⁴⁶ These small pleomorphic gram-negative coccoid bacteria appear intracytoplasmically in clusters of organisms called morulae (Figs. 28-1 and 28-2). Table 28-1 summarizes the monocytotropic ehrlichial species known to cause disease in animals throughout the world. Three members of the *E. canis* genogroup I, *E. canis*, *E. chaffeensis*, and *E. ruminantium*, infect monocytes of dogs. *N. risticii* (genogroup III) naturally infects horses, although dogs can be experimentally infected and an atypical strain infects dogs naturally. The following discussion concentrates on canine monocytotropic ehrlichiosis (CME) caused by *E. canis*, the principal member of the *E. canis* genogroup, for which the majority of the information is present. Where indicated, the other infections are described in more detail.

28.1.1.1

E. canis

E. canis was first identified by Donatien and Lestoquard in Algeria in 1935.¹³⁹ CME gained considerable attention when hundreds of American military dogs, many of which were German shepherds, died from the disease during the Vietnam War. *E. canis* received further attention in the late 1980s when the rickettsia was erroneously suspected to infect people. However, in 1991, a new species of the *Ehrlichia* genus, *E. chaffeensis*, was found to be the cause of human monocytotropic ehrlichiosis.

205

Fig 28-1 A mononuclear leukocyte containing a compact *E. canis* morula in the cytoplasm. (Courtesy Ken Latimer, University of Georgia, Athens, Ga.)

E. canis has a worldwide distribution (Asia, Africa, Europe, and the Americas). Despite the presence of suitable vectors, oceanic or island areas that have maintained quarantine, such as Australia and the United Kingdom, appear to be free of *E. canis* infection.^{252,335} Only recently has the first case been reported in a dog imported to Japan.⁵⁰¹ Although, in a recent epidemiologic survey of ticks collected from dogs in Japan, no positive polymerase chain reaction (PCR) results were found for *E. canis* in 1211 ticks examined.²³⁹ Vertebrate hosts for *E. canis* include members of the family Canidae. The coyote, fox, and jackal, in addition to the domestic dog, are considered reservoir hosts (see Fig. 28-2). New information suggests that *E. canis* or a closely related organism might also infect cats (see later discussion on Feline Monocytotropic Ehrlichiosis).⁷⁰ The arthropod vector of *E. canis* is the brown dog tick, *Rhipicephalus sanguineus*. This one-host tick preferentially feeds on dogs in all three stages of its life cycle and can live indoors in domiciled environments in which dogs are housed. Experimentally, infection has also been transmitted by *Dermacentor variabilis*, the American dog tick.²⁵⁷ The mode of transmission is transstadial. Because transovarial spread does not occur, the vector tick cannot be a true reservoir. Ticks acquire *E. canis* as either larvae or nymphs by feeding on rickettsemic dogs. They transmit infection to susceptible dogs for at least 155 days after infection.²⁰¹ This permits the pathogen to overwinter in the tick and then in the following spring allows the tick to infest and infect susceptible dogs. Most CME cases occur during the warm season when the vector ticks are abundant; however, unlike the other rickettsiae that depend on outdoor vectors, *E. canis*-induced disease has a more even seasonal distribution. This may also be a result of the prolonged subclinical period in chronically infected animals. The minimal time required of tick attachment to transmit *E. canis* infection

Infectious Diseases of the Dog and Cat, 3rd Edition

has yet to be determined, as it is known for some other tick-borne diseases.²⁷² Dogs living in or traveling to endemic regions are candidates for the disease.

28.1.1.2

E. chaffeensis

E. chaffeensis, the etiologic agent of human monocytotropic ehrlichiosis (HME) has been convincingly identified from people, deer, dogs, coyotes, one domestic goat, and one captive lemur, and from ticks only in the United States, mainly the south-central, southeastern, mid-Atlantic states, and from California (Fig. 28-3). White-tailed deer (*Odocoileus virginianus*) serve as excellent natural sentinels for both *E. chaffeensis* and *A. phagocytophilum*.⁵⁶² Detection of *E. chaffeensis* DNA by PCR amplification provided evidence for natural canine *E. chaffeensis* infection in southeastern Virginia, Oklahoma, and North Carolina.^{74,368,383,562} In the eastern United States, the rickettsia is transmitted by *Amblyomma americanum* (Lone Star tick) and to lesser extent by *D. variabilis*. Persistently infected white-tailed deer and possibly dogs or other carnivores, serve as reservoir hosts. Serologic evidence of *E. chaffeensis* has been reported from people residing in countries in Africa, South America, and Asia, as well as from Mexico and Russia. However, other closely related monocytotropic *Ehrlichia* such as *E. muris* are likely responsible for cross-reactive antibodies.³⁸³ PCR has been used to document the presence of *E. chaffeensis* DNA in ticks from southern China and South America, but more evidence is needed to determine if in fact the organism and disease is present outside North America.³⁸³

28.1.1.3

N. risticii

N. risticii, the etiologic agent of Potomac horse fever, was reported to cause monocytotropic ehrlichiosis in dogs, a disease described as atypical ehrlichiosis (see Table 28-1). Its significance in cats under natural conditions is uncertain. However, cats can be experimentally infected with *N. risticii* (see later discussion on Feline Monocytotropic Ehrlichiosis). This organism is closely related to *N. helminthoeca* and *N. sennetsu*, the etiologic agents of salmon poisoning disease and human Sennetsu fever, respectively.¹⁴⁶ The mode of transmission of *N. risticii* is unknown; however, *N. risticii* DNA was found in trematodes (virgulate cercariae from freshwater *Juga* snails from California and in virgulate xiphidiocercariae from *Elimia* snails in Ohio)^{38,262,434} and in various aquatic insects.¹⁰⁰ These findings suggest that they play an important role in the transmission of the rickettsia.

28.1.1.4

E. ruminantium

E. ruminantium, or a closely related organism, was genetically detected in the blood of clinically healthy and ill dogs from Kenya, Uganda, Ethiopia, and Mali.⁸ The organism was not isolated in culture or tested for its infectivity; therefore its virulence, potential vectors, and definitive classification are uncertain. Several closely related organisms comprise the clade of organisms in this group.

28.1.1.5

N. helminthoeca

N. helminthoeca, the cause of salmon poisoning disease, is more thoroughly covered in Chapter 27 and will not be discussed further in the present chapter.

Infectious Diseases of the Dog and Cat, 3rd Edition

28.1.2 Pathogenesis

A wide variety of factors, including the *E. canis* inoculum size, can influence the course and outcome of infection. The severity of the disease is greater with certain strains of the organism. An immunoblot analysis of the IgG response to *E. canis* has shown that antigenic diversity may exist among *E. canis* organisms from different parts of the world and has suggested that this may affect the severity of the disease.³⁷¹ Concomitant disease with other tick-borne parasites or other pathogens may also affect the severity and manifestation of the disease. Immunodeficient animals may develop more severe manifestations of disease and are more likely to have large numbers of circulating morulae. No age or sex predilection exists for CME; however, German shepherd dogs seem to be more susceptible than other breeds. Moreover, the disease in this breed is more severe and has a poorer prognosis than in other breeds.³⁷⁷ Variation in breed susceptibility can be attributed to breed differences in the ability to mount adequate cellular or humoral immune response, or both. The cellular immune response to *E. canis* infection is depressed in German shepherd dogs compared with beagle dogs, while no significant differences were recorded in the humoral response between the two breeds.³⁷⁷

206

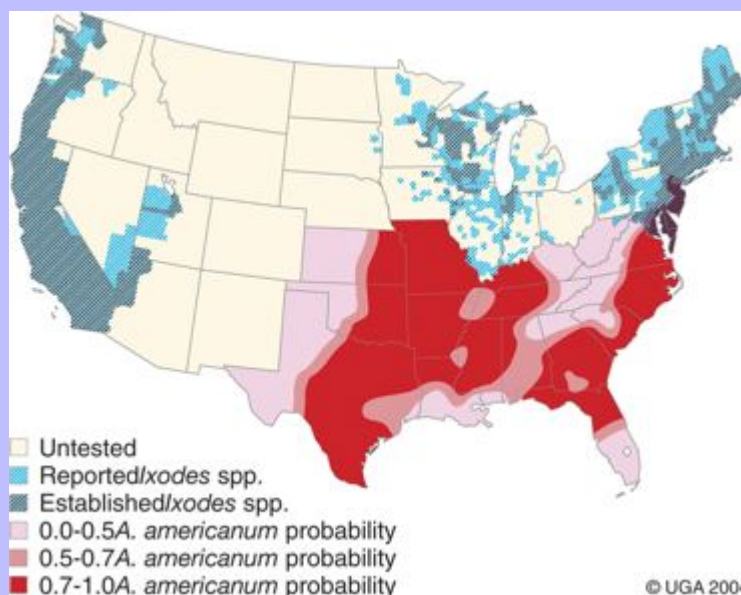

207

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 28-3 Map of distribution of some tick vectors of ehrlichiosis (*Amblyomma* spp.) and anaplasmosis (*Ixodes* spp.) in the United States. (Courtesy University of Georgia, Athens, Ga.)

Natural infection of the vertebrate host occurs when an infected tick ingests a blood meal and salivary secretions contaminate the feeding site. Iatrogenic spread can occur with blood transfusions from infected donors. During the incubation period of 8 to 20 days, organisms multiply in macrophages of the mononuclear-phagocyte system, by binary fission, spreading throughout the body (Fig. 28-4). The subsequent course of ehrlichiosis has been divided into three phases—acute, subclinical, and chronic—based on clinical signs and clinicopathologic abnormalities following experimental inoculation. However, with naturally occurring infection, accurate staging of the disease is difficult. The acute phase lasts 2 to 4 weeks during which signs such as fever, oculonasal discharge, anorexia, depression, petechiae, ecchymoses, lymphadenomegaly, and splenomegaly may be seen. Typical laboratory abnormalities in this phase include thrombocytopenia, mild leukopenia, and mild anemia. Most dogs recover from the acute disease with adequate treatment. Untreated and inappropriately treated dogs may enter the subclinical phase. During this phase, the dog's weight normalizes and the pyrexia resolves. Clinically, dogs appear healthy; however, their platelet counts may remain below

207

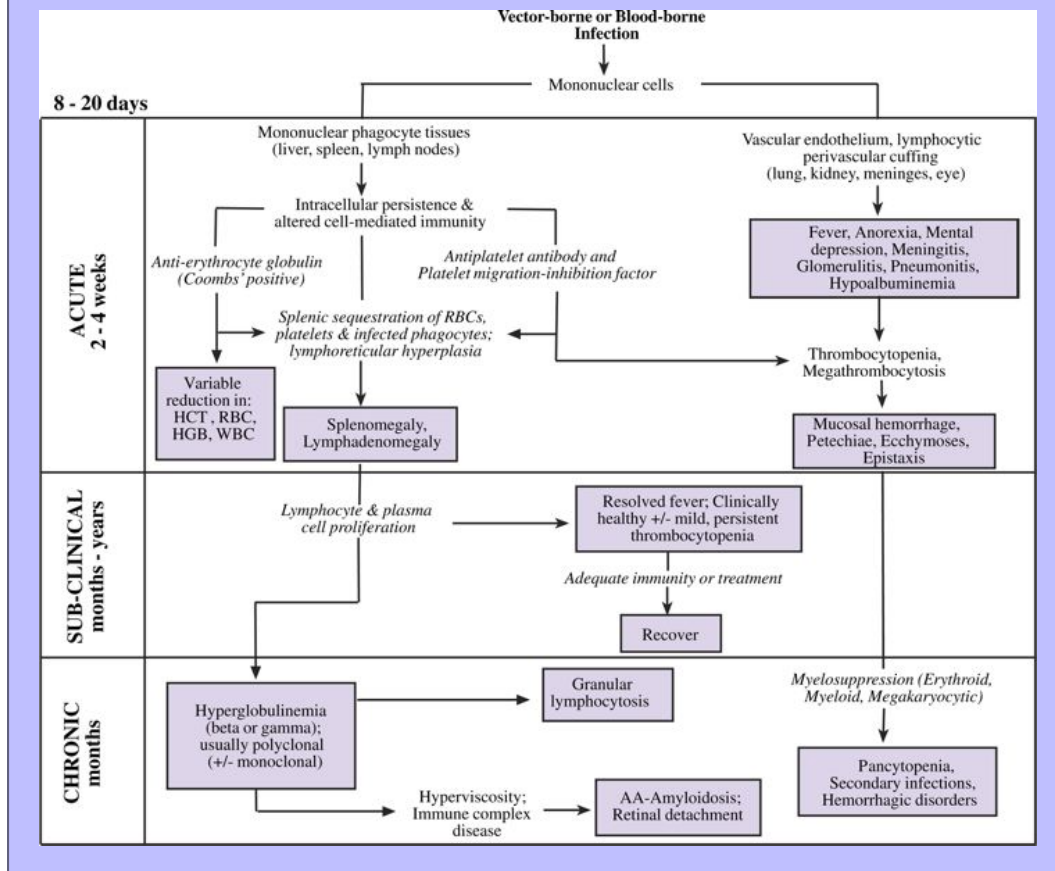

208

reference ranges.^{533,534} Dogs in the subclinical phase have the potential to remain persistent carriers for years as described in one 3-year follow-up study.²¹² Results of experimental infections indicate that the spleen is most likely to harbor *E. canis* organisms during the subclinical phase of CME and the last organ to accommodate the parasite before elimination. The spleen is believed to have an important role in the pathogenesis and expression of the disease. Splenectomized dogs, experimentally infected with *E. canis*, had mild clinical illness compared with nonsplenectomized dogs.²¹⁹ During the course of infection, repeated recombinations occur in the outer membrane major antigenic protein-genes of ehrlichiae leading to the generation of variations in immunogenic epitopes.⁴³² In this manner, the organisms may evade host defense mechanisms resulting in persistent infections. Immunocompetent dogs may eliminate rickettsiae; otherwise, they may remain carriers for life or may enter the chronic phase of infection. The chronic phase, in its severe

Infectious Diseases of the Dog and Cat, 3rd Edition

form, is characterized by impaired bone marrow production of blood elements, resulting in pancytopenia. The prognosis for dogs with the chronic severe form is grave. Dogs in this phase may eventually die of secondary infections or uncontrollable bleeding, or both. Therefore identifying the disease before dogs enter the chronic phase of CME is of utmost importance.

Fig 28-4 Pathogenesis of *E. canis* infection in dogs.

Survival and multiplication of ehrlichial organisms in infected cells rely on the organism's ability to inhibit phagosome-lysosome fusion, as shown for *N. risticii* and *N. sennetsu*.³⁷¹ Doxycycline was shown to restore the host's phagocytic ability, probably by inhibiting the synthesis of a bacterial fusion-hindering protein.⁵⁴⁴ Apparently, T cell-induced immunity and interferon (IFN)- γ secretion play a predominant role in recovery from and immunity to ehrlichial infections.^{78,535} The generation of nitric oxide accompanied by limited access of iron is the mechanism by which IFN- γ inhibits *N. risticii* in vitro.³⁹⁰ IFN- γ -activated human monocytes have been shown to inhibit *E. chaffeensis* infection by downregulation of surface transferrin receptors that lead to the limitation of available cytoplasmic iron.⁴⁰ Evasion of the immune response may be another means by which *E. canis* may establish chronic infection in its canine host. In vitro studies in mononuclear cell cultures have indicated downregulated expression of major histocompatibility complex class II receptors.²¹⁸ Lymphocyte subset alterations have been characterized by decreased CD4+:CD8+ ratio.²²⁴

Infectious Diseases of the Dog and Cat, 3rd Edition

Infection with *E. canis* results in the development of specific antibodies. IgM and IgA appear 4 to 7 days after infection; IgG generally increases beginning 15 days postinfection.⁵³⁵ The hypergammaglobulinemia is usually polyclonal; however, some dogs may develop monoclonal gammopathy.^{214,522} The role of antibody response in eliminating persistent intracellular ehrlichial infections is minimal. High *E. canis*–antibody titers do not provide protection when animals are challenged.^{40,446} Moreover, they may have a detrimental effect on progression of the disease because of their immunopathologic consequences.⁴⁴⁶ Increasing evidence supports the assumption that hyperimmune mechanisms are involved in the pathogenesis of CME. These include extensive plasma cell infiltration of the bone marrow and parenchymal organs; the occurrence of polyclonal hypergammaglobulinemia that does not correlate with specific *E. canis*–antibody titers; positive Coombs' and autoagglutination test results; the induction of antiplatelet antibody production following natural and experimental infection; and the recent detection of circulating immune complexes in dogs naturally and artificially infected with *E. canis*.^{199,209,215} The latter finding suggests that some pathologic and clinical manifestations in CME are immune-complex mediated. No antinuclear antibodies were found in dogs naturally or experimentally infected with *E. canis*, suggesting other mechanisms in the pathogenesis of CME.²⁰⁹ Dogs with monoclonal gammopathy may develop hyperviscosity with associated clinical signs and pathologic lesions. Cases of sudden blindness caused by subretinal hemorrhage associated with hyperviscosity have been documented.^{211,371} Reactive AA amyloidosis associated with proteinuria and glomerulopathy has been implicated as a pathologic complication of chronic *E. canis* infection.³¹⁸

Hematologic changes in CME are associated with inflammatory and immune processes triggered by the infection. Thrombocytopenia, the most common hematologic abnormality of dogs infected with *E. canis*, occurs in all phases of disease.^{183,215,221} Various mechanisms are involved in the pathogenesis of thrombocytopenia; these mechanisms include increased platelet consumption and decreased platelet half-life, probably as a result of splenic sequestration and immune-mediated destruction. Platelet-bound and circulating antiplatelet antibodies have been detected in whole blood and serum, respectively, of dogs in the acute phase after artificial and following natural infections with *E. canis*.^{371,537} In addition, a serum cytokine, platelet migration–inhibition factor (PMIF), has been found to exist in dogs with ehrlichiosis, and its level is related inversely to the platelet count.¹ Higher levels of PMIF are associated with more virulent strains of *E. canis* (Fig. 28-5). PMIF inhibits platelet migration and is produced by lymphocytes when they are exposed to infected monocytes. Decreased production of platelets as a result of hypoplastic bone marrow is considered to be the mechanism responsible for the thrombocytopenia in the chronic phase.²¹⁵ Platelet function, as measured by aggregation responses, is decreased in *E. canis*–infected dogs. This, in conjunction with the low platelet count, contributes to the hemorrhages seen with CME.^{216,217,221}

28.1.3 Clinical Findings

Canine ehrlichiosis is a multisystemic disorder that is now known to be caused by a variety of ehrlichial species. In the past, all clinical reports of this disease confirmed by cytologic or serologic means have been attributed to *E. canis* infections. In the United States, previously reported cases diagnosed cytologically as “granulocytotropic strain” infections may have been caused by *A. phagocytophilum* or by *E. ewingii* (see later discussion). Because of cross-reactivity with *E. canis*, serologically confirmed cases using only *E. canis* as antigen could have also been caused by *E. chaffeensis* or *E. ewingii*. The following discussion categorizes previously published clinical features based on body systems and primarily focuses on *E. canis* infection and

Infectious Diseases of the Dog and Cat, 3rd Edition

other monocytotropic ehrlichial species. For discussion of clinical features of the granulocytotropic ehrlichias, see later discussion on Canine Granulocytotropic Ehrlichiosis.

Fig 28-5 Graphs showing the temporal relationship between platelet counts and platelet migration inhibition (PMI) activity after infection with different strains of *E. canis*. (From Abeygunawardena I, Kakoma I, Smith RD. 1990. Pathophysiology of canine ehrlichiosis, pp 78-92. In Williams JC, Kakoma I [eds], *Ehrlichiosis*, Dordrecht, Netherlands. Reprinted with permission from Kluwer Academic Publishers.)

28.1.3.1 Multisystemic Signs

A common presentation is depression, lethargy, mild weight loss, and anorexia, with or without hemorrhagic tendencies. If present, the bleeding is usually exhibited by dermal petechiae or ecchymoses, or both. Although bleeding can occur from any mucosal surface, epistaxis is most frequent. Physical examination may also reveal lymphadenomegaly and splenomegaly in 20% and 25% of the patients, respectively.⁵⁶¹ Another point all clinicians should keep in mind when considering tick-borne disease as a cause for multisystemic signs is the issue of co-infection with multiple tick-borne pathogens.²⁸⁶ This concern is increasing and adds confusion in interpreting previously published reports (see later discussion on Concurrent or Secondary Infections).

28.1.3.2 Ocular Signs

Dogs may show changes in eye color or appearance or may develop blindness. Anterior uveitis and retinal disease, such as chorioretinitis, papilledema, retinal hemorrhage, retinal perivascular infiltrates, and bullous

Infectious Diseases of the Dog and Cat, 3rd Edition

retinal detachment (Fig. 28-6), are the more common findings and may result in acute blindness.¹⁹² Uveitis has also been associated with *A. platys* infection in the dog (see Canine Thrombocytotropic Ehrlichiosis).

28.1.3.3

Neuromuscular Signs

The neurologic signs of ehrlichiosis are the result primarily of meningitis from inflammation or bleeding, or both. Neurologic dysfunction occurs with damage to the adjacent central or peripheral nervous tissue.

Infections with *E. canis* and granulocytotropic strains have been most common,^{331,515} and signs are indistinguishable from those of Rocky Mountain spotted fever (RMSF) (see Chapter 29). Seizures, stupor, ataxia with upper or lower motor neuron dysfunction, acute central or peripheral vestibular dysfunction, anisocoria, cerebellar dysfunction, intention tremors, and generalized or localized hyperesthesia have been observed. Morulae have been found in cells from the cerebrospinal fluid (CSF) in some instances.^{331,356}

Two dogs that were seropositive for *E. canis* had polymyositis, and the signs consisted of acute-onset

progressive tetraparesis, hyporeflexia, and muscle wasting.⁸⁹ Skeletal muscles were atrophic and

characterized histologically by lymphoplasmacytic and immature lymphoreticular cellular infiltrates within areas of necrosis. Unfortunately, the histopathology of peripheral nerves was not reported.

209

210

Fig 28-6 Retinal detachment caused by subretinal hemorrhage in a dog with *E. canis* infection. (Courtesy University of Georgia, Athens, Ga.)

28.1.3.4

Polyarthrititis

Dogs with ehrlichiosis may develop lameness with a stiff gait secondary to polyarthropathy. Joint disease may occur from hemarthrosis or immune complex deposition with resultant arthritis and neutrophilic effusion into the joint. Most instances of polyarthrititis have been associated with infection by granulocytotropic strains (*A. phagocytophilum* or *E. ewingii*) or *N. risticii*.^{119,488,489} When titers have been

Infectious Diseases of the Dog and Cat, 3rd Edition

determined, approximately 81% of the dogs with the granulocytotropic strain had titers to *E. canis*, which cross-reacts with *E. ewingii*, and 8% had titers to *E. equi*.⁴⁸⁸

28.1.3.5 Concurrent or Secondary Infections

Ticks can harbor multiple pathogenic organisms resulting in co-infections in the infected dog.^{113,286} Positive results for antibody reactivity or nucleic acid detection methods should be interpreted with caution with regard to *Ehrlichia* being the sole cause of clinical illness unless a wide variety of potential pathogens have been evaluated. In addition, dogs with ehrlichiosis can become secondarily infected with opportunistic bacterial, fungal, or protozoal diseases.¹⁴⁰ Ehrlichial testing should be considered as an evaluation of host immunocompetence in dogs that are diagnosed with opportunistic infections.

28.1.3.6 Ehrlichial Species–Specific Signs

[Table 28-2](#) summarizes the clinical and laboratory findings of monocytotropic ehrlichial infections in dogs.

28.1.3.6.1 *E. canis*

E. canis infections can be acute or chronic in dogs. The dog acts as the reservoir host for this infection, and chronic persistent infections can result in pancytopenia or hyperglobulinemia. The hyperglobulinemia is usually polyclonal; however, on occasion, monoclonal gammopathy has been observed. Granular lymphocytosis, which has been confused with well-differentiated lymphocytic leukemia, has been observed in some dogs.

28.1.3.6.2 *N. risticii*

N. risticii (previously *E. risticii*) infection can be experimentally established in dogs and cats, producing minimal clinical illness.^{126,129,445} Of eight cats inoculated with *N. risticii*, one cat had mild, self-limiting disease consisting of intermittent diarrhea, and another cat had lymphadenomegaly, acute depression, and anorexia.¹²⁶ Even though this ehrlichial species appears to cause little, if any, clinical disease in experimentally infected dogs and cats, it has yet to be determined whether this is the case with natural infections.

In 100 cases of serologically atypical canine ehrlichiosis, with three deaths, the indirect fluorescent antibody (FA) test was negative for *E. canis* and *N. sennetsu* but positive for *N. risticii*.²⁶⁰ Subsequent genetic sequencing techniques characterized an isolated agent to be *N. risticii*. Clinicopathologic findings included vomiting, lethargy, anemia, thrombocytopenia, polyarthropathy, fever, or any combination. The 100 cases were distributed geographically as follows: California (32), Texas (26), Arizona (16), Illinois (10), Washington State (9), Florida (5), and Michigan (2). A new species name, *N. risticii* subsp.

atypicalis, was proposed.²⁶⁰ If typical signs of ehrlichiosis are present in a dog and it is seronegative for *E. canis*, evaluation for the presence of antibody titers to *N. risticii* should be considered.

Infectious Diseases of the Dog and Cat, 3rd Edition

28.1.3.6.3 *E. chaffeensis*

E. chaffeensis has been experimentally inoculated into pups, and signs were mild compared with corresponding *E. canis*-inoculated animals.¹²⁹ Only fever was apparent. This finding, which may be related to species differences or attenuation of the agent in cell culture, contrasts to the clinical syndrome observed in people infected with *E. chaffeensis*. The clinical significance of natural infections in dogs or cats is still being defined. Dogs experimentally infected with *E. chaffeensis* developed thrombocytopenia without other systemic manifestations of disease.⁵⁷⁵ Organisms could be cultured from the blood for up to 102 days following infection and DNA was found for up to 117 days. High antibody titers were maintained for up to 6 months of observation, suggesting that the dogs became chronic inapparent carriers and therefore possible reservoirs of disease. Serologic and PCR testing has suggested that dogs in animal shelters and kennels in southeastern Virginia are naturally infected.¹²⁸ Three dogs had naturally occurring clinical disease secondary to *E. chaffeensis* infection.⁷⁴ These dogs had signs very similar to classic *E. canis* infection consisting of anterior uveitis, epistaxis, and lymphadenopathy. In people, *E. chaffeensis*-induced illness is more severe in immunocompromised individuals⁴⁵³; similar findings might be expected in dogs.

28.1.3.6.4 *E. ruminantium*

E. ruminantium or a closely-related organism was detected in subsaharan Africa in the blood of clinically healthy dogs and in those with clinical illness typical of *E. canis* infection.⁸ Whether the signs were caused by or incidental to the infection with this organism is uncertain.

28.1.4 Diagnosis

The diagnosis of ehrlichiosis is usually made based on a combination of clinical signs, hematologic abnormalities, thrombocytopenias, and serologic findings. PCR and immunoblotting techniques are now being used more in the clinical setting to obtain a diagnosis, and specific comments regarding their use will also be addressed.

28.1.4.1 Clinical Laboratory Findings

Hematologic changes are best documented for infections caused by *E. canis* and include thrombocytopenia (82%), anemia (82%), which is usually nonregenerative, and leukopenia (32%, of which 20% had neutropenia).^{515,526} Pancytopenia is usually a result of hypoplasia of all bone marrow precursor cells and occurs in the severe chronic phase (18% of cases) and more often in German shepherd dogs.⁵⁶¹

Thrombocytopenia has been consistently reported in all stages of *E. canis* infection; because it is often a screening test for ehrlichiosis, this proportion may be overestimated.^{85a} In one study in an endemic area of Brazil, there was a general correlation between positive blood PCR results for *E. canis* and the presence of marked (<100,000 platelets/ μ l) thrombocytopenia.^{85a} However, ehrlichiosis should never be eliminated from consideration because the platelet count is normal. Serology should be performed if other clinical signs are compatible. In another study involving hospitalized dogs from Brazil, anemia was more of an epidemiologic risk factor for ehrlichiosis than thrombocytopenia.¹³⁷

211

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 28-2 Comparison of Naturally Occurring Canine Disease Caused by Ehrlichia spp., Neorickettsia risticii, and Anaplasma spp.

SPECIES	CLINICAL FEATURES	LABORATORY ABNORMALITIES	REFERENCES
Monocytotropic			
<i>E. canis</i>	Fever, anorexia, weight loss, hemorrhagic diathesis, CNS signs, lymphadenomegaly	Anemia, leukopenia, marked thrombocytopenia, hyperglobulinemia, pancytopenia, proteinuria, mononuclear pleocytosis	208, 210, 514, 371
<i>N. risticii</i> (subsp. atypicalis)	Fever, lethargy, hemorrhagic diathesis, polyarthritis, periarticular joint swelling	Anemia, thrombocytopenia	260, 259
<i>E. chaffeensis</i>	Anterior uveitis, vomiting, epistaxis, erythema multiforme, lymphadenomegaly	Thrombocytopenia, lymphocytic pleocytosis	74, 371
<i>E. ruminantium</i>	Asymptomatic	No data	8
Granulocytotropic			
<i>E. ewingii</i>	Fever, anorexia, lameness, joint swelling, CNS signs	Mild thrombocytopenia Mild nonregenerative anemia, neutrophilic polyarthritis, neutrophilic CSF pleocytosis	488, 489, 187
<i>A. phagocytophilum</i>	Fever, anorexia, lethargy, splenomegaly, hepatomegaly, CNS signs, lameness, joint swelling	Thrombocytopenia, mild hypoalbuminemia, high serum ALP activity, occasional neutropenia or regenerative left shift, neutrophilic polyarthritis, predominantly neutrophilic CSF pleocytosis	198, 256
Thrombocytotropic			
<i>A. platys</i>	Mild fever, uveitis, petechia and ecchymoses, often asymptomatic	Thrombocytopenia	207, 222

CNS, central nervous system; CSF, cerebrospinal fluid; ALP, alkaline phosphatase.

Granular lymphocytosis has been observed with *E. canis* infection.^{224,543} Affected dogs had absolute lymphocyte counts ranging from 5200 to 17,200 cells/μl with granularity to their cytoplasm typical of well-differentiated lymphocytic leukemia. Some of these dogs had monoclonal gammopathies, which may further lead to a misdiagnosis of lymphocytic leukemia. Therefore ehrlichial testing should be performed on dogs when well-differentiated lymphocytosis is observed.

The most frequent serum chemistry abnormalities have included hyperproteinemia (33%), hyperglobulinemia (39%), hypoalbuminemia (43%), and elevated alanine aminotransferase (ALT) and alkaline phosphatase (ALP) activities (43% and 31%, respectively).³⁷¹ The hyperproteinemia results from elevated globulin levels, but no direct correlation exists between the levels of serum globulins and serum *E. canis* antibodies. Serum electrophoresis generally shows a polyclonal hyperglobulinemia,²¹⁰ although monoclonal gammopathies can occur. An *E. canis*-antibody titer should be measured in all dogs in which a diagnosis of benign monoclonal gammopathy is contemplated or in which definitive evidence of myeloma,

Infectious Diseases of the Dog and Cat, 3rd Edition

leukemia, or macroglobulinemia is lacking. Infected dogs with pancytopenia generally have lower serum γ -globulin concentrations compared with nonpancytopenic dogs.²¹⁰ Dogs with *E. canis* often have plasmacytosis in the bone marrow or sometimes other tissues, which can be confused with plasma cell myeloma.³⁷¹

Other clinicopathologic findings include positive antinuclear antibody test results,^{479a} proteinuria, hematuria, prolonged bleeding time (even in some dogs that have normal platelet counts), and pulmonary interstitial radiopacity ranging from a mild linear pattern to marked interstitial infiltration with peribronchial opacities. Experimentally, peak urine protein loss, consisting principally of albumin, is observed 2.5 to 3.5 weeks after inoculation and resolves by 6 weeks after infection.^{114,115} During the peak loss, urine protein/creatinine ratios ranged from 4.5 to 23.2 (reference ratio less than 1.0). A corresponding drop in serum albumin concentrations was noted (mean 2.1 g/dl). CSF analysis in dogs with signs of central nervous system (CNS) disease has revealed increased protein level and predominant lymphocytic pleocytosis similar to that found in viral infections.⁴²⁹ Comparable CSF findings have been noted in human monocytotropic ehrlichiosis.

Fig 28-7 A segmented neutrophil from a dog that contains a morula of a granulocytic species of *Ehrlichia*. (Courtesy University of Georgia, Athens, Ga.)

28.1.4.2 Cytology

A definitive diagnosis of ehrlichial disease can be made by demonstration of morulae in leukocytes from blood smears or tissue aspirates such as spleen, lung, and lymph node. The finding of morulae is difficult and time consuming but may be optimized by performing buffy coat smears or examining thin blood smears made from a peripheral capillary bed of the ear margin. Morulae may be visualized within monocytes present in peripheral blood smears or within synovial fluid (or both) or rarely CSF (Fig. 28-7). Cytologic studies of peripheral blood, buffy coat, lymph node aspirates, bone marrow aspirates, and short-term culture of blood

Infectious Diseases of the Dog and Cat, 3rd Edition

specimens have shown highest sensitivity in detecting the organisms in buffy coat and lymph node aspirates.³⁶⁹ Morulae were more often found in lymphocytes than monocytes. Platelets, lymphocytic azurophilic granules, lymphoglandular bodies, and phagocytosed nuclear material can all be confused with ehrlichial inclusions.

28.1.4.3

Serologic Testing

A diagnosis of ehrlichiosis is usually based on positive results of an indirect FA test. This test detects serum antibodies as early as 7 days after initial infection, although some dogs may not become seropositive until 28 days after infection begins. Therefore a dog may be acutely infected and have no demonstrable serum antibody titer. When *E. canis* antibody titer results are negative, a follow-up examination in 2 to 3 weeks or serotesting for other agents is recommended. Serum antibody levels in untreated dogs peak at 80 days after infection. During the first 7 days postinfection, the titer consists of IgA and IgM, and by 20 days, the majority is IgG. Most laboratories measure this antibody. Methodology and reporting differ among laboratories; thus no consensus concerning an absolute level of reactivity has been reached. An IgG titer of 1:80 or greater is generally considered to be evidence of infection or exposure, or both, but this finding may vary with each laboratory's methods. Conversely, because of measurable titer persistence after treatment or potential recovery, a positive titer result does not necessarily mean that the animal's disease or clinical symptoms are strictly the result of ehrlichiosis, especially in endemic areas inhabited by asymptomatic animals with titers to *E. canis*.

In one study, 20.3% of healthy kennel dogs had antibody titers to *E. canis*.²³³ We have dealt with at least 30 dogs during the last 14 years in which platelet counts were less than 50,000/ μ l, each had positive titers to *E. canis* with no concurrent increase in platelet numbers following tetracycline therapy. However, all dogs had dramatic platelet count increases in response to immunosuppressive doses of glucocorticoids. These dogs most likely had immune-mediated thrombocytopenia coincidentally or as a result of exposure to *E. canis*. They developed antiplatelet antibodies but at the time were not clinically affected by the *Ehrlichia* infection.

After treatment, in most dogs, the titer progressively declines and generally becomes negative in 6 to 9 months. Some dogs may become asymptomatic after therapy but yet retain very high titers to *E. canis* for years.^{41,397} Whether the organism is persisting cannot always be determined.⁴¹ Treated dogs are assumed to have eliminated the organism if thrombocytopenia, hyperglobulinemia, and other clinical and laboratory abnormalities resolve progressively after treatment.

Antigenic cross-reactivity exists with *E. canis* and other organisms in different regions of the world.²²⁵ Differences can be detected in serologic response by Western immunoblotting. Some cross-reactivity also occurs between ehrlichial species, which may pose problems in the interpretation of indirect FA serology in certain geographic areas. A shift in reactivity to various antigenic determinants of *E. canis* has been detected in dogs during the course of infection.³⁵⁰ For information on cross-reactivity among *Ehrlichia*, *Neorickettsia*, and *Anaplasma*, see [Table 28-3](#). Little, if any, cross-reactivity occurs between *E. canis* and *Rickettsia rickettsii*, the etiologic agent of RMSF. Because the clinical presentation of these two diseases is similar, dogs with clinical signs of ehrlichiosis in the absence of a titer to *E. canis* should be tested for RMSF by collecting serum for paired IgG titers, acute and 2-week convalescent sera (see [Chapter 29](#)). *N. helminthoeca* will cause cross-reactions to *E. canis*, *N. risticii*, and *N. sennetsu* (see [Chapter 27](#)).⁴³⁷ Titers to other *Ehrlichia* should be examined depending on the geographic area and compatible clinical signs. Antibodies to *E. ewingii* cross-react with *E. canis* and *E. chaffeensis*, and the use of one of these antigens will detect infection with either of the three, while *E. canis* sera can cross-react with *A. phagocytophilum* antigens.^{495,538}

Infectious Diseases of the Dog and Cat, 3rd Edition

E. ewingii cannot be cultured in vitro beyond isolation in primary cells; therefore a specific serologic test is not available. Cross-reactive antigens are also present between *E. chaffeensis* and HGE agent using human but not dog sera.^{352,444} *E. equi* will detect infection with HGE agent or *A. phagocytophilum*, and some cross-reactivity exists between *N. risticii* and *N. sennetsu*. In addition to indirect FA, enzyme-linked immunosorbent assay (ELISA) can be used to detect antibodies in dogs to *E. canis* and circulating antigen.¹⁸⁰ A “point of care” ELISA test using recombinant proteins has been developed for in-clinic testing for *E. canis* antibodies (Snap Canine Combo or Snap3Dx, IDEXX laboratories Inc., Westbrook, Me.). This test was initially marketed to have positive results at a dilution of 1:100 or greater; however, this level was subsequently increased to a dilution of 1:500 or greater. Another ELISA-based point of care test, the Dip-S-Ticks (PanBio InDx, Inc., Baltimore, Md.) has been found to have higher sensitivity but lower specificity than the Snap Canine Combo and lower accuracy than the Snap3Dx test when these were compared with the indirect FA assay.⁵³ An ELISA in-house test using whole rickettsiae has also been developed in Israel (Immunocomb, Biogal, Kibbutz Gal'ed, Israel) that is clearly able to differentiate *E. canis* seronegative samples from those with titers of at least 1:320.⁵³⁹ Titers in the range of 1:80 to 1:160 were not adequately evaluated with a large number of samples; however, a positive reaction was set at 1:80. Both test kits have been able to differentiate *E. canis* seronegative samples from those with titers of over 1:320.²⁰⁶ In cases in which low titers are involved, repeating the serologic test after several weeks may give a positive result. For further information on these test kits, see [Appendix 6](#).

b Reactivity increases with time during the course of infection.⁵³³

c Occasional low cross reactivity noted in some dog sera.³⁴ Reactivity is: 0, none; +, weak; ++, low; +++, high; +++++, strong; (?), no data.

With the advent of readily available screening tests, clinically healthy animals have been found to have increased serum antibody titers to *Ehrlichia* or *Anaplasma*. Some of these results may be falsely positive in

Infectious Diseases of the Dog and Cat, 3rd Edition

that they are caused by exposure to cross-reacting, less pathogenic rickettsiae. When recombinant protein-based tests are used, clinically significant infections with other rickettsiae may not be detected, and in some cases, true infections may be missed. Western blotting or PCR may be needed to resolve some of these issues. Treatment of seropositive asymptomatic dogs is therefore a controversial matter. Clinically healthy infected animals might serve as a reservoir for *E. canis*, although this risk can be overcome by more intensive vector control. Whether all subclinically infected animals will progress to the phase of chronic illness is uncertain. Some animals may never develop permanent immunity, and with reexposure in their environment, infection may recur. Indiscriminant treatment of all seropositive animals may theoretically lead to future resistance of these organisms to tetracyclines; however, such resistance has not been reported to date.

28.1.4.4

Immunoblotting

On a research basis, Western immunoblotting and PCR have been used to characterize and distinguish between infection with different organisms causing ehrlichiosis, anaplasmosis, or neorickettsiosis and may prove clinically helpful in the future. * The immunoblots for *E. canis* show a large number of reacting antigens, the most prominent being those separating in a broad band at 22 to 30 kDa.^{225,343} A 30-kDa protein is the major antigen recognized by both naturally and experimentally infected dog sera.³⁸⁰ The major antigenic protein 2, a 27-kDa protein was recently characterized and suggested to serve as a diagnostic tool for CME.^{7,53} More recently, the 120-kDa protein (p 120) and the rP43 protein have been shown to be very specific for *E. canis* and may be a potential antigen for the serodiagnosis of canine ehrlichiosis.^{348,570} Western immunoblotting will detect *E. canis* antibodies as early as 2 to 8 days after exposure, and PCR tests have positive results as early as 4 to 10 days after exposure to *E. canis* in experimental studies.^{248,547} The indirect FA test also becomes positive within a similar time frame. From a practical clinical standpoint, the indirect FA test will continue to be the initial screening test of choice. Western immunoblotting has also been useful in distinguishing between infections with *E. canis* and *E. ewingii*.⁴⁴² This characteristic is beneficial because most dogs with *E. ewingii* infection will have positive indirect FA titers to *E. canis*. No indirect FA test is available for *E. ewingii*.

* References 80, 128, 225, 248, 249, 260, 343, 437, 442, 580.

28.1.4.5

Organism Cultivation

Blood cultures may take up to 8 weeks to yield growth. This method is expensive, not routinely available, and is highly specific for the organism causing infection; however, it is considered a research tool.

28.1.4.6

Nucleic Acid Detection

PCR has been shown to be a sensitive method for detecting acute experimental *E. canis* infection in dogs,^{160,349} often within 4 to 10 days postinoculation and before seroconversion occurs. The sensitivity of blood PCR in the naturally infected dog is not as clear. False negative results that will occur are caused by difficulties in extracting the organism, inherent problems in technique, and with inappropriate sample selection. The principal reason for false positive results is nonspecific amplification or sample contamination during handling or testing. Current laboratory techniques and reagents have not been standardized. Few reports have surfaced on the use of blood PCR for the initial diagnosis of naturally occurring canine ehrlichiosis, when the blood PCR result was compared with an indirect FA result. In one study, poor

213

214

Infectious Diseases of the Dog and Cat, 3rd Edition

correlation between indirect FA titers and PCR results was noted.⁴⁹⁷ In this study, only 13 of 49 (27%) had a positive blood-PCR result, while the indirect FA test results for antibody to *E. canis* were positive in all dogs. Poor correlation of blood-PCR results compared with indirect FA results was also found in a recent study in Tennessee, where 10 of 90 dogs had positive indirect FA test results and none were found to be blood-PCR positive.⁴⁶⁴ This lack of correlation, which may indicate either insensitivity of the blood-PCR method or exposure with clearance of the organism, has also been reported in people with HGE.²⁷ In this study, convalescent indirect FA titers were more sensitive than blood-PCR for diagnostic confirmation of HGE. Insensitivity of blood-PCR is evident in that ehrlichial DNA could be amplified from the spleen, while it could not be amplified from corresponding blood specimens.²¹² Appropriate selection of tissue or body fluid specimens is therefore important for a positive diagnosis by amplification of ehrlichial DNA. The sensitivity of blood-PCR for the initial confirmation of ehrlichial infections is not consistently high enough to recommend it as the only test for diagnosing ehrlichiosis. It should be used in conjunction with serology to detect acutely infected animals before seroconversion. PCR of splenic aspirates can be considered as a more sensitive alternative than blood-PCR, especially in follow-up treatment.^{210a} With localized infections, assays on joint fluid, CSF, or aqueous humor might be more beneficial. In addition, as PCR becomes more refined, it may prove useful in distinguishing treated animals with persistent *E. canis* infection from those that retain persistent high indirect FA titers after successful treatment.^{250,547} Other than organism cultivation, PCR is the most specific means of determining which rickettsial species is infecting an animal. Furthermore, primers can be constructed for genus-specific screening to minimize the number of specific reactions that must be performed. A real-time PCR assay has been developed for detecting *E. chaffeensis*.³¹⁶

28.1.5 Pathologic Findings

Gross pathologic findings of *E. canis*-infected dogs include petechial and ecchymotic hemorrhages on the serosal and mucosal surfaces of most organs, including the nasal cavity, lung, kidney, urinary bladder, gastrointestinal (GI) tract, and subcutaneous tissue. Generalized lymphadenomegaly, splenomegaly, and hepatomegaly are present most often during the acute phase.^{195,135} All lymph nodes may be enlarged and have a brownish discoloration. Emaciation with loss of overall body condition is an additional finding in chronic cases. Bone marrow is hypercellular and red in color in the acute phase but, with chronic disease, becomes hypoplastic and pale caused by fatty discoloration.

One of the more characteristic histopathologic findings is a perivascular plasma cell infiltrate in numerous organs, including the lungs, brain, meninges, kidneys, lymph nodes, bone marrow, spleen, and sometimes skin or mucosa. The degree of lymphoid and plasma cell infiltrates appears to increase in chronically affected dogs.⁵¹⁴ Ehrlichial organisms are difficult to detect histologically in tissues fixed in either formalin or Bouin's solution. Morulae are infrequently observed in mononuclear phagocytic cells of tissues stained with hematoxylin and eosin.¹⁹⁵ The difficulty with which organisms are found histologically may explain why the disease is not frequently diagnosed at necropsy.

In the CNS, a multifocal, nonsuppurative meningoencephalitis involving the brain stem, midbrain, and cerebral cortex is noted. Most lesions are located ventrally in the brain stem and around the periventricular gray and white matter.⁵¹⁴ Only a very mild encephalitis of the cerebellum occurs. Mild neuroparenchymal vascular cuffing and gliosis often accompany the meningitis in CME. The meningeal inflammatory cell infiltrate may be monocytic or lymphoplasmacytic, or both.^{371,388} Microscopic meningeal lesions are present in nearly all dogs at necropsy, yet few dogs demonstrate clinical signs of meningitis.

Infectious Diseases of the Dog and Cat, 3rd Edition

Ocular signs have been reported to involve nearly every structure of the eye. These signs include conjunctivitis, conjunctival or iridal petechiae and ecchymoses, corneal edema, uveitis, and hyphema. Subretinal hemorrhage and retinal detachment may also occur. In a study, the eyes of dogs experimentally infected with *E. canis* were histologically examined.³⁸⁸ Uveitis occurred in each of the dogs infected with the organism (see [Fig. 93-13](#)). The inflammatory infiltrate was predominately lymphocytic, monocytic, and plasmacytic. Ocular inflammation was most common in the ciliary body, becoming less intense in the choroid, iris, and retina, respectively.

Pulmonary changes in ehrlichiosis are consistent with interstitial pneumonia. Initially, subendothelial accumulation of mononuclear cells occurs, and interstitial and alveolar hemorrhages may be present. *E. canis* organisms may be found in septal mononuclear cells and macrophages of the pulmonary vascular endothelium.

Glomerulonephritis and interstitial plasmacytosis may occur in dogs with ehrlichiosis and may account for the proteinuria of some cases. Minimal histologic changes were noticed in the kidneys of dogs experimentally infected with *E. canis*. However, ultrastructural examination showed fusion of podocyte processes that coincided with the development of proteinuria.¹¹⁴

28.1.6 Therapy

28.1.6.1 Specific Drug Therapy

The treatment of canine ehrlichiosis consists of antirickettsial agents and supportive care. Efficacious drugs have included tetracyclines, chloramphenicol, imidocarb dipropionate, and amicarbalide ([Table 28-4](#)). Generally, the earlier treatment is initiated in the disease process, the more favorable the prognosis and outcome because dogs in the severe chronic stage are difficult to cure.^{369a} In these dogs, multisystemic inflammatory changes and myelosuppression may be difficult to resolve.

Tetracycline and oxytetracycline have been considered the initial drugs of choice in the past and still work well, but doxycycline and minocycline are used more frequently now. Doxycycline and minocycline are semisynthetic, lipid-soluble tetracyclines that are readily absorbed to produce high blood, tissue, and intracellular concentrations. Given that ehrlichiae may persist intracellularly, drug penetration in the cell is important in eliminating infection. Therefore lipid-soluble tetracyclines can be given for shorter duration and at a lower dose than tetracycline and still be effective. The suggested duration of therapy with doxycycline is 7 to 10 days, although one study found that doxycycline (10 mg/kg daily) for 7 days was ineffective in eliminating experimentally induced *E. canis* infection from 3 to 5 dogs.²⁴⁹ In other studies, doxycycline (5 mg/kg twice daily) used for 10 or 14 days was effective in eliminating experimentally induced *E. canis* from 8 of 8 and 13 of 13 acutely infected dogs, respectively.^{72,73,370,373} Whether these shorter treatment times are adequate in naturally occurring cases is still in question. Some authors have found that even a 6-week course of doxycycline may not be sufficient to clear *E. canis* parasites from all subclinically infected dogs.²¹³ The standard length of therapy in natural infection is 21 to 28 days, and the Ehrlichial consensus statement from the American College of Veterinary Internal Medicine recommends a minimum of 10 mg/kg daily for 28 days.³⁷² The dosage regimens for tetracyclines and other drugs are summarized in [Table 28-4](#).

214

Table 28-4 Antimicrobial Therapy for Canine Monocytotropic Ehrlichiosis and Neorickettsiosis

DRUG ^a	DOSE ^b (mg/kg)	ROUTE PREFERRED (ALTERNATIVE)	INTERVAL ^c (HOURS)	DURATION ^d (DAYS)
Doxycycline	10	PO (IV)	12–24	28
Minocycline	10	PO (IV)	12	28
Tetracycline	22	PO	8	28
Oxytetracycline	25	PO (IV)	8	28
Chloramphenicol	15–25	PO (IV, SC)	8	28
Imidocarb dipropionate ^e	5	IM	Once	Repeat in 2–3 wks
Amicarbalide	5–6	IM	Once	Repeat in 2–3 wks

PO, By mouth; IV, intravenously; SC, subcutaneously; IM, intramuscularly.

- a See Drug Formulary, [Appendix 8](#), for additional information.
- b Dose per administration at specified interval.
- c Expressed in hours unless otherwise stated.
- d For *E. canis* infection, current recommendations are for at least 28 days. Other monocytotropic rickettsiae may require shorter intervals.
- e The effectiveness of imidocarb over doxycycline has been questioned.³⁷²

Dramatic clinical improvement generally occurs within 24 to 48 hours after initiation of tetracycline therapy in dogs with acute-phase or mild chronic-phase disease. The platelet count correspondingly begins to increase during this time and is usually in the normal range by 14 days after treatment. Recovery is not equated with permanent immunity, and dogs can become reinfected with *E. canis* after a previously effective treatment. Partial immunity does develop given that experimental reinfection with heterologous strains has caused more severe disease manifestations than those with homologous strains.⁷² Intramuscular (IM) administration of long-acting repositol oxytetracycline can be considered when oral administration of drug is difficult because of GI or neurologic signs or when poor compliance of drug administration is anticipated.²⁷³

Chloramphenicol has been recommended for puppies younger than 5 months to avoid the yellow discoloration of erupting teeth from tetracyclines. However, doxycycline is less likely to produce this effect (see Drug Formulary, [Appendix 8](#)). Chloramphenicol should be used in dogs that have persistent infections despite therapy with tetracyclines.⁵¹⁴ However, because of the public health risks associated with chloramphenicol and because it directly interferes with heme and bone marrow synthesis, its administration in anemic or pancytopenic dogs should be avoided whenever possible.

Other antibacterial agents that are ineffective against monocytotropic *Ehrlichia* spp. in people are erythromycin, new macrolides (azithromycin, clarithromycin, and telithromycin), penicillins, and aminoglycosides. The efficacy of quinolones is variable according to the drug used and organism involved. *N. sennetsu* is susceptible to ciprofloxacin in vitro.⁸¹ Enrofloxacin has been shown to be effective for the treatment of experimental RMSF in dogs (see [Chapter 29](#)).⁷¹ In contrast, *E. chaffeensis* was resistant to ciprofloxacin but sensitive to doxycycline and rifampin in vitro.⁸² In addition to doxycycline, rifampin, and fluoroquinolones have in vitro activity against *E. phagocytophilum*.²⁷⁸ The effectiveness of enrofloxacin for treatment of experimentally induced *E. canis* infection has been evaluated.³⁷⁰ At a dose of 5 mg/kg twice

Infectious Diseases of the Dog and Cat, 3rd Edition

daily and 10 mg/kg orally (PO) twice daily for 21 days, 6 of 7 and 5 of 5 dogs, respectively, remained blood culture-positive and thrombocytopenic after each treatment regimen. Three of the latter five dogs had improved platelet counts at the end of enrofloxacin treatment, but all dogs had recurrence of thrombocytopenia 14 days after completion of enrofloxacin therapy. All 12 dogs were then treated with doxycycline (5 mg/kg twice daily, PO, for 10 days) and had culture negative blood results and platelet counts returned to normal. Based on these results, enrofloxacin would not appear to be effective against *E. canis*. Authors in another study treated six dogs with enrofloxacin (5 mg/kg once daily for 15 days) and found clinical and laboratory improvement in all six dogs on day 15 of the treatment period.²⁸⁴ Whether the platelet counts would have dropped several weeks posttreatment is unknown. It is interesting to note that recently, the effectiveness of enrofloxacin against *E. canis*, or lack thereof, has been evaluated with an in vitro study that showed that the *E. canis* genogroup had a natural gyrase-mediated resistance to fluoroquinolones.³⁴⁶

Imidocarb, an antiprotozoal drug, has been successful in treating resistant *E. canis* infections (see also Chapter 71 and Drug Formulary, Appendix 8).³⁴² This drug persists in the tissues for up to 1 month following one dose. When imidocarb was given as a single IM injection, 83.9% of dogs with ehrlichiosis recovered. Apparently, the successful treatment of *E. canis* with imidocarb results from prolonged exposure of the organism to the drug, given that in vitro growth of *E. canis* is unaffected by short-term (3 days) exposure to apparently low or high levels of imidocarb.²⁶⁷ Transient, dose-dependent side effects of imidocarb dipropionate include excessive salivation, serous nasal discharge, diarrhea, and dyspnea. These signs may be the result of an anticholinesterase effect. In a three-way comparison of the efficacy of doxycycline (10 mg/kg for 28 days) versus imidocarb dipropionate (5 mg/kg IM, twice, 2 to 3 weeks apart) versus doxycycline-imidocarb combination treatment (with the same dosage regimen) in naturally occurring ehrlichiosis, no statistically significant difference among treatment groups was found.⁴⁵⁹ Approximately 93% to 94% of dogs were considered responders in this study regardless of which treatment group they were assigned. Based on these and other findings, the clinical effectiveness of imidocarb dipropionate over doxycycline has been questioned.²⁷⁹ Amicarbalide is a closely related carbanilide that has been used to treat ehrlichiosis.

In addition to antimicrobial therapy, supportive therapy with fluids for dehydration or blood transfusions may be justified if the dog is severely anemic. Blood transfusions will not significantly increase platelet numbers; therefore platelet-rich plasma may be needed in an emergency situation. Data are lacking to support the use of growth factors such as erythropoietin (Epogen, Amgen, Thousand Oaks, Calif.) and granulocyte colony-stimulating factor (Neupogen, Amgen, Thousand Oaks, Calif.). However, results from a single case report suggest that they might be useful for treating severe chronic ehrlichiosis.¹⁷ See Drug Formulary, Appendix 8 for more information on these drugs.

215

216

Short-term (2 to 7 days) therapy with immunosuppressive doses of glucocorticoids (2 mg/kg prednisolone) may be beneficial early in the treatment period when severe or life-threatening thrombocytopenia is present. An immune-mediated mechanism is partially responsible for the thrombocytopenia and decreased platelet function. The rationale for prednisone therapy has some scientific basis. Some clinicians prefer to use glucocorticoids and tetracycline in combination initially because of the difficulty in distinguishing between canine ehrlichiosis and immune-mediated thrombocytopenia and because of the lag time before serologic test results are available. When serologic testing will not be performed, using tetracyclines alone initially allows for a therapeutic diagnosis by clinical improvement in 24 to 48 hours. Glucocorticoids should not be excluded in these situations if the hemorrhage is life threatening because they help reduce the tendency for hemorrhage in various causes of primary thrombocytopenic disorders. Glucocorticoids may also be helpful in

Infectious Diseases of the Dog and Cat, 3rd Edition

the treatment of other immune-mediated conditions associated with ehrlichiosis such as polyarthritis, vasculitis, and meningitis. In one dog with meningitis secondary to granulocytotropic ehrlichiosis, glucocorticoids were required in addition to doxycycline before clinical resolution of signs was achieved.³³¹

28.1.6.2

Monitoring Therapy

Monitoring response to treatment of ehrlichial infections is important because some species can cause persistent infections. Resolution of thrombocytopenia is the most rapid development that may occur within a 7- to 10-day period following treatment. Because infection can recrudesce after treatment is stopped, platelet counts should be evaluated at least 1 to 3 months after treatment is discontinued. Changes in serum proteins caused by hyperglobulinemia can take up to 6 to 12 months to resolve. Specific *Ehrlichia* antibody titers of high magnitude are very difficult to follow because most laboratories report a maximum value rather than an endpoint dilution, and the decline of such high levels is often not linear with time. Some dogs have a resolution of all clinical and laboratory abnormalities; however, they may have a persistently high antibody titer. In these instances, evaluation of PCR, perhaps of a splenic aspirate, may be warranted. In some of these instances, as with other infectious diseases, serum antibody titers may remain increased after elimination of the organism; however, all clinical and laboratory abnormalities should resolve in drawing this conclusion. Dogs can also become reinfected after recovery, especially when they reside in highly endemic environments. Therefore proving elimination of infection following treatment can be difficult. If an animal does not show clinical improvement following recommended treatment regimens, then another or compounding cause of illness should be considered. Most dogs with ehrlichial infections show some resolution of clinical illness within 24 to 48 hours following institution of treatment, even if clinical laboratory parameters remain abnormal. Although experimentally infected dogs can be predictably cleared of infection with appropriate regimens, anecdotal concern exists that natural infections in some areas of the world are more resistant to therapy. In addition, in one instance in which dogs with various ehrlichial infections were treated, *E. chaffeensis* appeared to be more resistant to doxycycline.⁷⁴ Possibly, this apparent resistance to treatment may really involve reinfection under natural conditions in tick-infested environments.

28.1.7

Prevention

A vaccine is not currently available; therefore chemotherapy, chemoprophylaxis, and tick-control measures are the primary means of prevention. Compared with untreated dogs, seroconversion was reduced in dogs entering an area endemic for *E. canis* infection if they were treated with once monthly fipronil application.¹²⁴ For *E. canis* infections in kennel dogs, tetracycline has been shown to be an effective prophylactic drug against initial infection or reinfection when administered PO at 6.6 mg/kg/day. Indiscriminant use of this drug to all dogs might theoretically lead to drug resistance.

Control in endemic areas can be accomplished by maintaining strict tick-control programs for dogs and premises, by using the indirect FA test to identify exposed and infected dogs, and by treating all infected dogs with the therapeutic regimen of tetracycline. All newly introduced animals into a kennel should be serotested, treated for ticks, and isolated until the results are available. When these measures fail, maintenance of all dogs (susceptible and successfully treated) on prophylactic levels of tetracycline may be the only recourse. If these guidelines are followed, the cycle of *E. canis* infection in the tick should be broken, because transovarian transmission of *E. canis* does not occur in the *Rhipicephalus* tick. Being a domiciled tick, and having the preference of all stages feeding on dogs, *R. sanguineus* is important in the maintenance of *E. canis* infections in kennel environments. Importation of *E. canis*-infected dogs or infected *R. sanguineus* ticks is a continual risk for countries such as the United Kingdom where canine ehrlichiosis is not endemic.⁴⁷³ Precautions must be

Infectious Diseases of the Dog and Cat, 3rd Edition

taken to screen incoming dogs for ehrlichiosis using serologic methods. For the other ehrlichial, anaplasma, and neorickettsial species, outdoor ticks are potential sources of infection in conjunction with multiple, as yet unidentified wildlife reservoir hosts. Tick-control measures on the susceptible dog are the only solution.

28.1.8 Public Health Considerations

Before 1986, the only ehrlichial species recognized as infecting people was *N. sennetsu* (see Table 28-1). This agent, first isolated in Japan, is responsible for a mild mononucleosis-like syndrome. Two new ehrlichial agents have since been reported to cause disease in people in the United States. The first is *E. chaffeensis*, the causative agent for HME,^{12,462,483} which is exhibited as an acute influenza-like illness characterized by fever, headache, malaise, and sometimes death in severely affected people. *E. chaffeensis* is closely related to *E. canis*, and although dogs can be experimentally infected, they do not develop clinical disease.¹²⁹ Natural infections in dogs may develop a different course (see previous discussion on Clinical Signs). HME, which is predominant in the south-central and southeastern United States, likely involves a sylvan cycle in nature, with deer or rodents, or both, as reservoir hosts, and *A. americanum* (or possibly *D. variabilis*) being the most likely vectors. Although wildlife reservoirs are most important, dogs might be carriers of *E. chaffeensis* in endemic geographic regions. Dogs may be involved in transporting ticks in closer proximity to people, and the role of handling ticks or their excretions or body fluids might be a possible risk. See later discussion for further information on zoonotic aspects of *Anaplasma* infections. In addition, the Venezuelan human ehrlichiosis agent has been suggested to be a variant of or a subspecies of *E. canis* transmitted by *R. sanguineus* ticks.^{371,518} Therefore, in South America, dogs may serve as a reservoir for Venezuelan human ehrlichiosis, and *R. sanguineus* may serve as the vector. The potential risk of transmission of ehrlichiosis to dogs via blood transfusions has been known for years, and this is also becoming an increasing concern in human transplantation medicine.*

P. Jane Armstrong

28.2.1 Etiology and Epidemiology

E. ewingii is the causative agent of one of a pair of zoonotic diseases that have each previously been given the name “granulocytic (meaning, granulocytotropic) ehrlichiosis” (GE). In mammalian hosts, morulae of *E. ewingii* can be seen in peripheral blood neutrophils, eosinophils, and rarely monocytes, and in neutrophils in synovial fluid.^{86,185,385,488}

When canine *E. ewingii*-GE was first described in 1971, the etiologic agent was believed to be a granulocytic form of *E. canis*.¹⁶³ In 1992, after amplifying and sequencing the bacterial 16S rRNA gene from the blood of a dog with GE, *E. ewingii* was identified as a distinct species, separate from, but closely related to *E. canis* and *E. chaffeensis*.¹³ The 16S rRNA genes of all bacteria of the genus *Ehrlichia* are at least 97.7% homologous (i.e.,

Infectious Diseases of the Dog and Cat, 3rd Edition

nearly 98% of the 1400 nucleotides are identical). *E. ewingii* is 98.0% similar to *E. canis* and 98.1% similar to *E. chaffeensis*.^{13,146}

To date, *E. ewingii* infection has been found only in the United States and almost exclusively in the southern and southeastern sections, except for one case of an infected dog from New York state that had traveled multiple times to Boston but had not visited southern or southeastern sections.^{*} Disease attributed to this organism has been reported in domestic and wild canids and people.[†] *E. ewingii* infection has been diagnosed in dogs from Missouri, Arkansas, Oklahoma, Tennessee, Virginia, North Carolina, Mississippi, and New York.^{185,187,488,563} Human cases have been diagnosed in Missouri, Oklahoma, and Tennessee.^{86,385} The only tick proven to be a competent vector of *E. ewingii* is the ixodid tick, *A. americanum*, the Lone Star tick. In an experimental study, *A. americanum* successfully transmitted *E. ewingii* transstadially between dogs, while *D. variabilis* did not succeed.¹⁶ However, *E. ewingii* DNA has been found in field-collected *A. americanum*, *D. variabilis*, and *R. sanguineus* ticks from Oklahoma.³⁶⁸ No published report has been produced of successful transmission using *R. sanguineus* or *Ixodes scapularis*. In North Carolina, *E. ewingii* DNA has been found in field-collected *A. americanum* ticks, but not *D. variabilis* or *I. scapularis* ticks.⁵⁵⁶ *E. ewingii*-PCR-positive-*A. americanum* ticks have also been found in Arkansas, Georgia, Kentucky, and South Carolina.⁵⁵⁶ *A. americanum* is commonly found throughout much of the southeastern United States, including Texas, Oklahoma, Arkansas, Missouri, and the Atlantic coast states. White-tailed deer are an important reservoir for *E. ewingii*.⁵⁶³

* References 13, 86, 185, 187, 286, 368, 385, 488, 563.

† References 86, 185, 187, 385, 488.

28.2.2 Pathogenesis

E. ewingii reside within phagosomes in vertebrate leukocytes after they have been internalized via endocytosis.⁴⁰⁶ Within the phagosome they evade phagosome-lysosome fusion by an unknown mechanism. After intracellular invasion, ehrlichiae proceed to replicate for 2 to 3 days by binary fission. Replication within the vacuole can produce up to 50 organisms,⁴⁰⁶ forming the classic morula ("mulberries") seen with light microscopy, a hallmark of acute ehrlichial infections (Fig. 28-8). Host cell mitochondria and endoplasmic reticulum aggregate around the ehrlichial-laden phagosome, and these organelles tend to remain in close contact with the morulae.⁴⁰⁶ The phagosomal membrane and the host cell plasma membrane eventually rupture, releasing organisms into circulation to infect new cells. Incubation for ehrlichial diseases is 1 to 2 weeks.⁴⁸⁸ The actual length of feeding time required for ticks to transmit ehrlichial agents to a susceptible mammalian host is unknown. In mammals, ehrlichial organisms tend to be most abundant in tissues of the mononuclear-phagocyte system (bone marrow, spleen, liver, and lymph node),¹⁴² but the mechanisms by which the organisms cause disease are poorly understood.

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 28-8 Ultrastructure of *E. canis* morula in a monocyte showing a “mulberry appearance” because the intracytoplasmic inclusion is made up of numerous organisms.

28.2.3 Clinical Findings

Disease caused by *E. ewingii* was originally described as an acute polyarthritis syndrome.⁴⁸⁸ Although polyarthritis is a common feature of *E. ewingii* infection,^{185,187,488} dogs may have nonspecific signs of illness, including fever, depression, and lethargy (see [Table 28-2](#)).^{185,187} Dogs having neurologic manifestations frequently display ataxia, paresis, proprioceptive deficits, anisocoria, intention tremors, or vestibular dysfunction.¹⁸⁷ Vomiting and diarrhea have been reported infrequently.^{185,187} Clinical and hematologic abnormalities found with *E. ewingii* and *E. canis* infections are often similar, but clinical disease caused by *E. ewingii* appears to be milder than that of *E. canis*. To date, no reported canine or human deaths have been attributed to *E. ewingii*.^{*} *E. ewingii* infection has also been documented in clinically healthy dogs, presumably reflecting chronic subclinical ehrlichemia.¹⁸⁷ Dogs with immune-mediated, inflammatory, endocrine, or other diseases have been diagnosed with concurrent *E. ewingii* asymptomatic infection or clinical disease.^{185,187}

* References 86, 185, 187, 385, 488.

28.2.4 Diagnosis

E. ewingii causes a seasonal and regional disease that depends on the activity and geographic range of its tick vector, *A. americanum*. These ticks are active feeders (i.e., are actively seeking hosts) from spring to late autumn. Large tick populations have been found in forested areas frequented by deer. Acute disease caused by *E. ewingii* is less likely to be seen during the winter because disease incubation is 1 to 2 weeks following a tick bite; however, chronic asymptomatic canine infections have been documented in winter months.¹⁸⁷ In addition, weather does influence tick activity (i.e., long warm autumn months may result in cases being diagnosed into the winter months). Travel histories are important to identify dogs that have recently traveled to, but do not live

Infectious Diseases of the Dog and Cat, 3rd Edition

in, *A. americanum*—endemic regions. *E. ewingii* infection should be high on a disease differential list for dogs in southern, southeastern, and Atlantic coastal states of the United States that have acute fever, lameness, or neurologic abnormalities in the spring through autumn. History, clinical signs, hematologic findings, presence of morulae in granulocytes of blood or synovial fluid, and serologic findings can all be used to help make a presumptive diagnosis of *E. ewingii* infection, but definitive diagnosis currently relies on microbial DNA analysis via PCR.

28.2.5 Clinical Laboratory Findings

The only consistent hematologic abnormality is mild-to-moderate thrombocytopenia with or without large platelets.^{185,187,488} Normochromic normocytic nonregenerative anemia may be present.^{185,187,488} Neutrophil and lymphocyte counts vary and reactive lymphocytes are frequently present.^{187,488} Ehrlichial morulae have been seen in 1% to 26% of neutrophils and occasional eosinophils of peripheral blood.^{86,385,488} In experimental *E. ewingii* infections, ehrlichial morulae are evident in circulation for up to 6 days maximum¹⁶; therefore the lack of morulae in circulating granulocytes does not preclude a diagnosis of *E. ewingii* infection. Dogs treated with glucocorticoids for thrombocytopenia, immune-mediated anemia, or polyarthritis are more likely to have morulae present in neutrophils of peripheral blood.¹⁸⁷ No consistent serum chemistry abnormalities have been associated with *E. ewingii* infection. Mild increases in serum ALP or ALT activities are present in less than one half of dogs diagnosed with *E. ewingii* infection.^{185,187} *E. ewingii* infection frequently causes neutrophilic polysynovitis in dogs.^{185,187,488} The synovial fluid from dogs with polyarthritis should be examined for neutrophils containing morulae. Morulae are found in 1% to 7% of neutrophils from affected joints.¹⁸⁵

28.2.5.1 Serologic Testing

No specific serologic test has been produced for *E. ewingii* because this organism has yet to be cultivated in vitro. Because bacteria within the genus *Ehrlichia* are closely related, polyclonal antibodies to one species within the genus frequently cross-react to antigens of the other species within the genus (see [Table 28-3](#)).²⁰² *E. canis* indirect FA is recommended as a preliminary screening tool for *E. ewingii* infection.^{185,187,488} As with most infectious diseases, the usefulness of serologic testing relies on acute to convalescent seroconversion to diagnose active ehrlichial disease. Because no serologic test is specific for *E. ewingii*, *E. canis* seroconversion in dogs simply indicates potential infection with *E. canis*, *E. ewingii*, or *E. chaffeensis*. Sera from *E. ewingii*-infected dogs also occasionally display low-level indirect FA cross-reactivity to *A. phagocytophilum* antigens.¹⁴²

Serologic cross-reactivity is caused by cross-reactive immunodominant surface proteins that are of similar molecular size, particularly those of the family of immunodominant outer membrane proteins of 27 to 32 kDa present in *E. canis*, *E. ewingii*, *E. chaffeensis*, *E. ruminatum*, and *E. muris* (see [Table 28-3](#)).²⁰² Additionally, a similar family of proteins in *A. phagocytophilum* are likely responsible for the occasional low-grade serologic cross-reactivity between *E. ewingii* or *E. canis* and *A. phagocytophilum*.⁵⁷⁷ Because *E. canis* and *E. chaffeensis* can be cultivated in vitro, expressed recombinant *E. canis* and *E. chaffeensis* genes of this family are used to make Western and dot blot immunoassays for species-specific serodiagnosis; monoclonal antibodies made to expressed proteins usually do not cross-react with the related proteins of another species.⁸⁰ Positive *E. canis*-indirect FA seroconversion can be followed up by *E. canis*-specific and *E. chaffeensis*-specific Western blot or dot blot assays to confirm infections with one of these two agents. However, because of the possibility that dogs can be co-infected with two or more of these ehrlichial species,

Infectious Diseases of the Dog and Cat, 3rd Edition

E. ewingii-PCR may be necessary to determine if *E. ewingii* infection is present. Species differentiation among these organisms is of greater academic and zoonotic importance than of clinical relevance to the infected dog. Therapy for all three of these agents is identical, as well as all identified members of genera *Ehrlichia* and *Anaplasma*, is the same: all of these agents are susceptible to doxycycline.

Table 28-5 Antimicrobial Therapy for Canine Granulocytotropic Ehrlichiosis and Anaplasmosis

DRUG ^a	DOSE ^b (mg/kg)	ROUTE PREFERRED (ALTERNATIVE)	INTERVAL (HOURS)	DURATION ^c (DAYS)
Tetracycline	22	PO	8	14–21
Doxycycline	5–10	PO (IV)	12–24	10
Minocycline	10	PO (IV)	12	10
Chloramphenicol	15–25	PO (IV, SC)	8	14–21

PO, Orally; IV, intravenously; SC, subcutaneously.

a See Drug Formulary, [Appendix 8](#), for additional information.

b Dose per administration at specified interval.

c For *E. canis* infection, current recommendations are for at least 28 days; however, shorter intervals are effective with other rickettsiae.

28.2.5.2 Nucleic Acid Detection

PCR assays that amplify 16S rRNA, groESL, and p28 genes specific for *E. ewingii* have been developed.^{13,202} PCR testing of blood using 16S rRNA was used to identify *E. ewingii* infected symptomatic and nonsymptomatic naturally infected dogs in Missouri.³⁰⁵ A single positive PCR test implies active infection. Commercial veterinary 16S rRNA PCR assays are available from a small number of diagnostic laboratories (see [Appendix 6](#)). Optimally, ethylenediaminetetraacetic acid (EDTA)-anticoagulated peripheral blood, obtained before antibiotic administration, should be submitted for PCR testing.

28.2.5.3 Organism Cultivation

Currently, this diagnostic method is not available because cell lines that can support *E. ewingii* growth in vitro have not been identified.

28.2.6 Pathologic Findings

E. ewingii infection is not considered a life-threatening disease in dogs or people. No postmortem or surgical biopsy findings have been published.

28.2.7 Therapy

The tetracyclines are almost exclusively recommended for treating canine ehrlichial diseases ([Table 28-5](#)). Tetracycline (22 mg/kg, PO, every 8 hours for 14 to 21 days) or doxycycline (5 to 10 mg/kg, PO, every 12 to 24 hours for 10 days) is the recommended treatment protocol. Minocycline has been substituted at an equivalent dose. For puppies younger than 1 year, chloramphenicol has been recommended to avoid yellowing of teeth ([Table 28-5](#)).³⁷¹ No proof has been produced that long-term treatment beyond the recommended intervals is

Infectious Diseases of the Dog and Cat, 3rd Edition

beneficial for *E. ewingii* infection. Although evidence for persistent *E. canis* infection exists, despite treatment, persistent *E. ewingii* infection has not been documented.³⁷¹ Dogs exhibiting acute polyarthritis respond rapidly to treatment and frequently are clinically normal 24 to 48 hours after initiation of therapy.^{185,488} Dogs with other clinical signs or with concurrent diseases may require weeks of therapy for complete resolution of clinical or laboratory abnormalities.¹⁸⁵ Concurrent illnesses should be treated appropriately. If response to tetracycline antibiotics is poor, the probability that the dog has a concurrent disease is high.

28.2.8 Prevention

At present, no vaccine is available to prevent *E. ewingii* infection or any other ehrlichial infection. Prevention relies on (1) avoiding exposure to the tick vector, *A. americanum*, during its active feeding season, spring through fall; (2) using antiacaricides; or (3) administering prophylactic tetracycline–doxycycline when visiting *A. americanum* tick–endemic regions.

28.2.9 Public Health Considerations

Human *E. ewingii* GE was first reported in 1999 in four male residents of Missouri.⁸⁶ Since then, the disease has been diagnosed in people from Tennessee and Oklahoma.³⁸⁵ Most patients have been male and most have been immunocompromised.^{86,385} Human *E. ewingii* GE cannot be distinguished clinically from monocytotropic ehrlichiosis caused by *E. chaffeensis* or GE caused by *A. phagocytophilum*.^{86,385} The most consistent physical examination and laboratory findings in human *E. ewingii* infections are fever, headache, malaise, leukopenia, and thrombocytopenia.^{86,385} Peripheral blood neutrophils containing morulae were found in only one half of reported cases.^{86,385} Diagnosis relies on *E. ewingii*–specific PCR.^{86,385} The potential for dogs to be a zoonotic risk factor for human *E. ewingii* infection is not known. Both dogs and people are likely incidental hosts for this infection.

28.3 CANINE GRANULOCYTOTROPIC ANAPLASMOSIS (*A. PHAGOCYTOPHILUM* INFECTION)

Barbara Greig

P. Jane Armstrong

28.3.1 Etiology and Epidemiology

A. phagocytophilum is the causative agent of one of a pair of tick-transmitted zoonotic diseases that have each previously been given the name “granulocytotropic ehrlichiosis” (see [Table 28-1](#)). See previous discussion on Canine Granulocytotropic Infection. The term *granulocytotropic ehrlichiosis* is now a misnomer for *A. phagocytophilum* infections because the causative agent has been removed from the genus *Ehrlichia* and placed into the genus *Anaplasma* (see previous discussion, introduction of chapter).¹⁴⁶ The disease caused by *A. phagocytophilum* is appropriately termed *canine granulocytotropic anaplasmosis*.

Bacteria of the family *Anaplasmataceae* are gram-negative, nonmotile, coccoid to ellipsoid organisms, varying in size from 0.2 to 2.0 μm diameter. They are obligate aerobes, lacking a glycolytic pathway, and all are obligate intracellular parasites. All species in the genus *Anaplasma* inhabit membrane-lined vacuoles in

Infectious Diseases of the Dog and Cat, 3rd Edition

immature or mature hematopoietic cells of mammalian hosts.¹⁴⁶ *A. phagocytophilum* infects neutrophils and the term *granulocytotropic* refers to infected neutrophils. Rarely, organisms have been found in eosinophils.

The geographic distribution of the disease in people and domestic animals worldwide follows that of its *Ixodes* spp. vectors that feed on larger mammals. As a result of a common vector, the distribution of this disease follows that caused by *Borrelia burgdorferi sensu lato* (see Fig. 45-2,B). Co-infections with these two organisms are common among these ticks, and an onset of illness within 20 days following exposure to these ticks is more likely caused by *A. phagocytophilum* rather than *B. burgdorferi*, which has a longer incubation period of up to 60 to 90 days. Although these ticks are co-infected, their reservoir hosts and maintenance cycles in nature are likely different. Studies comparing larval and nymphal ticks have shown markedly different carriage rates of the two organisms in a given geographic region.^{290,301} In North America, *A. phagocytophilum* is found in upper midwestern and northeastern regions of the United States, and the western coastal regions from California to British Columbia. In South America, a single *A. phagocytophilum*-PCR-positive dog has been found in Venezuela.⁴⁹⁶ In the European region, reports have been from the United Kingdom, Norway, Sweden, Switzerland, Germany, Netherlands, and Slovenia.* In Korea, *A. phagocytophilum* has been genetically detected in *I. persulcatus* and *Haemaphysalis longicornis* ticks that were field collected or found on domestic animals.²⁷⁴ Additionally in Asia, an *A. phagocytophilum*-PCR-positive dog has been identified in Thailand, and PCR-positive *I. persulcatus* ticks have been identified in western Siberia, Russia^{497,360}; the disease potential of these organisms is uncertain. In upper midwestern and northeastern United States, human and canine disease caused by *A. phagocytophilum* is diagnosed in spring to early summer and again in the fall; few cases are diagnosed midsummer and in the winter months.^{26,29,197} In Sweden, canine cases have been diagnosed midsummer through autumn.¹⁵⁸ The seasonality and the geographic distribution of *A. phagocytophilum* infections are determined by the feeding habits and ranges of its particular tick vectors. Several ixodid ticks of the genus *Ixodes* are vectors of *A. phagocytophilum*. *I. scapularis* is the vector in upper midwestern and northeastern United States; *I. pacificus* is the vector in California and British Columbia; and *I. ricinus* is the vector in Europe and the United Kingdom.[†] *Ixodes* ticks are three-host ticks. Because *A. phagocytophilum* is transferred transstadially only between ticks, only nymph and adult stages are potential disease carriers.¹⁴⁶ A significant number of small mammals and deer have been implicated as natural reservoirs of *A. phagocytophilum*. In the United States, the white-footed mouse, eastern chipmunk, dusky-footed wood rat, southern red-backed vole, and white-tailed deer are all considered reservoirs.^{57,387,482,531} In Europe, the bank vole, wood mouse, yellow-necked mouse, common shrew, and roe and red deer are likely natural reservoirs.^{312,400} In addition to terrestrial mammals, birds may be important in the geographic distribution or spread of infection. Larval *I. ricinus* feeding on migratory birds in Sweden have been shown to be infected with *A. phagocytophilum*.⁶¹ These birds have wintering grounds in continental Europe and Africa. Similarly, birds in North America have been infected, and evidence suggests that, in addition to spreading infection, they also can act as reservoirs by transmitting infection to tick larvae that co-feed with infected nymphs.¹²⁰

Although tick-transmission is the predominant means of infection, perinatal transmission has been documented in people²³² and transplacental infection has been documented in cows.⁴¹³ Infections with these organisms can cause abortions in cows and sheep, and the organism has been found in milk from infected cows; therefore the risk of spread of these infections directly to newborns should be considered.

A. phagocytophilum sensu lato causes infection and potential clinical illness in domestic dogs; horses; in European cattle, sheep, and goats; and in llamas, cats, and people.* Within this newly combined species, *A. phagocytophilum*, the strains derived from *E. phagocytophila*, *E. equi*, and HGE agent display genetic and

Infectious Diseases of the Dog and Cat, 3rd Edition

biologic differences. Disease caused by the *E. phagocytophila* strain was the first ever described “granulocytic ehrlichial disease” in 1932 in Scottish sheep.¹⁸⁹ Not until 1969 was equine *E. equi*–“granulocytic ehrlichiosis” reported in horses from California.³²¹ *E. phagocytophila* and *E. equi* were originally determined to be separate species based on ultrastructural morphology and phenotypic expression, the previously established tools for microbial phylogenetic classification. In the early 1990s, 16S rRNA gene sequencing became available for microbial phylogenetic classification. This process coincided with the emergence of HGE in 1990 in Minnesota and Wisconsin patients. When a 1433 nucleotide sequence of the 16S rRNA genes of the HGE agent, *E. phagocytophila*, and *E. equi* were compared, these three agents were found to be very closely related but not genetically identical. The 1433 nucleotide sequence differs by two nucleotides between *E. phagocytophila* and *E. equi* and by two and three nucleotides between the agent of HGE and *E. phagocytophila* and *E. equi*, respectively.^{108,146,197} Because of the speculation that these three differently named agents actually were of the same species, the causative agent of HGE was not initially given a species designation but was simply called “the human granulocytic ehrlichiosis agent.” In 2001, when the order Rickettsiales was reorganized, the HGE agent was brought together with *E. phagocytophila* and *E. equi* into the single *A. phagocytophilum* species (see previous discussion, introduction to chapter).¹⁴⁶

Despite their genetic similarities, the three strains of *A. phagocytophilum* are dissimilar in the mammalian species in which they cause disease and in their geographic distributions (see Table 28-1). The *E. phagocytophila* strain causes disease only in domestic ruminants of many European countries (Sweden, Norway, Finland, Great Britain, Ireland, Holland, Switzerland, France, Austria, Germany, and Spain).[†] No strain of *A. phagocytophilum* has ever been isolated from domestic or wild North American ruminants. All European isolates from people, dogs, and cats are of the HGE strain.^{62,158,401,418} All United States isolates from dogs and cats are of the HGE strain, and all human isolates are identical to the HGE strain, except for isolates from several patients in California that differ by one nucleotide base.[‡] All equine isolates from midwestern and northeastern United States are of the HGE strain, but horses from California have either the *E. equi* strain or the HGE strain with one nucleotide difference.[§] Cattle and sheep do not become ill when infected with the HGE strain, but they do seroconvert.^{411,425} Experimental *E. phagocytophila*–strain infection in horses and *E. equi*–strain infection in cattle produce asymptomatic infections with seroconversion that provide cross-protection against subsequent infections with *E. equi*–strain and *E. phagocytophila*–strain, respectively.^{411,425} Experimental cross-infections have shown the strong antigenic relatedness among these three strains.

In addition to the previously mentioned genetic and biologic differences, other less well-defined genetic variations of *A. phagocytophilum* have been revealed. Sequence analyses of the ankyrin gene from various animal and human isolates have identified conserved genetic sequences that differ between isolates from different regions in the United States and between isolates from the United States and from Europe.^{337,524} Clinicians have isolated 16S rRNA HGE-strain variants from ticks and deer but none have been found in dogs or people. The potential pathogenicity of these variants is not known.^{57,336,329} A variety of minor nucleotide differences in the *E. phagocytophila*–strain 16S rRNA gene have been identified between different Norwegian sheep isolates from the same flock and between isolates from different flocks; and these differences are associated with discordant serologic responses.⁴⁹⁴ Antigenic diversity among *A. phagocytophilum* isolates exists also, denoted by the occurrence of variable serologic reactions to isolate-specific *A. phagocytophilum* immunoblot assays among sera from infected animals of different geographic regions.²² The investigation to identify additional genetic and phenotypic variations and to determine their significance is ongoing.

Infectious Diseases of the Dog and Cat, 3rd Edition

Although genetic and phenotypic differences do exist among the *E. phagocytophila*, *E. equi*, and HGE strains, all three share 99.1% 16S rRNA gene sequence homology and display strong antigenic serologic cross-reactivity.¹⁴⁶ By comparison, *A. phagocytophilum* has only 94.1% 16S rRNA gene sequence homology with any species in the newly organized *Ehrlichia* genus, and serologic cross-reactivity between *A. phagocytophilum* and *E. canis*, *E. chaffeensis*, and *E. ewingii* is uncommon to rare.¹⁴⁶

The first published report of canine *A. phagocytophilum* infection came from Sweden in 1995, but cases were likely seen in Sweden as early as 1989.²⁵⁶ *A. phagocytophilum* was identified in Minnesota and Wisconsin dogs in 1990, simultaneous with the discovery of human infections in Minnesota and Wisconsin.^{26,197} Canine *A. phagocytophilum* infection has been reported in dogs from Minnesota, Wisconsin, Rhode Island, California, Sweden, Switzerland, and Slovenia. HGE caused by *A. phagocytophilum* has been identified in Minnesota, Wisconsin, New York, Massachusetts, Connecticut, California, Slovenia, Sweden, Norway, Netherlands, and Switzerland.*

28.3.2 Pathogenesis

A minimum feeding time of 24 hours and up to 48 hours or more is required for *Ixodes* spp. ticks to transmit *A. phagocytophilum* to susceptible mammalian hosts.^{138,263} Disease incubation following a tick bite is 1 to 2 weeks. The average disease incubation period for horses in experimental tick-transmission of *A.*

phagocytophilum is 10.5 days.⁴²¹ In vitro, *A. phagocytophilum* infects both granulocytic and monocytic bone marrow progenitor cells, but the more differentiated cells of the neutrophil lineage are most susceptible to infection.²⁷⁵ P-selectin ligand-1 is one known neutrophil surface receptor for *A. phagocytophilum*; this cell

surface glycoprotein is rich on the surface of neutrophils.^{205,275} After binding to the cell surface receptor, *A. phagocytophilum* bacteria enter neutrophils via endocytosis and are incorporated into phagosomes. The organisms prevent phago-lysosome fusion, block the cellular oxidative respiratory burst activity of the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase enzyme complex, and inhibit cellular

apoptosis.^{30,176,363,540} By these mechanisms, *A. phagocytophilum* bacteria prevent their destruction by cells designed to kill microbes. Inside the phagosome, the bacteria proceed to multiply by binary fission. Replication produces twenty or more organisms, forming the classic “morula” (mulberry) seen with light microscopy, a

hallmark of ehrlichial diseases (see Fig. 28-7).⁴⁰⁶ The bacteria-laden phagosome and the host cell plasma

membrane eventually rupture, releasing organisms to infect new cells. Cells infected with *A. phagocytophilum* are found in neutrophils in peripheral blood and in tissues of the mononuclear phagocytic system (spleen, liver, and bone marrow).^{146,155,157}

Infectious Diseases of the Dog and Cat, 3rd Edition

Exactly how *A. phagocytophilum* causes disease remains unknown. The cytokine alterations in the host are not typical in that the organism does not possess endotoxin, and the classic proinflammatory cytokines, interleukin (IL)-1, IL-6, or tumor-necrosis factor- α are not released by infected cells. Other mechanisms have been found to cause thrombocytopenia, leukopenia, and anemia in infected hosts. In vitro, *A. phagocytophilum*-infected neutrophils stimulate increased production of IL-8 and other cytokines (MIP-1 α , MIP-1 β , MCP-1, and RANTES). MIP-1 α , MIP-1 β and IL-8 inhibit hematopoiesis in vitro.^{275,276} IL-8 is chemotactic to neutrophils and naïve T lymphocytes, enhances phagocytosis, enhances the neutrophil cellular respiratory burst activity, and enhances angiogenesis.^{63,85} MIP-1 α and MIP-1 β are chemoattractant to monocytes, macrophages, and T lymphocytes.^{63,85} MCP-1 and RANTES activate monocytes, macrophages, and T lymphocytes.^{63,85} The production of these leukocyte attractants, which are also capable of suppressing hematopoiesis, results in myelosuppression. Thrombocytopenia may be compounded by additional mechanisms. In a mouse model of *A. phagocytophilum*-induced thrombocytopenia, immune-mediated splenic removal and decreased platelet production were shown to be unlikely mechanisms for the thrombocytopenia that occurs in acute infection.⁶⁴ Increased production of monocyte tissue procoagulant activity in peripheral blood mononuclear cells has been documented in vitro.⁵² Therefore increased coagulatory consumption of platelets is suspected. Serum levels of IFN- γ rise early in *A. phagocytophilum* infections, during the initial 8 to 10 days.⁴ This increase in IFN- γ appears to be important for early control of the degree of bacteremia.⁴ After the initial 8 to 10 days of infection, cellular and humoral immunity is believed to be responsible for infection control.^{4,334}

Sheep infected with *E. phagocytophila* strains are predisposed to opportunistic and secondary infections that can be fatal.⁴⁹⁴ No canine deaths have been associated with *A. phagocytophilum* infection.^{158,196,197} Human deaths have occurred but were attributed to opportunistic infections or concurrent immunocompromising diseases.²⁶

28.3.3 Clinical Findings

28.3.3.1 Natural Infection

All reported natural cases of canine *A. phagocytophilum* infection were identified by finding morulae in circulating neutrophils.^{158,196,197} In each published study of natural cases, *A. phagocytophilum* infection was confirmed by the sequencing of the microbial 16S rRNA gene from only a proportion of the dogs. The other genetically unconfirmed canine cases came from *A. phagocytophilum*-endemic regions that were outside the range of *E. ewingii* or its vector tick, *A. americanum*, and infection with *A. phagocytophilum* had been presumed.^{158,196,197} Reported clinical findings are almost exclusively from acute disease, during the bacteremic phase. Chronic *A. phagocytophilum* natural disease has not been documented, although at least one Swedish dog was ill for 30 days before the diagnosis was made.¹⁵⁸ Given that the dog is an unnatural host for this infection, self-limiting infection would be expected.

No sex predisposition for canine *A. phagocytophilum* infections has been found.^{158,196,197} Although breed predilection may be established in the future, documented cases are currently too few to draw any conclusions. Of 178 Minnesota and Wisconsin dogs with *A. phagocytophilum* infection, 28% have been Labrador retrievers, 18% golden retrievers, 14% mixed breed, 9% cocker spaniel, 6% Samoyed, 4% shih tzu, 3% Brittany spaniel, 3% chow-chow, and 3% springer spaniel. Of these 178 dogs, there were two Doberman

Infectious Diseases of the Dog and Cat, 3rd Edition

pinschers, two Vizslas, two Pomeranians, two pugs, and one each of 11 other breeds.^{196,197} Of the 14 Swedish dogs reported to have *A. phagocytophilum* infections, six were golden retrievers, two Samoyeds, and one each of six other breeds.¹⁵⁸ Golden and Labrador retrievers are very popular dogs, and the high number of infections in these two breeds may represent only their popularity.

Age may be a susceptibility factor for *A. phagocytophilum* infection. Thirty-seven percent of Minnesota and Wisconsin dogs diagnosed with *A. phagocytophilum* infection were age 8 to 10 years; 56% were at least age 8 years.^{196,197} One-third of reported cases of Swedish canine infections were over 9 years of age.¹⁵⁸ Only 3% of Minnesota and Wisconsin dogs were less than 1 year, and no Swedish cases were less than 1 year.^{158,196,197} Of interest, human patients tend to be in their fifth and sixth decades, and infection is rare in children.^{26,28,56} The canine age data need to be compared with canine population demographics before conclusions can be made about age-related susceptibility.

The majority of dogs with *A. phagocytophilum* infections have nonspecific signs of illness (see [Table 28-2](#)). Fever (at or above 39.2° C [102.6° F]), lethargy or depression, and anorexia are the most consistent findings, occurring in over 75% of dogs.* Musculoskeletal pain or discomfort is evident in over one half of dogs, characterized by reluctance to move, stiffness, weakness, soreness, and lameness.^{158,196,197} Fewer than 10% of dogs display overt joint pain.^{158,196,197} Neutrophilic synovitis was documented in one Minnesota dog at the same time the dog had circulating morulae in neutrophils; the dog had positive *E. equi* and *Borrelia burgdorferi* (Lyme) indirect FA results and a negative *E. canis* indirect FA result (no convalescent sample was tested).¹⁹⁶ These results indicate that dogs infected with *A. phagocytophilum* may exhibit inflammatory arthritis. A low number of dogs have vomiting or diarrhea (or both) or respiratory signs of coughing or labored breathing.^{158,196,197,418} Dogs may also exhibit lymphadenomegaly, splenomegaly, hepatomegaly, and CNS signs (seizures, ataxia, and so forth).† Unlike manifestations associated with *E. canis* or *A. platys*, dogs do not show signs of a bleeding disorder. Concurrent diagnoses of malignant lymphoma, phosphofructokinase deficiency, systemic lupus erythematosus, cardiomyopathy, and epilepsy have been documented, but major concurrent systemic diseases are unusual.^{197,418}

Dogs appear to be susceptible to reinfection with *A. phagocytophilum*. Individual dogs have been diagnosed as having *A. phagocytophilum* infections twice, with 5 months or more of disease-free intervals occurring between documented infections.^{158,196} Serum antibody levels in treated dogs revert to low or negative levels by 7 to 8 months posttreatment, which would likely leave them susceptible to reinfection.¹⁵⁸

* References 158, 196, 197, 418, 512.

† References 158, 194, 196, 197, 331.

28.3.3.2

Experimental Infection

Experimental canine *A. phagocytophilum* infections have been carried out in Sweden. All dogs were infected with Swedish isolates of *A. phagocytophilum*. All infected dogs developed fevers, and some became depressed and anorectic for several days; one dog displayed lameness and one displayed staggering.^{155,157,307} In one study, spontaneously recovered dogs were administered glucocorticoids at immunosuppressive dosages at least 1 month after they had recovered from clinical illness and had eliminated bacteria from circulation, as evidenced by lack of circulating morulae and negative *A. phagocytophilum*PCR. Following immunosuppression, the dogs became bacteremic again, although all

221

222

Infectious Diseases of the Dog and Cat, 3rd Edition

remained asymptomatic for disease. This condition was seen even when immunosuppression occurred 6 months after initial infection.¹⁵⁷ This study reveals that dogs have the potential to become chronic asymptomatic carriers, which has significance because of recrudescence of latent infection, as well as the potential for disease transmission. Whether treated dogs also remain subclinical carriers is unknown. Chronic experimental canine *A. phagocytophilum* infections with clinical illness, have not been documented.¹⁵⁷

28.3.4 DIAGNOSIS

A. phagocytophilum causes seasonal and regional disease, depending on the activity of its particular tick vector (*I. scapularis* in upper midwestern and northeastern United States, *I. pacificus* in California and British Columbia, and *I. ricinus* in Europe). In midwestern and northeastern United States, *I. scapularis* ticks actively feed in early spring into early summer and again in the fall. This seasonal tick activity corresponds with the incidence of human and canine *A. phagocytophilum* infections diagnosed in Minnesota and Wisconsin.^{26,28,197} Eighty percent of canine infections in Minnesota and Wisconsin are diagnosed in May, June, October, and November.^{196,197} In contrast, Swedish canine *A. phagocytophilum* infections have been diagnosed continuously midsummer through autumn.¹⁵⁸ Infections are rare to none in midwinter, midsummer, and early autumn in Minnesota and Wisconsin.¹⁹⁶ Weather does influence tick activity (i.e., early spring or warm falls and winters can result in cases occurring at unexpected times). Season, history, clinical signs, hematologic (particularly seeing morulae in neutrophils) and clinical chemistry data, and serology can all assist in making a strong presumptive diagnosis of *A. phagocytophilum* infection, but definitive diagnosis relies on microbial DNA analysis via PCR.

28.3.5 Clinical Laboratory Findings

28.3.5.1 Natural Infection

All reported natural cases of canine *A. phagocytophilum* infection were identified by finding morulae in circulating neutrophils using light microscopy with routine hematologic stains. The morulae of *A. phagocytophilum* cannot be differentiated from the morulae of *E. ewingii* using light microscopy. At the time of diagnosis, 7% to 37% of neutrophils contained *A. phagocytophilum* morulae.^{158,197,418} Almost all reported clinical laboratory findings are from samples collected during the bacteremic phase, which can be short lived, lasting for 1 to 9 days in experimental infections.^{155,157,307}

Excluding the presence of morulae, the most diagnostically helpful laboratory finding is mild to severe thrombocytopenia, present in more than 80% of cases.^{158,196,197,418} Additionally, over 90% of infected dogs from Minnesota and Wisconsin are lymphopenic, many severely so.^{196,197} Dogs from Sweden and Switzerland have also been lymphopenic.^{158,418} Most dogs are eosinopenic.¹⁹⁶ Neutrophil counts are almost always within reference range, with no significant increase in the number of band neutrophils.^{158,196,197,418} Less than 50% of dogs have a mild to moderate nonregenerative normochromic normocytic anemia.^{158,196,197} One half of dogs from Minnesota and Wisconsin have mild to moderate hypoalbuminemia.^{196,197} Serum ALP activity is mildly to moderately increased in 65% or more of dogs from Minnesota and Wisconsin, but this abnormality is rarely reported in Swedish dogs.^{158,196,197} Proteinuria has been documented, but only a small number of dogs were sampled, and significant proteinuria was confirmed

Infectious Diseases of the Dog and Cat, 3rd Edition

in only one Swedish dog.^{158,197} Serum amylase activity was examined in a small number of dogs and was increased in 50% of them.¹⁹⁷

28.3.5.2 Experimental Infection

Dogs experimentally infected with the Swedish strain of *A. phagocytophila* developed thrombocytopenia with increased mean platelet volume, a lymphopenia of 1 to 3 days' duration followed by a lymphocytosis with the presence of blast-stimulated erythrocytes, a mild nonregenerative normochromic normocytic anemia, and morulae in 3% to 34% of circulating neutrophils.^{155,157} Morulae were seen in neutrophils for 4 to 9 days.^{155,157,307} Eosinopenia occurred while the dogs were bacteremic.³⁰⁷ Decreased serum iron and decreased total iron-binding capacity developed during bacteremia, but levels returned to normal 1 week after the disappearance of morulae.³⁰⁷ Hypoalbuminemia and hyperfibrinogenemia occurred when dogs were febrile, and values returned to reference range levels 1 week after fevers abated.¹⁵⁵

28.3.5.3 Nucleic Acid Detection

PCR is a more sensitive diagnostic tool than finding circulating morulae and provides a reliable species-specific diagnosis. A genogroup-specific PCR has been developed for *A. phagocytophilum*.⁴¹⁴ PCR allows for a specific diagnosis whereas serologic testing can be hampered by cross-reactivity to closely related rickettsial bacteria. Experimentally infected dogs are *A. phagocytophilum*-PCR-positive 6 to 8 days earlier than the first appearance of morulae in peripheral blood.¹⁵⁵ PCR testing for the 16S rRNA gene of *A. phagocytophilum* is available from a small number of state diagnostic or private diagnostic veterinary laboratories (see [Appendix 5](#)). Submitting EDTA-anticoagulated peripheral blood for PCR testing is optimal. Samples need to be taken before antibiotic administration.

28.3.5.4 Serologic Testing

Experimental studies in horses and dogs have documented that seroconversion to *A. phagocytophilum* occurs 2 to 5 days after the first appearance of morulae in peripheral blood.^{155,421} Antibody titers to *A. phagocytophilum* can revert to nondetectable (negative) levels by 7 to 8 months postacute experimental canine infection or can remain detectable at low levels for at least 7 to 8 months.¹⁵⁸ Diagnosis of *A. phagocytophilum* infection may require serologic testing if no morulae are found in peripheral blood neutrophils and if a PCR assay is not available. Both polyclonal indirect FA and Western immunoblot serologic assays have been developed, but most veterinary laboratories only offer indirect FA testing. Using indirect FA, acute to convalescent fourfold seroconversion to *A. phagocytophilum* is necessary to diagnose active infection confidently because up to 40% of acutely ill, morulae-positive dogs can be seronegative at the time of presentation and because dogs may have detectable levels of antibody from previous exposure.^{158,196,197} This latter point is important to consider when interpreting a single titer in a sick or healthy dog that is negative for circulating morulae. Strain differences are enough among isolates of *A. phagocytophilum* that titers may vary on the same sera sent to different laboratories.³²⁶ Therefore using the same laboratory is especially important when serial assays are being used to determine a changing titer for diagnosis or a reduction in titer in response to treatment.

For antibody determination, the immunoblot assays are more species-specific, but cross-reactivities to other related species can occur with immunoblotting as with indirect FA testing. Serologic cross-reactivity is

Infectious Diseases of the Dog and Cat, 3rd Edition

caused by immunodominant surface proteins that are of similar molecular size, particularly those of the family of immunodominant outer membrane proteins present on both *Ehrlichia* spp. and *A.*

phagocytophilum.¹⁴⁶ Serologic cross-reactivity between *A. phagocytophilum* and other microbes, particularly 222

other tick-transmitted agents, has been evaluated. Serologic cross-reactivity is strong between the strains of 223

A. phagocytophilum, is uncommon between *A. phagocytophilum* and ehrlichial agents (*E. canis*, *E. ewingii*, or *E. chaffeensis*) (see Table 28-3), and is nonexistent between *A. phagocytophilum* and *B. burgdorferi*,

Bartonella sp., or *R. rickettsii*.^{*} The immunodominant outer surface membrane 44-kDa protein (p44) on *A. phagocytophilum* used in Western immunoblotting has been identified as a consistent marker for *A.*

phagocytophilum seroconversion, with minimal cross-reactivity with *Ehrlichia* and other *Anaplasma*

species.^{237,238,327} Acute and convalescent antisera, from dogs naturally infected with *A. phagocytophilum* in

Minnesota and Wisconsin, did not cross-react to *E. canis* antigens.^{196,197} No cross-reactivity occurred

between *E. canis*-positive antisera and *A. phagocytophilum*-positive antisera from dogs from New York and

Connecticut using both indirect FA and Western immunoblotting.³²⁵ In contrast, in a report of natural canine

A. phagocytophilum infections in Sweden, all acute phase sera were indirect FA seronegative to *E. canis*, but

one half of convalescent phase sera were seropositive to *E. canis*.¹⁵⁸ Additionally, two dogs from North

Carolina and Virginia with PCR-confirmed *E. ewingii* infections seroconverted to *A. phagocytophilum*

antigen using indirect FA.¹⁸⁵

In spite of cross-reactivity, serologic testing still remains the most common method of diagnosing *A.*

phagocytophilum infection if morulae are not present or if it is desirable to differentiate between *E. ewingii*

and *A. phagocytophilum* infections. In the upper midwestern United States, canine *E. ewingii* and *E. canis*

infections are rare to nonexistent, and a positive seroconversion to *A. phagocytophilum* predictably confers a

diagnosis of *A. phagocytophilum* infection. Because all *Ehrlichia* spp. and *Anaplasma* spp. infections are

tetracycline-responsive, differentiating between infections with these different organisms is usually of more

zoonotic or academic importance than it is of clinical relevance to the ill dog. Ruling out *E. canis* infection is

the exception because *E. canis* does have the potential to cause life-threatening chronic disease.

* References 144, 146, 158, 325, 328, 495, 529.

28.3.5.5 Organism Cultivation

All strains of *A. phagocytophilum* can be cultivated in vitro in a human leukemic cell line, HL-60 cells.¹⁸⁶

This method has been used extensively in the laboratory for the study of this disease; however, it is not available commercially.

28.3.6 Pathologic Findings

Pathologic lesions of *A. phagocytophilum* infections from human patients and experimental infections of dogs,

monkeys, mice, horses, and sheep are mild.[†] Splenic lymphoid depletion or hyperplasia occurs with

histiocytosis and erythrophagocytosis. Lymph nodes exhibit benign histiocytosis with either lymphopenia or

benign mild paracortical hyperplasia. The liver displays scattered hepatocellular apoptosis, mild periportal or

peribiliary lymphohistiocytic infiltrates, mild lobular hepatitis, and mild benign sinusoidal histiocytosis.

Throughout many tissues, mild lymphohistiocytic perivascular infiltrates can be found. The bone marrow is of

normal cellularity or is hypercellular and may exhibit mild plasmacytosis and mild benign histiocytosis.[‡] A

human patient in the recovery phase of disease developed bone marrow plasmacytosis with intramedullary

lymphoid follicles. Pulmonary interstitial infiltration is also observed in some human patients.⁴³³ In one equine

Infectious Diseases of the Dog and Cat, 3rd Edition

study, vasculitis and marked perivascular mixed inflammatory cell populations within skeletal muscle and tendons were reported.³⁰⁰

† References 64, 155, 174, 230, 231, 300, 334.

‡ References 64, 174, 230, 231, 300, 307, 334.

28.3.7 Therapy

Susceptibility testing of *A. phagocytophilum* shows doxycycline, rifampin, and levofloxacin to be most effective.³⁴⁷ Tetracyclines are almost exclusively recommended for treating *A. phagocytophilum* infections. For puppies under 1 year of age, chloramphenicol can be used to avoid yellowing of teeth. (see Table 28-5) Doxycycline (5 to 10 mg/kg, PO, every 12 to 24 hours for 10 days) or tetracycline (22 mg/kg, PO, every 8 hours for 14 to 21 days) is the recommended treatment protocol. No proof has been produced that long-term treatment beyond the previously recommended interval is beneficial because no evidence exists of chronic disease. Although evidence does exist of chronic subclinical infections from Swedish studies, no clinical signs were seen, and whether antibiotics will eliminate this carrier state are unknown. Most dogs respond rapidly to treatment and are frequently clinically normal 24 to 48 hours after initiation of therapy, but owners occasionally report that weeks or years are needed for their dogs to completely recover.^{158,196} Concurrent illnesses should be treated appropriately. If response to tetracycline antibiotics is poor, the probability that the dog has a concurrent disease is high.

28.3.8 Prevention

No vaccine is available to prevent *A. phagocytophilum* infection. Prevention relies on (1) avoiding exposure to the tick vectors (*I. scapularis*, *I. pacificus*, *I. ricinus*) from spring through fall, (2) prophylactic use of antiparasitics, and (3) prophylactic use of doxycycline or tetracycline when visiting *I. scapularis*, *I. pacificus*, or *I. ricinus* tick-endemic regions.

28.3.9 Public Health Considerations

Human *A. phagocytophilum* infection was first reported in 1994 in residents of Minnesota and Wisconsin.²⁶ Since then, human infections have been diagnosed in Massachusetts, California, Rhode Island, Connecticut, New York, and Slovenia.* Clinical disease is indistinguishable from that seen with *E. chaffeensis* and *E. ewingii* infections and from many other systemic infectious diseases. The most frequent clinical signs are fever, malaise, headache, and myalgia.^{26,28,528} Less frequently exhibited, but still common signs, are arthralgia, vomiting, diarrhea, coughing, a stiff neck, and confusion. Rarely, a rash is present.^{26,28,528} The most consistent laboratory findings are thrombocytopenia, leukopenia, and mild increases in serum ALT and aspartate aminotransferase activities.^{26,28,528} Peripheral blood neutrophils containing morulae are present in only 80% of cases, and even when morulae are present, only a low number of neutrophils may be infected.²⁸ Patients with *A. phagocytophilum* infections have died, but all deaths have been caused by complications resulting from opportunistic infections.⁵²⁸ A small proportion of recovered patients complain of persistent symptoms of illness for 1 to 3 years after treatment.⁴²⁸ The potential for dogs, horses, sheep, and other domestic animals to be zoonotic risks for human *A. phagocytophilum* infection is not known. Wildlife hosts such as rodents are probably the maintenance reservoirs, with immature tick stages as vectors; deer may become infected or involved in vector maintenance. The vectors are *Ixodes* spp. ticks, which also transmit *Borrelia* spp. (see

Infectious Diseases of the Dog and Cat, 3rd Edition

Chapter 45) explaining the superimposed worldwide geographic distribution of these diseases. Co-infections with *Borrelia* and *Ehrlichia* spp. may result in more severe disease in infected hosts. The suspicion holds that people have become infected while handling deer blood or carcasses or engorged infected ticks.^{28,507} The affected individuals had butchered a large number of deer carcasses and sustained numerous cuts during the process. An electric saw, which produces aerosolized blood particles, was also used. Precautions should always be taken when necropsies are performed on animals suspected of harboring this infection.

Fig 28-9 *Ehrlichia* inclusion in the mononuclear cell of a cat. (Courtesy Mike Lappin, Colorado State University, Fort Collins, Colo.)

28.4 FELINE MONONUCLEAR EHRLICHIOSIS

Michael R. Lappin

Edward B. Breitschwerdt

28.4.1 Etiology and Epidemiology

The species of *Ehrlichia* that infect cats after natural exposure have not been fully determined (Table 28-6). To date, only two studies of naturally infected cats have confirmed DNA from a strain of *Ehrlichia* generally found in mononuclear cells.^{47,70} In the North American report,⁷⁰ DNA most consistent with *E. canis* was documented in the blood of three clinically ill cats. In the French report,⁴⁷ the 16S rDNA *Ehrlichia* sequences obtained from two cats were identical to those obtained from North American cats. In other reports, *Ehrlichia*-like bodies or morulae have been detected in peripheral lymphocytes or monocytes of naturally exposed cats in the United States (Fig. 28-9),⁶⁶ Kenya,^{88,90} France,^{46,49-51,107} Brazil,¹⁰ and Thailand.²⁵⁵ Electron microscopic (EM)

Infectious Diseases of the Dog and Cat, 3rd Edition

assessment of an isolate from feline mononuclear cells revealed organisms from 0.54 to 1.3 μm , intermediate in size between *E. canis* and *N. sennetsu*.⁸⁸

To the authors' (MRL and EB) knowledge, only two experimental inoculation studies of cats with *Ehrlichia* spp. have been conducted.^{126,291} Morulae of *N. risticii*¹⁴⁶ were detected in mononuclear cells from two of six cats inoculated intravenously (IV) (but not subcutaneously [SC]); diarrhea developed in one cat, and depression, anorexia, and lymphadenomegaly developed in the other.¹²⁶ When cats were inoculated SC with an *E. canis* strain (North Carolina State University canine isolate) maintained in cell culture, organismal DNA or antibodies that reacted to *E. canis* morulae were not detected in an 8-week follow-up period.²⁹¹ These results can be interpreted in the following manner: the *E. canis*-like DNA amplified from naturally infected cats may be a different *Ehrlichia* sp. more infective to cats (not all *E. canis* strains will infect cats, and not all cats are susceptible to infection by *E. canis*) or SC inoculation is not an effective method for infecting cats with *E. canis*.⁷⁰

Sera from cats have been assessed for *Ehrlichia* spp. antibodies using indirect FA or Western immunoblot. However, standardization of methodologies between laboratories has not been performed, and the most appropriate cutoff values have not been determined. Results of serologic tests performed by different laboratories have not had 100% concordance.⁷⁰ Additionally, variable serologic cross-reactivity occurs among *Ehrlichia* spp., *Neorickettsia* spp., and *Anaplasma* spp.; therefore seroreactivity to a specific test antigen does not definitely document exposure to the *Ehrlichia* spp. morulae used for testing.^{80,144,372,490} Thus results of antibody-based surveys should be interpreted with caution until such time as laboratories can correlate serologic results with feline *Ehrlichia* spp. isolates or PCR assay findings.

By the use of indirect FA, serum antibodies that react with *E. canis* morulae have been detected in cats from multiple states of the United States,^{66,490} France,^{50,51} Italy,¹⁵⁴ and Kenya.³⁴⁵ By use of immunofluorescence, antibodies to *N. risticii* were detected in serum of 26.4% and 16.6% of the cats tested in Maryland¹²⁶ and Virginia,³⁹⁸ respectively. Antibodies to *N. risticii* were detected by indirect FA and Western immunoblot in five cats in a household in California.³⁹⁴ In a neighborhood in Colorado from which a cat with a mononuclear form of *Ehrlichia* was identified, 14 of 17 cats (82.4%) and 9 of 17 cats (52.9%) had serum antibodies against *E. canis* and *N. risticii*, respectively, detected by indirect FA.⁶⁶ Cats with antibodies against both species generally had higher titers to *E. canis* antigens.

The way in which the clinically ill, naturally exposed cats with ehrlichiosis described in the literature were infected is unknown. Documentation of arthropod exposure in proven cases has been variable. However, *Haemaphysalis leachi* was found on each of four cats with clinical ehrlichiosis in Kenya.^{88,90}

28.4.2 Pathogenesis

Pathogenesis of disease associated with ehrlichiosis in cats is unknown. Based on clinical, laboratory, and radiographic findings, pathogenesis of disease is likely similar to that for *E. canis* infection of dogs. In the three cats with *E. canis*-like DNA in blood, antinuclear antibodies were detected, similar to results reported for infected dogs.⁷⁰

Infectious Diseases of the Dog and Cat, 3rd Edition

28.4.3 Clinical Findings

Clinical manifestations of ehrlichiosis have been described in 22 cats with suspected morulae in mononuclear cells^{*} and in three cats with *E. canis*-like DNA in blood⁷⁰ (see Table 28-6). Ehrlichiosis has also been suspected in 33 reported feline cases in which the diagnosis was presumptively based on the combination of positive *E. canis* or *N. risticii* serology, clinical or laboratory findings consistent with ehrlichial infection, and response to known antiehrlichial drugs.[†] Thus at least 55 cases have been reported in which feline ehrlichiosis was implicated.

Most cats for which age was reported were older than 1 year and were domestic shorthaired. Both male and female cats have been affected. Fever and the nonspecific signs of lethargy, inappetence, and weight loss are common clinical manifestations and have been exhibited by most cats. Hyperesthesia, joint pain, and irritable disposition were also common. Dyspnea, vomiting, diarrhea, and weight loss also occurred in some cats. Splenomegaly, lymphadenomegaly, dyspnea, petechiae, retinal detachments, vitreous hemorrhages, and pale mucous membranes were reported physical examination abnormalities. Concurrent diseases detected in some cats included *Haemobartonella felis* (now *Mycoplasma haemofelis* and *Candidatus Mycoplasma haemominutum*), *Cryptococcus neoformans*, feline leukemia virus and feline immunodeficiency virus infections, and lymphosarcoma.

226

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 28-6 Summary of Clinical Mononuclear Ehrlichiosis in Cats

SIGNALMENT (COUNTRY)	CLINICAL FINDINGS	LABORATORY FINDINGS	DIAGNOSIS	TREATMENT/RESPONSE	REFERENCE
10 yr, FS, DSH (United States)	Fever, anorexia, hyperesthesia	Nonregenerative anemia, hyperglobulinemia	Morulae in mononuclear cells; <i>E. canis</i> and <i>N. risticii</i> seropositive	Doxycycline/excellent	66
10 yr, M, DSH (Kenya)	Fever, anorexia, dyspnea, splenomegaly, pale mucous membranes	Nonregenerative anemia, hyperglobulinemia, interstitial lung disease	Morulae in mononuclear cells, rarely in neutrophils	Tetracycline/excellent	88
4 yr, M, DSH (Kenya)	Fever, anorexia, splenomegaly, pale mucous membranes	Nonregenerative anemia	Morulae in mononuclear cells, rarely in neutrophils	Imidocarb/excellent	88
2 yr, F, DSH (Kenya)	Fever, anorexia, dyspnea, splenomegaly, pale mucous membranes, lymphadenomegaly	Nonregenerative anemia, neutropenia, interstitial lung disease	Morulae in mononuclear cells, rarely in neutrophils	Imidocarb/excellent	88
Adult lioness (Kenya)	Lethargy, emaciation, lymphadenomegaly	Neutrophilic leukocytosis	Morulae in mononuclear cells	Not treated	91
6 yr, MC, DSH (France)	Fever, anorexia, pale mucous membranes, depression	Regenerative anemia, <i>Mycoplasma</i> <i>haemofelis</i> leukocytosis, lymphocytosis, monocytosis, hyperbilirubinemia	Morulae in mononuclear cells	Tetracycline/Groulade,	107
11 yr, FS, DSH (France)	Fever, weight loss, anorexia, depression, joint pain	Nonregenerative anemia, leukopenia, hypoalbuminemia, hyperglobulinemia	Morulae in lymphocytes, <i>E. canis</i> seropositive	Doxycycline/glucocorticoids/euthanasia	49
9 yr, MC, DSH (France)	Anorexia, gingivitis, pale mucous membranes, polyuria, polydipsia, weight loss	Anemia, FeLV positive, FIV positive, hyperglobulinemia	Morulae in lymphocytes, <i>E. canis</i> seropositive	Euthanasia	49
14 yr, MC, DSH (France)	Dyspnea, pale mucous membranes, weight loss, lethargy	Pleural effusion, hyperglobulinemia	Morulae in lymphocytes, <i>E. canis</i> seropositive	Euthanasia/lymphosarcoma	49
M, Male; DSH, domestic shorthair; F, female; MC, male, castrated; FS, female, spayed; FeLV, feline leukemia virus; FIV, feline immunodeficiency virus.

Infectious Diseases of the Dog and Cat, 3rd Edition

† References 46, 50, 51, 66, 394.

28.4.4 Diagnosis

28.4.4.1 Hematology

Complete or partial blood cell evaluations were available for many of the cats. Anemia was most commonly nonregenerative and occurred in cats with chronic disease histories. One cat with regenerative anemia was co-infected with a hemotropic *Mycoplasma* species (previously *H. felis*).¹⁰⁷ Leukopenia, leukocytosis, neutrophilia, neutropenia, lymphocytosis, monocytosis, and thrombocytopenia occur in some cats; alone or in combinations. Bone marrow evaluation of cats with cytopenias revealed primarily hypoplasia of the effected cell line. However, one cat had bone marrow cytologic characteristics consistent with myeloid leukemia.⁷⁰ Based on the cases reported to date, ehrlichiosis should be considered on the differential list for cats with unexplained leukocytosis or cytopenias.

28.4.4.2 Biochemistry

Biochemical abnormalities were infrequently reported in cats with suspected clinical ehrlichiosis and were apparently nonspecific. Hyperproteinemia is the most consistent abnormality; polyclonal gammopathy was detected in four of the cats assayed by protein electrophoresis.^{46,49} In a separate study, an epidemiologic association was made between monoclonal gammopathy and cats seropositive for *E. canis* antibodies.⁴⁹⁰ Based on these results, ehrlichiosis should be on the differential list for cats with hyperglobulinemia.

28.4.4.3 Radiographic Findings

Of the cats with historical or physical examination findings consistent with respiratory disease, interstitial lung patterns were the only abnormalities that were reported in association with feline ehrlichiosis. Thoracic and abdominal radiographs were commonly considered within normal limits.

28.4.4.4 Serologic Testing

Not all cats with ehrlichiosis reported to date were tested with the same antibody methodology, and comparison studies of indirect FA tests between laboratories do not show 100% concordance.⁷⁰ Standardized serologic tests for detection of antibodies against ehrlichial species in cats are needed.

Most of the cats with morulae documented in mononuclear cells have had antibodies in serum that react with *E. canis* morulae. However, some cats with clinical ehrlichiosis are seronegative on initial evaluation, and thus clinicians may have to perform more than one serologic assessment to document seroconversion. Of the three cats with *E. canis*-like DNA in blood, none had antibodies that reacted with *E. canis* morulae in two different laboratories.⁷⁰ Five cats with presumed ehrlichiosis had serum antibodies that reacted with *N. risticii* morulae but not to *E. canis* morulae.³⁹⁴ In addition, *A. phagocytophilum* causes similar clinical signs in cats and usually does not induce antibodies that cross-react with *E. canis* antigens.^{62,292} Thus ehrlichiosis cannot be excluded in cats based on failure to detect seroreactivity to *E. canis* morulae by indirect FA testing.

Infectious Diseases of the Dog and Cat, 3rd Edition

Many healthy cats have serum antibodies that react with *E. canis* or *N. risticii* antigens; however, similar serologic cross-reactivity may occur among ehrlichial species as observed for dogs (see Table 28-3).⁴⁹⁰ A diagnosis of clinical ehrlichiosis therefore should never be based on positive serologic test results alone. Clinicians should always exclude other potential causes of the clinical syndrome.

28.4.4.5 Other Testing

Antinuclear antibody tests results were positive in some cats.⁷⁰ Coombs' test results were usually negative. Neutrophilic polyarthritis and increased CSF protein concentrations were confirmed in one cat.⁷⁰ Lymph node aspirates, when performed, showed lymphoid or plasma cell hyperplasia.

28.4.4.6 Organism Detection

The presence of morulae can be used to strengthen the diagnosis of ehrlichiosis in cats. Infected cells were reported to be more common in blood collected from an ear vein than a large vein.⁴⁹ However, false-positive and false-negative results can occur. In addition, documentation of morulae cannot be used to determine the *Ehrlichia* spp. involved. For example in four cats with presumed *E. canis* infection, neutrophils and mononuclear cells were infected.^{11,88}

28.4.4.7 Organism Cultivation and Nucleic Acid Detection

Infection by *Ehrlichia* spp. can be confirmed by cell culture or PCR. The organism was isolated from whole blood on monocyte cultures in the domestic cat cases⁸⁸ but not from a lioness from Kenya.⁹⁰ Monocyte cultures failed to document *N. risticii* infection in the seropositive cats from California, but morulae were not seen in circulating blood of these cats.³⁹⁴ Although results of PCR assays will likely be used to help further define feline ehrlichiosis, clinicians should assist research laboratories in efforts to obtain feline *Ehrlichia* spp. isolates for comparative microbiologic studies. PCR assays should be used that amplify *Ehrlichia*, *Anaplasma*, and *Neorickettsia* genus DNA, (i.e., these PCR primers should amplify all members of the genus), subsequently, a species-specific PCR assay, DNA sequencing, or both, can be used to determine which organism is involved. However, further information concerning the diagnostic sensitivity of species-specific PCR testing is needed. Although PCR testing has been used successfully in some feline cases,^{70,292} PCR of blood using *N. risticii*-specific primers proved negative in the seropositive cats tested in California.^{21,394}

In summary, until diagnostic testing of cats for ehrlichiosis is better defined, clinicians will need to combine PCR assay results with those of serum antibody testing against multiple *Ehrlichia* spp. so as to confirm or exclude these organisms from the differential list for clinically ill cats.³⁷²

28.4.5 Pathologic Findings

Before treatment, pyogranulomatous lymphadenitis was detected in a mesenteric lymph node from a cat from Colorado with antibodies against *E. canis* and *N. risticii*.⁶⁶ Perivascular plasma cell and lymphocyte infiltrates were detected in the lungs, kidneys, and liver of the untreated lioness in Kenya.⁹⁰ After doxycycline treatment

Infectious Diseases of the Dog and Cat, 3rd Edition

in one cat, an acute respiratory distress syndrome developed that resulted in death.⁷⁰ Neutrophilic and histiocytic myocarditis and pneumonia, multifocal lymphoplasmacytic nephritis, and multifocal lymphoplasmacytic pancreatitis were the predominant findings. However, *Ehrlichia* spp. or other infectious causes were not identified after death.

28.4.6 Therapy

Therapy with tetracycline, doxycycline, or imidocarb dipropionate was attempted in most of the cases with suspected clinical feline mononuclear ehrlichiosis (Table 28-7). Administration of doxycycline at 5 mg/kg, twice daily, PO, for 21 days resulted in resolution of clinical signs of disease in three cats.⁶⁶ One cat was seropositive 180 days after discharge but seronegative 1365 days after discharge. Serologic follow-up was available for multiple presumptive cases in France^{50,51}; the majority became seronegative with time. However, increasing or persistent titers can occur as reported for the dog.⁴¹ Recurrence of disease and serum antibodies were reported in the five *N. risticii*-seropositive cats in California treated with a lower dose of doxycycline, but these cats appeared to respond when administered doxycycline at 10 mg/kg, PO, twice daily for 21 days.³⁹⁴ Imidocarb dipropionate administered at 5 mg/kg, IM, and repeated in 14 days resulted in clinical resolution of disease of two cats in Kenya.⁸⁸ This drug has been used for the treatment of infected dogs³⁴² and has been shown to be safe when administered to cats with chronic haemoplasmosis.²⁹⁴ Enrofloxacin was used to treat two cats with presumed mononuclear ehrlichiosis.⁵¹ However, this drug is considered to be inferior to tetracyclines for the treatment of ehrlichiosis in dogs.^{372,373} The Infectious Disease Study Group of the American College of Veterinary Internal Medicine currently recommends treating cats with suspected clinical ehrlichiosis with doxycycline at 10 mg/kg, PO, every 24 hours for a minimum of 28 days.³⁷² Whether the treatment protocols used to date eliminate the organism is currently unknown.^{249,548}

Table 28-7 Antimicrobial Therapy for Feline Monocytotropic Ehrlichiosis and Granulocytotropic Anaplasmosis

DRUG ^a	DOSE ^b (mg/kg)	ROUTE PREFERRED (ALTERNATIVE)	INTERVAL ^c (HOURS)	DURATION (DAYS)
Tetracycline	22	PO	8	21
Doxycycline	10	PO ^d	24	28
Doxycycline	5–10	PO ^d	12–24	10–28
Chloramphenicol	25	PO (IV, SC)	12	≤ 14 ^e
Imidocarb dipropionate ^f	5	IM	once	Repeat day 14

PO, By mouth; IV, intravenously; SC, subcutaneously; IM, intramuscularly.

- a See Drug Formulary, [Appendix 8](#), for additional information.
- b Dose per administration at specified interval.
- c Expressed in hours unless otherwise stated.
- d Doxycycline tablets or powder can cause esophagitis so they should be dosed to the nearest whole size of tablet or capsule and water should be given after each dose.
- e Myelosuppression is a concern and repeat blood counts should be done at the conclusion of therapy.
- f The effectiveness of imidocarb is uncertain in infected cats.

Infectious Diseases of the Dog and Cat, 3rd Edition

Euthanasia was chosen for two cats with documented morulae in mononuclear cells because of treatment failures with tetracycline¹⁰⁷ or doxycycline⁴⁹ and because one cat died.⁷⁰ Some cats with suspected ehrlichiosis based on clinical signs and positive serologic test results failed to respond to doxycycline administration.⁴⁶ However, because ehrlichiosis was not definitively diagnosed by culture or PCR, whether these cases represent treatment failures is also unknown. For a summary of the drugs and dosages recommended for treatment of feline ehrlichiosis, see [Table 28-7](#).

28.4.7 Prevention

Because routes of transmission for naturally infected cats are unknown, definitive statements concerning prevention cannot be made. In addition, further studies are needed to determine whether *E. muris* infection of rodents can be transmitted to cats.^{264,546} Exposure of cats to potential arthropod vectors and ingestion of rodents should be avoided. Apparently, *Ehrlichia* spp. can be transmitted by blood; therefore cats used as blood donors should be screened for infection, ideally using both serologic and PCR testing. Cats with positive results should be excluded as donors.

28.4.8 Public Health Consideration

Although *Ehrlichia* spp. might infect both people and cats, human infection has never been associated with cat contact. If cats are housed indoors and arthropod control is maintained, the risk to people should be minimal.

28.5 FELINE GRANULOCYTOTROPIC ANAPLASMOSIS

Michael R. Lappin

Anneli Bjöersdorff

Edward B. Breitschwerdt

28.5.1 Etiology and Epidemiology

A. phagocytophilum (previously *E. equi*, *E. phagocytophila*, canine granulocytotropic *Ehrlichia*, and HGE agent)¹⁴⁶ is known to infect a variety of animals, including small mammals,^{67,531} mountain lions,¹⁷² coyotes,⁴¹⁶ sheep,³⁷⁸ cattle,⁴²⁵ deer,⁵⁷ dogs,^{157,286} horses,^{21,415,425} and people ([Table 28-8](#)).

Susceptibility of cats to *A. phagocytophilum* infection was first documented in an experimental inoculation study.³⁰² Although clinical abnormalities were not reported, two of five cats inoculated with *E. equi* developed morulae in eosinophils and eosinophilia. More recently, cats with and without FIV were inoculated with *A. phagocytophilum* and developed clinical signs of disease.¹⁷⁵

DNA consistent with *A. phagocytophilum* has been detected in blood from naturally infected cats in Sweden,^{62,502} Denmark,⁴⁷⁰ Ireland,⁴⁶⁹ and the United States.²⁹² Morulae consistent with *A. phagocytophilum* have been detected cytologically in neutrophils of naturally infected cats in Sweden,^{62,502} Brazil,^{10,11} Kenya,⁸⁸ and Italy.⁵⁰⁵ With the exception of the cases in Sweden, whether the morulae-like structures were *A. phagocytophilum* or another organism is unknown.

Infectious Diseases of the Dog and Cat, 3rd Edition

A. phagocytophilum is transmitted by *Ixodes* ticks.^{*} Of the six naturally infected, clinically ill cats with *A. phagocytophilum* DNA in blood, all lived in an *I. scapularis*, *I. pacificus*, or *I. ricinus*—endemic region, all were allowed to roam outdoors, and four were known to be infested by *Ixodes* spp. at the time of initial examination.^{62,292} Therefore this genus of ticks can also likely serve as the vector for transmission of *A. phagocytophilum* to cats. Although rodents are commonly infected with *A. phagocytophilum*, whether ingestion or direct contact with rodents plays a role in *A. phagocytophilum* infection of cats is currently unknown.^{67,531}

* References 36, 67, 162, 378, 415, 386.

28.5.2 Pathogenesis

Pathogenesis of disease associated with *A. phagocytophilum* in cats is unknown. Based on clinical, laboratory, and radiographic findings, pathogenesis of disease is likely similar to that for infection of other species. Some cats experimentally inoculated with *A. phagocytophilum* developed antinuclear antibodies and increased IFN- γ mRNA suggested that an immune pathogenesis of disease may contribute to the clinical findings.¹⁷⁵

Table 28-8 Clinical and Laboratory Findings from Six Cats with Molecular and Serologic Evidence of Anaplasma phagocytophilum Infection in North America and Sweden

CAT ^a	SIGNALMENT	UNITED STATES OR OTHER COUNTRY	PRIMARY ABNORMALITIES	DAY	MORULAE	PCR ^b	RECIPROCAL INDIRECT FA TITERS ^c

a Cats 1–5, see reference 291; cat 6, see reference 62 on the CD.

b The PCR assays and sequencing used for Cats 1–5 are discussed in reference 291, and for cat 6 in reference 62.

Infectious Diseases of the Dog and Cat, 3rd Edition

c Cats 1–5 were tested for antibodies using indirect FA slides coated with *A. phagocytophilum* (*E. equi*) infected cells; cat 6 had equivalent results with indirect FA with *E. equi*, *E. phagocytophilum* and a Swedish isolate of granulocytotropic *Ehrlichia*-infected cells.

28.5.3 Clinical Findings

The cats with morulae in neutrophils that came from Brazil¹⁰ and Kenya⁸⁸ had larger numbers of morulae in mononuclear cells. Thus the following information, which is summarized in [Table 28-8](#), comes from the six animals with documented *A. phagocytophilum* infections based on positive PCR testing and gene sequencing.^{62,292} Fever, anorexia, and lethargy were the most common clinical abnormalities. The cat from Sweden was also tachypneic. *Ixodes* ticks were detected on 4 to 6 cats. Overall, clinical signs associated with *A. phagocytophilum* infection in these cats were mild and resolved quickly after initiating tetracycline therapy.

28.5.4 Diagnosis

28.5.4.1 Clinical Laboratory Findings

Each of the cats listed in [Table 28-8](#) had erythrocyte counts within reference limits. Thrombocytopenia (reference range of 175,000 to 500,000/ μ l) was detected in cat 3 (118,000/ μ l), cat 4 (84,000 μ l), and cat 5 (66,000/ μ l), but platelet clumps were reported for cat 5. Neutrophilia with a left shift and lymphopenia were detected in cat 6. Morulae were detected in 24% of the neutrophils in cat 6.⁶² The abnormalities resolved quickly after doxycycline treatment was initiated.

Mild hyperglycemia detected in cats 2 and 6 was attributed to stress. No other serum biochemical abnormalities were detected in the cats.

In cat 5, urinalysis was normal and aerobic urine culture failed to grow bacteria. Each cat was negative for FeLV p27 antigen and antibodies against FIV in serum (Snap Combo, IDEXX Laboratories, Portland, Md.; see [Appendix 6](#)).

28.5.4.2 Serologic Findings

On day 0, two of three cats tested for antibodies against *A. phagocytophilum* were seronegative, but all six cats ultimately seroconverted (see [Table 28-8](#)). None of the six cats developed antibodies that reacted with *E. canis* morulae. Thus diagnostic laboratories providing serologic test results to veterinarians that practice in *Ixodes* spp.–endemic areas must offer assays that detect antibodies against *A. phagocytophilum*, not just *N. risticii* and *E. canis*. In three cats with molecular evidence of infection by an *E. canis*–like organism, antibodies that reacted with *E. canis* morulae were not detected by two research laboratories, even though chronic disease existed.⁷⁰ These results suggest that not all cats seroconvert when infected with *Ehrlichia* spp. or that another organism molecularly similar to *E. canis* that does not induce cross-reacting antibodies is present. Thus, in addition to serologic testing, also recommended is that blood of cats with suspected clinical ehrlichiosis or anaplasmosis also be evaluated with a PCR assay that amplifies all sequenced *Ehrlichia* spp. 228
and *Anaplasma* spp. Because animals can be infected with more than one organism concurrently, sequencing 229
of the PCR products or additional PCR testing with species-specific primers can be used to define the *Ehrlichia* spp. or *Anaplasma* spp.–causing infection.^{62,70,292,500}

Infectious Diseases of the Dog and Cat, 3rd Edition

As with canine ehrlichiosis, clinical illness apparently can develop before seroconversion in cats (see [Table 28-8](#), cats 5 and 6), and thus a single negative antibody result in an acutely infected cat does not exclude infection. *A. phagocytophilum* DNA was amplified from the blood of eight mountain lions that did not have serum antibodies that reacted with the organism in indirect FA tests.¹⁷² Therefore, when confronted with an acute illness consistent with feline anaplasmosis, both acute and convalescent serum samples should be examined or PCR testing should be used to document infection. Reevaluation of antibody titer results from cats 5 and 6 also suggested that administration of antibiotics during the acute phase of infection did not completely attenuate seroconversion (see [Table 28-8](#)).

28.5.4.3 Organism and Nucleic Acid Detection

In the six cats with *A. phagocytophilum* DNA in blood, only one had detectable morulae (see [Table 28-8](#)). This cat (cat 6) was cytologically negative on all subsequent test dates. DNA of *A. phagocytophilum* was detected in all six cats on Day 0, and therefore PCR testing may be more sensitive than antibodies for diagnosing acute anaplasmosis.

28.5.5 Pathologic Findings

None of the cats with naturally occurring *A. phagocytophilum* infections have had tissue biopsies or necropsies performed; thus pathologic findings are unknown. No gross or microscopic lesions attributed to *A. phagocytophilum* infection could be found in experimentally inoculated cats.³⁰²

28.5.6 Therapy

Supportive care consisting of SC or IV administration of balanced electrolyte solutions was provided to all six cats with molecular evidence of *A. phagocytophilum* infection.^{62,292} Antimicrobial therapy was also administered to the cats listed in [Table 28-8](#). Enrofloxacin (cats 1 and 2), penicillin and gentamycin (cat 3), or chloramphenicol (cat 4), was administered parenterally for 1 day before administering doxycycline at approximately 5 mg/kg, PO, for 28 to 30 days. Cat 5 was treated with two doses of doxycycline IV but developed phlebitis at the catheter site. Ampicillin was administered for 1 day, and the cat was discharged with amoxicillin plus clavulanate to be administered at 13.75 mg/kg for 10 days. Lethargy and inappetence recurred after discontinuing the antibiotic.²⁹² Given that the *A. phagocytophilum* results were known to be positive at that time, the referring veterinarian prescribed tetracycline at 22 mg/kg, PO, every 8 hours for 21 days. Cat 6 was initially treated with doxycycline at 10 mg/kg, IV, once and then doxycycline at 10 mg/kg, PO, daily for 20 days. All cats (cat 5 after recurrence of clinical signs) became normal within 24 to 48 hours after initiation of tetracycline administration, and recurrence was not reported. The clinical and hematologic abnormalities in these six cats might have resolved without treatment. Clinically ill cats with serologic or molecular evidence of *E. canis*-like infections have generally had more severe cytopenias and have been more refractory to treatment than the cats described here.⁷⁰ In dogs, infection with *E. canis* also seemingly induces a more severe disease than infection with *A. phagocytophilum* or *E. ewingii*.³⁷²

After 21 to 30 days of tetracycline treatment, serum from all cats in [Table 28-8](#) still had antibodies that seroreacted with *A. phagocytophilum* when tested 32 to 242 days after cessation of therapy. These results are similar to those that occur in *E. canis*-infected dogs, which frequently have persistence of antibody titers after treatment.⁴¹ Cats 2 and 3 were still PCR positive 17 days and 90 days after treatment (see [Table 28-8](#));

Infectious Diseases of the Dog and Cat, 3rd Edition

experimentally infected dogs can also be infected for months.^{157,212} These results, when combined with the persistence of antibody titers, suggest that treatment with tetracyclines for 21 to 30 days may be inadequate for eliminating the organism from the body. The four cats that became PCR-negative may have been persistently infected despite treatment with the organism sequestered in low numbers in tissues such as the spleen, as has been reported for dogs.²⁴⁹ At this time, whether cats can be reinfected is unknown.

28.5.7 Prevention

A. phagocytophilum is apparently transmitted to people and cats by *Ixodes* spp. Thus exposure of cats to potential arthropod vectors should be avoided or tick control maintained with acaricidal products that are approved for use on cats. *A. phagocytophilum* can likely be transmitted by blood; therefore cats used as blood donors should be screened for infection by using serum antibody tests or PCR assay, and positive cats should be excluded as donors.

28.5.8 Public Health Considerations

Although *A. phagocytophilum* is known to infect both people and cats, no association has ever been exhibited between human infection and cat contact. If cats are housed indoors and arthropod control is maintained, the risk to people should be minimal.

28.6 THROMBOCYTOTROPIC ANAPLASMOSIS (*A. PLATYS* [*E. PLATYS*] INFECTION)

John W. Harvey

28.6.1 Etiology

28.6.1.1 Dogs

Infectious cyclic thrombocytopenia of dogs is caused by a small rickettsial parasite of platelets originally classified as *E. platys*.^{178,223} Based on comparisons of the sequences of the 16S rRNA gene, this organism is more closely related to *Anaplasma* organisms than it is to *Ehrlichia* organisms. Consequently, *E. platys* has been reclassified as *A. platys*.¹⁴⁶ This classification as an *Anaplasma* species is further substantiated based on nucleotide sequences determined for the groEL heat shock protein gene, groESL heat shock operon, and the gltA citrate synthase gene.^{242,572} *A. platys* was first reported in the United States in 1978²²³ and has subsequently been reported in Western Europe,^{285,456,481} Asia,^{*} South America,^{19,496} the Middle East,²⁰⁷ Australia,⁸⁴ and Africa.⁴⁶⁰

A. platys organisms appear as blue inclusions in platelets when blood films are stained with Giemsa or new methylene blue (Fig. 28-10). Ultrastructurally, organisms range from 350 to 1250nm in diameter, are round, oval, or bean shaped, and are surrounded by a double membrane. Infected platelets may contain one to three single membrane-lined vacuoles with 1 to 15 organisms per vacuole (Fig. 28-11).^{19,223,340} Organisms appear to enter platelets by adhering to the platelet surface followed by endocytosis. Therefore the vacuolar membrane probably is derived from the external platelet membrane. Repeated binary fission of organisms within the vacuole results in the formation of a morula.

Infectious Diseases of the Dog and Cat, 3rd Edition

Megakaryocytes in bone marrow have not been observed to contain organisms, either before or during parasitemia. <i>A. platys</i> antigen has been identified in macrophages using immunofluorescent staining of	229
frozen tissues 14 days after experimental infection, but this may represent the fate of infected platelets rather than a site of replication. Attempts to culture the organism have been unsuccessful.	230

Fig 28-10 *A. platys* morula in a platelet from a dog with thrombocytic anaplasmosis (Giesma stain, original magnification x2500). *Inset*, Platelet containing morula of *A. platys* (new methylene blue, x2300).

Fig 28-11 Ultrastructure of *A. platys*. Platelet with a membrane-lined vacuole containing seven visible organisms. (From Harvey JW et al. 1978. Cyclic thrombocytopenia induced by a *Rickettsia*-like agent in dogs, *J Infect Dis* 137:182-188. Reprinted with permission from the University of Chicago.)

Rights were not granted to include this figure in electronic media. Please refer to the printed book.

* References 102, 234, 239, 241, 244, 361, [497](#).

28.6.1.2

Cats and Other Animals

Inclusions that appeared identical to *A. platys* have been seen in platelets in a stained blood film from a cat in Brazil⁴⁶¹ but an attempt to infect a cat by IV inoculation with the canine isolate from Florida was unsuccessful. Transmission electron micrographs prepared from the blood of seven South African impala revealed similar organisms in platelets.¹⁵⁰ In addition, 16S rRNA gene sequences have been identified in blood from South African sheep that were 99.5% identical to *A. platys*; however, the morphology of these parasites and the cells they infect have not been identified. Infection with *A. platys* was suspected in people from Venezuela based on the appearance of inclusions in platelets in stained blood films. However, the morphology of these inclusions visualized using transmission electron microscopy was not consistent with *A. platys*, and patients were seronegative against *A. platys* antigens.¹⁸

Fig 28-12 Percentage of parasitized platelets and platelet counts from a dog inoculated IV with *A. platys*; 0 on the abscissa represents the day of inoculation. (From Harvey JW et al. 1978. Cyclic thrombocytopenia induced by a *Rickettsia*-like agent in dogs, *J Infect Dis* 137:182-188. Reprinted with permission from the University of Chicago.)

Rights were not granted to include this figure in electronic media. Please refer to the printed book.

28.6.2 Pathogenesis

The natural mode of transmission has not been demonstrated conclusively, but it likely involves a tick vector. Although attempts to transmit the agent with *R. sanguineus* ticks were not successful,⁴⁷⁸ *A. platys* has been detected by PCR in *R. sanguineus* ticks in Okinawa, Japan,^{247,361} and the Democratic Republic of the Congo, Africa.⁴⁶⁰ The sequences of the amplified 16S rRNA gene fragments from these ticks were identical to sequences obtained from dogs infested by the ticks. *A. platys* have also been detected in *Dermacentor auratus* ticks collected from dogs in Thailand.³⁹¹

The incubation period following experimental IV infection in dogs is 8 to 15 days. The highest percentage of parasitized platelets occurs during the initial parasitemic episode (Fig. 28-12). Within a few days after the appearance of parasitized platelets, platelet count decreases precipitously, and organisms are usually no longer

Infectious Diseases of the Dog and Cat, 3rd Edition

seen. Platelet counts generally drop below 20,000/ μ l in association with parasitemic episodes. After the disappearance of microorganisms, platelet counts increase rapidly, reaching normal values within 3 to 4 days.

Parasitemias and subsequent thrombocytopenic episodes recur at 1- to 2-week intervals (see Fig. 28-12). Although the percentage of infected platelets decreases to as low as 1% or less with subsequent parasitemias, thrombocytopenic episodes are as severe as those following the initial parasitemia. Whereas initial thrombocytopenia may develop primarily as a consequence of direct injury to platelets by replicating organisms, immune-mediated mechanisms of platelet removal may be more important during subsequent thrombocytopenic episodes.¹⁷⁸ The cyclic nature of the parasitemias and thrombocytopenic episodes diminishes with time, resulting in mild, slowly resolving thrombocytopenia in association with sporadically occurring organisms in blood platelets. 230 231

In some instances, transient decreases in total leukocyte counts have occurred concomitantly with parasitemias, but values usually do not fall below the reference interval for dogs. Mild normocytic normochromic anemias may occur during the first month of infection. Based on serum iron and bone marrow studies, decreases in hematocrit may be attributed to the anemia of inflammation syndrome. Slight to moderate increases in acute phase proteins and immunoglobulins and slightly decreased albumin may be present in serum samples.

28.6.3 Clinical Findings

Minimal clinical signs have been recognized in experimentally infected dogs in the United States. A slight increase in rectal temperature has sometimes been noted during initial parasitemias, and slight hematochezia has been recognized in some thrombocytopenic dogs. Splenectomy before experimental infection results in higher preinoculation platelet counts, but it does not alter the periodicity of the parasitemias or the severity of disease. The age of the animal does not appear to have a significant effect on the course of infection; clinical and hematologic findings in a group of three weanling pups were similar to that in mature dogs.¹⁷⁸ Minimal clinical signs appear in most naturally infected dogs as well,⁶⁸ but more severe clinical signs, including fever and uveitis in one dog and petechial and ecchymotic hemorrhages and epistaxis in another dog, have been reported in natural cases in the United States.⁵⁵¹

More pathogenic strains of *A. platys* are reported to occur outside the United States.^{207,285} Clinical signs, including fever, lethargy, pale mucous membranes, petechial hemorrhages of skin and oral mucosae, decreased appetite, weight loss, purulent nasal discharges, and lymphadenomegaly, have been reported in both experimental and natural studies of dogs infected with a Greek strain of *A. platys*²⁸⁵ and in natural cases of dogs infected with *A. platys* in Israel.²⁰⁷ Although *E. canis* serology was negative in some of these ill, *A. platys*-positive dogs, PCR-based assays were not done to determine whether the dogs were also infected with other tick-transmitted diseases. Co-infection with as many as six tick-borne pathogens has been reported in dogs using PCR-based assays²⁸⁶; consequently, infection with one or more additional agents may have contributed to the clinical signs that have been reported in dogs with *A. platys* infections.

The occurrence of *A. platys* with other infectious agents (e.g., *E. canis*, *Babesia canis*) may potentiate the clinical disease produced by these agents alone. As with *E. canis*, certain breeds of dogs or individual animals may be more severely affected compared with the dogs studied experimentally. Dogs with thrombocytopenia may bleed following trauma or surgery. Finally, even if *A. platys* infection seldom produces clinical illness as a single agent in the United States, it must be considered in the differential diagnosis of thrombocytopenia in dogs.

Infectious Diseases of the Dog and Cat, 3rd Edition

28.6.4 Diagnosis

A diagnosis of *A. platys* infection may be made by finding organisms within platelets on stained blood films. In most instances, this method of diagnosis is not reliable because the parasites are either absent or present in very low numbers. An avidin-biotin immunocytochemical staining procedure has been described that can specifically identify *A. platys* morulae in platelets and can help differentiate organisms from large platelet granules or remnants of megakaryocyte nuclei.⁴⁷⁷ In addition, inclusions in platelets stained positively in an indirect FA test using mouse anti-*A. phagocytophilum* serum.²⁴¹

An indirect FA test for detection of serum antibodies to *A. platys* is commercially available. Using indirect FA tests, serologic cross-reactivity between *A. platys* and *E. canis* does not appear to occur, but serologic cross-reactivity between *A. platys* and closely related *A. phagocytophilum* organisms is likely.²⁴¹ Sera of dogs experimentally infected with *A. platys* change from negative to positive coincident with or shortly after the peak of the first parasitemia.^{134,178} Based on serologic studies, *A. platys* infection is apparently widely distributed in the United States. As many as one-third of thrombocytopenic dogs in Florida and Louisiana have positive titers, and over 50% of dogs seropositive for *E. canis* also have positive titers to *A. platys*. Evidence for positive serologic reactions to both organisms in serum samples from some dogs probably represents combined infections, because other dogs have positive titers to either agent alone.⁴⁵⁶ Combined infections with *A. platys* and *E. canis* have been confirmed using PCR and 16S rRNA gene sequence analyses.^{234,286,496} PCR has also documented infection in dogs and their associated *R. sanguineus* ticks.⁴⁸¹

PCR-based assays have been used to detect *A. platys* infected dogs.* Selection of appropriate primers for PCR-based assays is critical. A primer combination believed to be specific for *A. phagocytophilum* was found to also amplify *A. platys*.²⁰⁴ Nearly 28% of free-roaming dogs in subtropical Okinawa Prefecture, Japan, were positive for *A. platys* infection using PCR.²⁴⁴

* References 102, 103, 204, 241, 332a, 340.

28.6.5 Pathologic Findings

Generalized lymph node enlargement was the only gross finding at necropsy in an experimental study of dogs euthanized during the early weeks of infection.²⁵ Histologic lesions were generally mild and included lymphoid hyperplasia and plasmacytosis in lymph nodes and the spleen, crescent-shaped perifollicular hemorrhages in the spleen, and multifocal Kupffer cell hyperplasia in the liver. Megakaryocyte numbers in the bone marrow were normal or increased.

28.6.6 Therapy and Prevention

Based on preliminary studies, tetracyclines and enrofloxacin at dosages recommended for *E. canis* infections are apparently effective against *A. platys* (Table 28-9).^{178,284} Because ticks (and possibly other arthropods) are undoubtedly responsible for natural transmission of this disease, adequate vector control is recommended to prevent its spread.

Infectious Diseases of the Dog and Cat, 3rd Edition

28.7 WOLBACHIA INFECTION

Craig E. Greene

Organisms of the genus *Wolbachia* have been identified as endosymbionts living within filarial parasites. *Wolbachia* spp. have been identified in the filarial parasite *Onchocerca volvulus*, a cause of human filariasis. One hypothesis asserts that the microorganism may have a role in the pathogenesis of the inflammatory reaction caused by the filarid.⁴⁵⁴ A *Wolbachia* sp. was detected in the blood of a dog from Japan suspected to be infected with *Ehrlichia*.⁵¹⁹ The *Wolbachia* sp. had the closest genetic identity to one previously identified in *Dirofilaria immitis*. These findings suggest that *Wolbachia* sp. might have a role in canine febrile illnesses or heartworm disease. *Wolbachia pipientis* is also found as a symbiont in insects and it was found in 17.8% of cat fleas from France and the United States.^{448,190} The potential or frequency of this infection spreading to dogs and cats from infected fleas, and any clinical significance of such infections, is unknown.

29 CHAPTER 29 Rocky Mountain Spotted Fever, Murine Typhuslike Disease, Rickettsialpox, Typhus, and Q Fever

Craig E. Greene

Edward B. Breitschwerdt

29.1 ROCKY MOUNTAIN SPOTTED FEVER

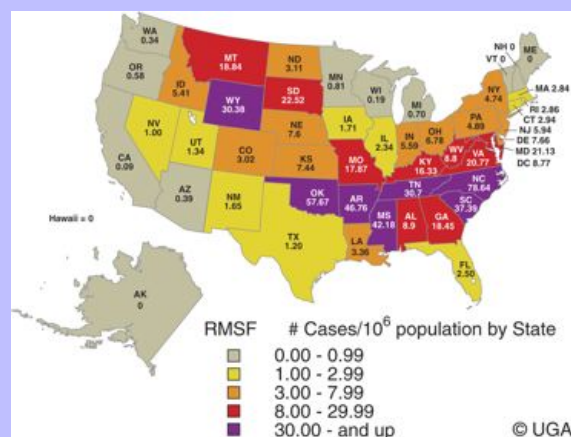

29.1.1 Etiology and Epidemiology

Rocky Mountain spotted fever (RMSF) is a tickborne, rickettsial disease of the Americas that affects dogs and people. RMSF was first recognized in the western United States before 1930. RMSF is now known to occur throughout the contiguous United States with the exception of Maine. Overall, the reported prevalence of human disease appears to have increased since its discovery; the highest yearly incidence is now reported to be from the eastern United States (Fig. 29-1). Presumably, this increase reflects better recognition and reporting rather than true geographic spread of the disease.

The disease has been reported in people living in western Canada, Mexico, Panama, Costa Rica, Honduras, Nicaragua, Colombia, Argentina, and Brazil.⁴³ Deciduous forests, increased humidity, and warmer temperatures are factors associated with the high prevalence of this tick-transmitted disease in these areas. Infections in people have even been acquired in urban foci such as in the South Bronx, N.Y., and Philadelphia, Penn.

233

Fig 29-1 Distribution of RMSF cases in people in United States from 1981 to 2002 reported as average yearly incidence per million population. (Data from Dalton MJ, et al. 1995. *Am J Trop Med Hyg* 52:405-413 and subsequent reports from the Centers for Disease Control and Prevention, Atlanta, Ga. Map courtesy University of Georgia, Athens, Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 29-2 *R. rickettsii* in yolk sac culture (×15,000).

Rickettsia rickettsii, the etiologic agent of RMSF, is an obligate intracellular bacterium in the family Rickettsiaceae (Fig. 29-2). Members of the spotted fever group (SFG), such as *R. rickettsii*, are most closely related to the typhus group of rickettsiae (Table 29-1) but are distinct from other rickettsial genera. Serologically, genetically, and pathogenically distinct strains of SFG rickettsiae have been described throughout the world.^{29,39} Four main SFG species—*R. rickettsii*, *Rickettsia montana*, *Rickettsia rhipicephali*, and *Rickettsia bellii*—are isolated from ticks on dogs in the United States.²⁹ *R. rickettsii* is the only SFG species in the Western Hemisphere known to be pathogenic for people and animals. However, serologic evidence supports potential infection with *Rickettsia canada* or other as yet uncharacterized rickettsiae in dogs and people.¹⁷ In addition, the role of nonpathogenic SFG rickettsiae in immunocompromised individuals has not been clarified.

Fig 29-3 Geographic range of two primary ticks that transmit RMSF. (Courtesy University of Georgia, Athens, Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Diseases similar to RMSF and caused by SFG rickettsiae have been described in people the Eastern Hemisphere. *Rickettsia conorii*—the etiologic agent of boutonneuse, or Mediterranean spotted fever—is an analogous organism transmitted by dog ticks of the genus *Rhipicephalus*.^{65-67,129} Dogs and rodents have a transient rickettsemia with *R. conorii* and are subclinically infected. Their role in MSF is as carriers of ticks and occasional reservoirs.^{83,128} Queensland tick typhus (*Rickettsia australis*), Flinder's Island spotted fever (*Rickettsia honei*), African tick bite fever (*Rickettsia africae*), Astrakhan fever (Astrakhan fever rickettsia), Japanese spotted fever (*Rickettsia japonica*), North Asian tick typhus (*Rickettsia sibirica*), and European tickborne lymphadenopathy (*Rickettsia helvetica*, *Rickettsia mongolotimonae*, *Rickettsia slovaca*), are analogous diseases of people caused by other SFG rickettsiae and transmitted by arthropods in geographically distinct regions.^{11,63,108} The clinical significance or reservoir status of dogs or cats for these infections in the Eastern Hemisphere has not been determined. In this chapter, RMSF as it occurs in the United States is emphasized as the model disease for SFG rickettsiosis in dogs. Although cats and other domestic animals can be seropositive, knowledge concerning the occurrence of disease in these other animals is minimal.⁹⁰

The natural history and distribution of RMSF in the United States appears to center primarily on the distribution of two ticks, *Dermacentor andersoni* and *Dermacentor variabilis*, which serve as natural hosts, reservoirs, and vectors for *R. rickettsii*. *D. andersoni* (the wood tick) is a three-host tick that is found in the region from the Cascade Mountains to the Rocky Mountains (Fig. 29-3). It is the principal vector of RMSF in the western United States and is also present in Canada in the provinces of southern British Columbia, Alberta, and Saskatchewan. *D. variabilis* (the American dog tick) is a three-host tick found from the Great Plains region eastward to the Atlantic coast of the United States and southern Canada. It has also been reported in California, southwestern Oregon, southern Washington, and Idaho.

Three other ticks have been incriminated in the United States in the transmission of RMSF to animals and people, but their significance is uncertain. The Lone Star tick (*Amblyomma americanum*) is found in the United States from Texas eastward to the Atlantic Coast. The brown dog tick, *Rhipicephalus sanguineus*, is found throughout the United States, southern Canada, Mexico, and South America. Unlike the other vector ticks, *R. sanguineus* feeds on dogs during all three stages and has rarely been reported to feed on people. *Haemaphysalis leporispalustris*, the rabbit tick, resides throughout the Western Hemisphere. Although some rickettsiae recovered from this tick have been antigenically similar to *R. rickettsii*, they do not produce disease in laboratory animals. *R. sanguineus* and *Amblyomma cajennense* are the most commonly implicated ticks in transmission of *R. rickettsii* to people in Mexico or Central America and South America, respectively.

^b Also includes spotted fever group (SFG)-rickettsiae causing recognized human illnesses: Queensland tick typhus (*Rickettsia australis*:

Queensland and New South Wales, Australia), North Asian tick typhus (*Rickettsia sibirica*: Siberia, Mongolia), African tick bite fever (*Rickettsia africae*: Africa, West Indies; *Rickettsia aeschlimannii*: Mediterranean region, Africa), European tickborne lymphadenopathy (*Rickettsia slovaca*: Hungary, France; *Rickettsia helvetica*: Switzerland, France, Slovenia, Sweden; *Rickettsia mongolotimonae*: Europe), and Flinders Island spotted fever and Indian and Thai tick typhus (*Rickettsia honei*: southeastern Victoria, Flinders Island and Tasmania, Australia; India; Thailand).

Astrakhan fever *Rickettsia* is closely related to Israel tick typhus *Rickettsia*, and both are genotypes in the *Rickettsia conorii* complex. *R. parkeri*, which was previously thought to be

c In Japan, *Rickettsia felis* has been also identified in ticks.

c In Japan, *Rickettsia felis* has been also identified in ticks.

234

235

The diagram illustrates the life cycle of the dog tick (*Rhipicephalus sanguineus*). The cycle begins with a female tick (♀) feeding on a human, dog, or rodent. After feeding, the tick lays a mass of infected eggs. These eggs hatch into uninfected larvae. The larvae then feed on a rodent, becoming infected nymphs. The nymphs feed on a rodent and then on a dog, becoming infected adults. The adults feed on a dog and then on a human, completing the cycle by laying more infected eggs.

SFG rickettsiae. In endemic areas, less than 10% of the ticks contain *R. rickettsii*.¹⁴⁶

Infectious Diseases of the Dog and Cat, 3rd Edition

For reasons that are not completely understood, ticks do not usually infect a new host until they have been attached for a minimum of 5 to 20 hours. A reactivation period within the tick with an apparent increased rickettsial virulence is thought to occur after ticks reattach and take their first blood meal of the season. A period of feeding also may be needed for the continued replication of infective rickettsiae in the salivary glands. Delayed transmission may also relate to the ticks' need to produce a cement collar around their mouth parts before they begin feeding. Although infections that people acquire from tick bites require extended attachment, those acquired from contact of mucous membranes with feces or hemolymph from preengorged ticks on animals or contact with laboratory-infected cultures or mammalian blood do not appear to involve extended contact periods.

29.1.2 Pathogenesis

R. rickettsii usually enter the body through the bite of infected ticks (Fig. 29-5). Rickettsiae are disseminated via the circulatory system and invade and replicate in endothelial cells of smaller arteries and venules. Phospholipase and proteases have been incriminated as mechanisms for rickettsial damage to cell membranes. Subsequent endothelial cell damage initiates a vasculitis with platelet activation and activation of the coagulation system accompanied by decreased plasma levels of antithrombin III and plasminogen and increased fibrinogen degradation products (FDPs). These hematologic changes are consistent with simultaneous activation of the fibrinolytic and coagulation systems. Coagulation factor consumption is not usually extensive enough to cause hypofibrinogenemia or overt disseminated intravascular coagulation (DIC).¹⁴⁵ Results of coagulation factor analysis suggest activation of the extrinsic and intrinsic pathways. Elevated platelet-associated immunoglobulin in dogs with experimentally and naturally induced RMSF suggests an immune-mediated cause of the thrombocytopenia.⁴⁹ Progressive necrotizing vasculitis may be caused sequentially by complement activation, cellular chemotaxis, and subsequent vascular necrosis and extravasation of blood. Organs with endarterial circulation, such as the skin, brain, heart, and kidneys, are most adversely affected.

Significantly increased plasma and extracellular fluid volume have been described in experimental infections of nonhuman primates. Accumulation of extracellular fluid and electrolytes, renal water retention, and edema were correlated with increased concentrations of aldosterone and antidiuretic hormone (ADH) in people. Hyponatremia, which occurs in dogs and people, may be related to the syndrome of inappropriate ADH release. Fluid overload in the circulation and edema of the medulla oblongata in experimental animals suggest that intravenous fluid therapy be used sparingly in the management of dogs with RMSF. Central nervous system (CNS) signs and death may relate to cardiorespiratory depression through edema involving medullary centers. Fulminant infection may result in peripheral vascular collapse and death in the first week of infection, before proliferative and thrombotic lesions occur. Acute renal failure, a fatal complication of RMSF in people, has not been frequently reported in dogs.

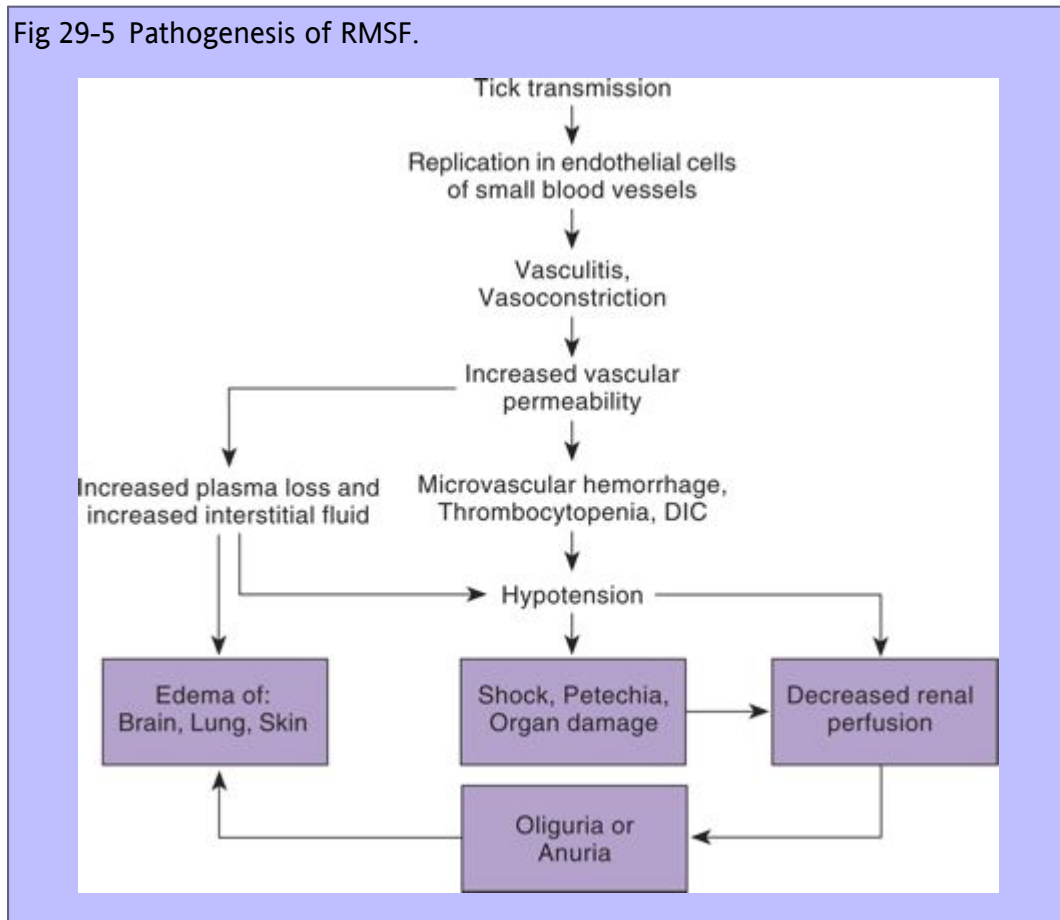

29.1.3 Clinical Findings

Clinical and subclinical illnesses have been reported in dogs with naturally occurring and experimentally produced RMSF. Naturally acquired immunity has an important role in protection against clinical illness.	235
Anti-SFG rickettsial antibodies can be found in the healthy canine population in endemic areas. This observation may be a consequence of subclinical infections or the result of exposure to nonpathogenic SFG rickettsiae in ticks. Immunogenic contact with <i>R. rickettsii</i> induces a protective response in experimental dogs to reinfection for at least up to 3 years. ¹⁸ Most dogs are examined for illness during the months of March to	236

Infectious Diseases of the Dog and Cat, 3rd Edition

October. Purebred dogs appear to be more prone to develop clinical illness than mixed breed dogs, and the German shepherd dog has a particularly high prevalence of disease. People with glucose-6-phosphate dehydrogenase deficiency and English springer spaniels with suspected phosphofructokinase deficiency have a more fulminant course of illness and are more likely to develop dermal necrosis,¹⁵¹ as are animals in which treatment is delayed. Clinical signs of illness in dogs are similar to those of naturally infected people (Tables 29-2 and 29-3).

Fig 29-5 Pathogenesis of RMSF.

Fever, one of the first and most consistent findings, can occur within 2 to 3 days after tick attachment. The range of the incubation period is 2 to 14 days. Early cutaneous lesions in some dogs consist of edema and hyperemia of the lips, penile sheath, scrotum, pinna, other extremities (Fig. 29-6), and rarely the ventral abdomen. Discrete clear vesicles and focal erythematous macules have been observed on the buccal mucosa. Male dogs that develop scrotal edema or epididymal swelling often have a stiff gait and are reluctant to walk. Gait abnormalities are a result of inflammation of joints, muscles, and meninges.

Petechial and ecchymotic hemorrhages may develop subsequent to the acute illness in some dogs and if present occur on ocular, oral, and genital mucous membranes rather than the skin (Fig. 29-7). Fundoscopic examination provides a more sensitive means of detecting these hemorrhagic lesions (see Fig. 93-14).³² Epistaxis, melena, and hematuria may be noted in severely affected animals.

Infectious Diseases of the Dog and Cat, 3rd Edition

Neurologic signs of generalized cerebral and spinal cord involvement have been found (see [Table 29-2](#)). More severe neurologic abnormalities caused by meningitis progressing to encephalomyelitis are found in dogs and people in which the diagnosis and treatment are delayed. Focal or localizing neurologic signs, such as vestibular disease, are common in the early phases of illness and are often the reason the animal is taken to the veterinarian.

Table 29-2 Medical Problems Associated with Rocky Mountain Spotted Fever

History

Lethargy, anorexia, weight loss, vomiting, diarrhea, seasonal (warm months)

Physical Examination

Fever, ocular signs (e.g., scleral congestion, conjunctivitis, anterior uveitis, iridal hemorrhage, retinitis), lymphadenomegaly, edema, hyperemia, tachycardia, tachypnea, dyspnea, cutaneous necrosis, subcutaneous edema, icterus, hepatomegaly, petechiae, ecchymoses, myalgia, arthralgia, joint swelling and stiffness, neurologic signs (e.g., hyperesthesia, tetraparesis, ataxia, vestibular signs, seizures)
--

Ancillary Diagnostics

Hematologic tests: Thrombocytopenia, leukocytosis with shift, hypoalbuminemia, elevated serum ALP activity, hyperbilirubinemia, hyponatremia, artifactual hypocalcemia, prolonged coagulation times

<i>Cytologic examination:</i> Suppurative polyarthritis, suppurative meningitis, lymph node hyperplasia

<i>Radiography:</i> Interstitial pneumonia
--

Infected dogs may make a rapid and complete recovery if they are mildly affected or antimicrobial therapy is instituted early. Permanent organ damage, particularly resulting in residual neurologic dysfunction, may occur within 1 to 2 weeks of onset of clinical signs in severely affected dogs that survive the acute stages of illness. Necrosis of the extremities and previously hyperemic or edematous portions of the body may occur at this time ([Fig. 29-8](#)). Dogs may die in the acute stages of illness as a result of hemorrhagic diathesis or from thrombosis of vital organs. Cardiovascular, neurologic, and renal damage are the most consistent causes of death or permanent organ dysfunction. Death in some severely affected dogs has been caused by disseminated, rapidly progressing meningoencephalitis. Shock, cardiovascular collapse, and oliguria become apparent in the terminal stages of illness.

29.1.4 Diagnosis

29.1.4.1 Clinical Laboratory Findings

Mild leukopenia, which may develop early in the course of illness, is followed by a moderate leukocytosis generally characterized by a stress leukogram or accompanied by a minimal left shift and toxic granulation of neutrophils. The longer the duration of clinical signs before diagnosis, the more pronounced the leukocytosis. A normocytic normochromic anemia and elevated erythrocyte sedimentation rate are nonspecific hematologic changes. Fibrinogen concentration, which increases as a result of an acute-phase

Infectious Diseases of the Dog and Cat, 3rd Edition

reaction in mildly to moderately affected dogs, may be decreased in severely affected dogs as a result of rapid consumption secondary to vasculitis.

Thrombocytopenia is one of the most consistent hematologic abnormalities in infected dogs. Platelet counts generally range from 23,000/ μ l to 220,000/ μ l. Megathrombocytosis is usually detectable in a majority of cases. Thrombocytopenia in RMSF is often not less than 75,000/ μ l; however, lower trends have been reported.⁴⁴ Electronic counting of thrombocytopenic specimens below this level generally gives lower counts than hemocytometer methods on the same specimen when correlations are made. A mild prolongation of the activated clotting time may be the only coagulation abnormality.^{30,31} Rarely, overt DIC characterized by prolongation of the activated coagulation time, prothrombin time, activated partial thromboplastin time, and thrombin time with elevated FDPs occurs in dogs.³²

Biochemical abnormalities may include mildly increased serum glucose concentration and elevated serum	237
alkaline phosphatase, alanine transferase, and aspartate transferase activities. Hypercholesterolemia has been	238

one of the more consistent findings in affected dogs. Hypoalbuminemia is often observed and probably caused by leakage associated with generalized vascular endothelial damage. Hyponatremia, hypochloremia, and metabolic acidosis are variable findings. The serum urea nitrogen may increase in terminal stages of the disease corresponding with oliguria and renal failure. Proteinuria and hematuria occur as a result of incoagulability or glomerular and tubular injury. Bilirubinuria and hyperbilirubinemia occur in some dogs, but these are usually mild. Serum creatine kinase has been mildly to moderately increased in some dogs. Cerebrospinal fluid analysis is frequently normal; however, mildly increased protein (greater than 25 mg/ μ l but less than 100 mg/ μ l) and polymorphonuclear or mononuclear cells may be found. Analysis of synovial fluid in dogs with accompanying polyarthritis has shown inflammatory changes, with a predominant increase in neutrophils. Results of lupus erythematosus cell, rheumatoid factor, antinuclear antibody, platelet autoantibody, and Coombs' testing and of bacterial blood culture are usually negative. The presence of co-infections with other tickborne agents such as *Ehrlichia* or *Babesia* organisms may cause positive Coombs' test results (see [Chapters 28](#) and [77](#), respectively).

Infectious Diseases of the Dog and Cat, 3rd Edition

If present, electrocardiographic abnormalities consist of sinoatrial node dysfunction, ST-segment and T-wave depressions, and premature ventricular contractions. Thoracic radiography reveals diffuse increased interstitial density, especially in dogs having dyspnea and coughing.³⁴

29.1.4.2

Serologic Testing

Measurement of *R. rickettsii* serum antibodies is the primary method of confirmation of RMSF in clinical practice. Mammalian hosts differ in regard to the specificity of their immune response to rickettsiae. Well-adapted hosts, such as mice, develop highly specific antibody titers against each species of organism. Human serologic responses generally react strongly with group-reactive antibodies but do not consistently distinguish between typhus group and SFG rickettsiae. Seroreactivity of dogs appears to be between that of rodents and people. Cross-reactions in dog sera develop between SFG antigens; however, the titer is generally highest to the specific rickettsial species causing infection. Generally, minimal reactions to typhus group or other rickettsiae occur. Clinically healthy dogs on the Atlantic seaboard have between 5% and 15% seropositivity to SFG rickettsiae, indicating infection by antigenically related avirulent rickettsiae or subclinical infection. Some ill dogs have shown stronger reactivity to nonpathogenic *R. bellii* and typhus group antigens than *R. rickettsii*, suggesting that another yet unidentified *Rickettsia* organism may be pathogenic.¹⁷

238

239

Several serologic tests have been developed to detect antibodies to RMSF in people, including Weil-Felix, complement fixation, microscopic immunofluorescence (Micro-IF), microagglutination, indirect hemagglutination, enzyme-linked immunosorbent assay (ELISA), and latex agglutination (LA).⁶² The Micro-IF, ELISA, and LA tests appear to be the best suited to examine canine sera.⁴⁷

An increased IgM titer or fourfold increase in IgG titer is needed to confirm active infection with *R. rickettsii*. The Micro-IF test, an indirect fluorescent antibody (FA) test, and the ELISA have the advantages of requiring small amounts of sera and reagents, having high sensitivity, and classifying antibodies to *R. rickettsii* as IgM or IgG. Measurement of IgG antibodies to *R. rickettsii* using the Micro-IF method is used by most diagnostic laboratories that test canine sera (see [Appendix 5](#)). Acute and convalescent IgG titers have been generally less than 1:64 in uninfected dogs and in those with ehrlichiosis, although titers vary among laboratories. Actively infected dogs may or may not have increased titers 1:64 by the time clinical signs are apparent and the first sample is taken. IgG titers in experimentally infected dogs with disease manifestations by 3 to 6 days after infection have not increased until 2 to 3 weeks after infection. Therefore seronegative results do not discount the possibility of RMSF, and a convalescent sample should be tested at a later date. An IgG titer increase of fourfold or greater is required to document active infection definitively. High IgG titers that develop in actively infected dogs generally decrease after 3 to 5 months, although some may remain elevated (1:128) for at least 10 months.^{40,48} Thus unless single titers are markedly increased (1:1024), active infection cannot be absolutely ascertained, and paired samples must be obtained. Differences can be found among laboratories performing the test and within laboratories testing the same sample at a later date. Therefore it is recommended that acute and convalescent serum samples be submitted together. Simultaneous assessment of IgM and IgG titers can provide more accurate assessment as to the time course of infection when evaluating a single serum sample. Seroconversion to *R. rickettsii* antigen is suppressed by administration of antimicrobials early in the disease.¹⁹

A modification of the test that allows for measurement of IgM has advantages in permitting more specific diagnosis of recent infection with a single convalescent titer, and IgM titers can be increased before increases

Infectious Diseases of the Dog and Cat, 3rd Edition

in IgG titers. The IgM titers in naturally and experimentally infected dogs only increase ($\geq 1:8$) during the first week after infection and decrease after 4 to 8 weeks or less. The maximum measured titers are generally two to four dilutions lower in magnitude than the corresponding IgG titers in the same animal.

The LA test appears to be a rapid and specific assay for recent *R. rickettsii* infection in dogs.⁴⁸ Because the sensitivity is lower than the Micro-IF test, false-negative results occur, although a single increased titer (1:32) appears to be diagnostic for RMSF in dogs.

29.1.4.3

Direct Immunodetection

Direct FA staining of infected tissues has been used in the past for rapid clinical or postmortem diagnosis of RMSF. Direct FA procedures have also been used to detect organisms in embryonated eggs or tissue culture, tissues at necropsy, ticks, and skin biopsies from acutely infected people and dogs. Full-thickness skin biopsies should be surgically removed from visible lesions on the skin or mucosae and placed in isotonic saline on melting ice or in formalin at room temperature until they are processed. Formalin fixation causes some decrease in sensitivity of rickettsial detection. Rickettsiae can be found in approximately 75% of specimens taken from affected lesions and are rarely found in unaffected skin. Trypsin digestion and deparaffinization are needed to examine specimens that have been processed for light microscopy. Tissue sections are stained by fluorescein-conjugated antibody to *R. rickettsii* for the presence of coccobacillary organisms in endothelial cells and vascular walls of the dermis.

The advantages of the direct FA procedure on tissue are that it may be able to confirm the diagnosis on a single sample as early as the third or fourth day of disease. Direct FA procedures can be performed by veterinary or human laboratories without regard to host species differences. Few false-positive results are found with the direct FA test, but many (30% to 40%) false-negative reactions can occur and are usually a result of prior therapy with chloramphenicol or tetracycline or failure to obtain a sample through an area of vasculitis. Specimens should be obtained early in the course of infection because organisms are eliminated from the tissue within a few days, especially after institution of antimicrobial therapy. Because of the usual absence of cutaneous petechiae in dogs, biopsy specimens could be obtained from mucosal hemorrhages or from vesicles that may develop in the buccal mucosa. Adaptation of this method using immunoperoxidase staining increases the test sensitivity and specificity.⁷⁷ Immunohistochemical methods have been used to substantiate infection in people dying of RMSF that was not detected by serologic means.¹⁰⁵

29.1.4.4

Genetic Detection

The polymerase chain reaction (PCR) has made it possible to detect DNA from low numbers of rickettsiae in whole blood or tissue specimens and for comparison of isolates.^{131,144} Amplification of a unique region of the 16S rRNA gene sequence of *R. rickettsii* facilitates acute-phase diagnosis of RMSF, but with current techniques it has not been highly sensitive. A nested PCR is more sensitive than culture in detecting rickettsial DNA in dogs after treatment and may remain positive for longer periods because of the persistence of nonviable nucleic acid.¹⁹ PCR has documented that many dogs infected with *R. rickettsii* may be coinfecting with various *Ehrlichia*, *Bartonella*, *Babesia*, other *Rickettsia* species, or all of these, making a specific diagnosis uncertain and causing higher morbidity than with a single-agent infection.⁷²

Infectious Diseases of the Dog and Cat, 3rd Edition

29.1.4.5 Rickettsial Isolation

Bioassays involving isolation of *R. rickettsii* in susceptible species of laboratory animals have been a means of diagnosing RMSF in the research laboratory.²⁹ Fresh- or deep-frozen ($-80\frac{1}{4}$ C) tissue such as liver, spleen, or brain or clotted blood from biopsy or necropsy specimens can be inoculated into meadow voles or guinea pigs. Their serum may be tested for the presence of antibody to *R. rickettsii*. Tissues or blood of the affected or laboratory animal may be inoculated into embryonated chicken eggs or tissue culture to isolate and purify the agent. A described shell vial method which involves using concentrated inoculum to infect a small number of cells permits detection in cell culture in as few as 24 to 48 hours.¹⁰⁶ A staining technique using carbol basic fuchsin is widely used for the identification of SFG and typhus group rickettsiae. Rickettsiae may replicate sufficiently within several days with in vitro isolation procedures, whereas bioassays often require a month to complete. Isolation of *R. rickettsii* requires an appropriate tissue culture system and a biosafety level 3 laboratory and could infect laboratory workers by inadvertent parenteral or aerosol inoculation.

239

29.1.5 Pathologic Findings

When RMSF proves fatal, gross lesions (if present) consist of widespread petechial and ecchymotic hemorrhages in all tissues. Generalized hemorrhagic lymphadenomegaly and splenomegaly are usually found.

Microscopic findings consist of necrotizing vasculitis with perivascular polymorphonuclear and lymphoreticular cell infiltrations. Vascular lesions are most prominent in the skin, epididymis, testicle, gastrointestinal tract, pancreas, kidneys, urinary bladder, myocardium, meninges, retina, and skeletal muscle. Acute meningoencephalitis with vasculitis and small focal nodular gliosis is found in brain parenchyma of dogs with acute infections (Fig. 29-9). Focal myocardial and hepatic necrosis and acute interstitial pneumonia are common lesions. Rickettsiae can be detected in many tissues by previously described staining and isolation procedures but not by routine histologic methods.

240

29.1.6 Therapy

Mortality in dogs with RMSF is usually associated with incorrect diagnosis and treatment or rapidly progressive shock or severe CNS infections. Antibody titers are generally not available when the dog is admitted and even then, results from the first sample may not be diagnostic because it may take 1 to 3 weeks for maximal IgG response. For this reason a response to therapy is used to increase the index of suspicion. It is judicious to begin treatment immediately after obtaining samples for diagnostic testing. Presumptive diagnosis of RMSF can be made based on the seasonal occurrence and clinical and laboratory abnormalities. The antibiotics used to treat RMSF are considered to be rickettsiostatic (Table 29-4). Although they slightly prolong the duration of rickettsemia, antiinflammatory and immunosuppressive doses of glucocorticoids do not increase the severity of disease in experimentally infected dogs.¹⁶ They may help avert the signs of the concurrent immune-mediated thrombocytopenia⁴⁹; however, their use is not generally recommended because appropriate antimicrobial therapy is curative. Tetracyclines are the antibiotics of choice to treat RMSF.⁵⁷

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 29-4 Therapy for Rocky Mountain Spotted Fever

DRUG ^a	DOSE ^b (mg/kg)	PREFERRED ROUTE (ALTERNATE ROUTE)	INTERVAL (HOURS)	DURATION (WEEKS)
Tetracycline	22–30	PO (IV)	8	1
Chloramphenicol	15–30	PO (IV, SC, IM)	8	1
Doxycycline	10–20	PO (IV)	12	1
Enrofloxacin	3	PO (SC)	12	1

PO, By mouth; IV, intravenous; SC, subcutaneous; IM, intramuscular.

a For additional information on each drug, see [Appendix 8](#).

b Dose per administration at specified interval.

Tetracycline or oxytetracycline should be given for at least 7 days. Lipid-soluble tetracyclines, such as minocycline or doxycycline, have been shown to be as effective in treating rickettsial infections in people when they have been used for fewer than 7 days. Their use early in the course of illness may attenuate the serologic response to infection but in most instances, it does not interfere with serologic confirmation (a fourfold change in antibody titer) of RMSF. Chloramphenicol is also effective and might be considered for pregnant animals or in young (younger than 6 months old) puppies to avoid dental staining; however, use of doxycycline has minimal effects on dental color and has been more effective than chloramphenicol.^{81,110} Fluoroquinolones such as enrofloxacin or trovafloxacin are also effective;^{15,19} however, because they can cause cartilaginous injury, their use must be restricted to older animals. Josamycin, a newer macrolide antimicrobial with activity similar to erythromycin, has been used successfully in treating pregnant women with *R. conorii* infection.³³ Azithromycin and clarithromycin, newer erythromycin derivatives, have been used effectively to treat SFG rickettsioses in people, especially children in whom tetracyclines are contraindicated.^{22,127} Azithromycin was less effective in clearing RMSF rickettsemia in dogs as compared with doxycycline or trovafloxacin¹⁹ and therefore is not recommended. Parenteral administration of antimicrobial drugs may be required in patients that

Infectious Diseases of the Dog and Cat, 3rd Edition

are semicomatose or have nausea or are vomiting. Dogs treated early in the course of illness have rapid clinical improvement, generally within 24 to 48 hours after therapy is instituted. Defervescence within 12 hours is not unusual. Delayed or incomplete recovery is associated with organ failure or CNS damage. Some dogs treated with chloramphenicol and although less common, with tetracycline, develop depression, nausea, and vomiting, which can appear to delay their clinical recovery. Antibiotics are only effective in reducing the severity of the illness if they are given before the development of advanced pathologic changes, such as thrombosis and tissue necrosis. The extremities of dogs that develop acryl gangrene and recover eventually heal but have permanent scarring or disfigurement.

240

241

Supportive care must be used in dogs with shock, coagulation disorders, and clinical or laboratory evidence of organ failure. IV fluid therapy must be used with caution because increased vascular permeability and expanded extracellular fluid volume can give rise to pulmonary and cerebral edema.

29.1.7 Prevention

Dogs recovering from infection with *R. rickettsii* have been immune to reinfection when challenged 6 to 36 months later. Experimentally, infection with nonpathogenic rickettsiae such as *R. montana* does not seem to protect dogs from subsequent infection with the more virulent *R. rickettsii*. Naturally infected dogs that recover from RMSF have never been shown to be reinfected.

No vaccines are available for use in dogs or people. Challenge infection in people after vaccination with inactivated products has been associated with a prolonged incubation period, a shorter and milder course of illness, and reduced prevalence of relapses, but reinfection is not prevented. Experimental, inactivated, tissue-culture origin vaccines appear to offer protection against infection in experimental animals. Specific antigenic components of *R. rickettsii* responsible for producing protective antibody response were identified. Vaccines containing recombinant outer membrane proteins A of *R. rickettsii* or *R. conorii* have been shown to be immunoprotective in rodents.^{4,27,142}

The best means of prevention of RMSF in dogs is avoidance of tick-infested areas and rapid, safe removal of attached ticks. Pets should be protected with an insecticide-impregnated collar or topical or systemic acaricides if they frequent areas inhabited by ticks. Tick eradication in the environment is impossible because of the maintenance of the life cycle by rodents and other reservoir hosts. Elimination of small ground rodents is difficult if not impossible to achieve. Some reduction in tick numbers has been achieved locally in the eastern and southern United States through insecticide application to surrounding vegetation in the form of aqueous suspension or dust.

29.1.8 Public Health Considerations

SFG rickettsial infections are important zoonotic diseases because of their endemic nature, high prevalence, and severity when mistreated or misdiagnosed. Of the more than 1000 cases of rickettsial diseases reported each year in the United States, approximately 90% are RMSF. The mortality rate in people, which is highest among the tickborne illnesses, remains between 2% and 10%.^{28,89} The yearly incidence rate probably reflects a summation of factors, including encroachment of people on undeveloped wooded areas, improved recognition and reporting of disease, and a periodic cyclicity of infection. The prevalence of seropositive reactions in dogs within a given area usually parallels risk of human infection.

The seasonal occurrence of RMSF in people parallels that in dogs.²⁸ The rate of infection is highest in children and young adults and is higher in males than females. Patients from rural areas have a greater proportion of

Infectious Diseases of the Dog and Cat, 3rd Edition

confirmed diagnoses than those from suburban and urban areas. Approximately 60% of infected people have reported a tick bite, and an additional 30% said that they were in a wooded area just before the clinical illness developed. The lack of known exposure does not eliminate tick involvement in infection, especially because small larval and nymphal stages can feed transiently and remain undetected. Most exposures in the eastern United States occur at the place of residence, but a number have been related to an outdoor recreational activity. Approximately 10% of reported human cases occur only after known exposure to dogs or their ticks, but this should not imply an absolute association; common exposure to the same tick population is a more likely source of infection. The high mortality of the human disease in large part is a result of its severe manifestations; however, the diagnosis of many cases is delayed because of the broad geographic region and sporadic nature of its occurrence and its diverse clinical manifestations. Veterinarians can play an important role in recognition of the human illness because dogs in a household have often been ill in association with or before their human counterparts.^{36,104} Veterinarians should be proactive by educating their clients and contacting human health caregivers should the human form of the illness be observed in association with a dog with SFG rickettsial infection.

In addition to common exposure to ticks, dogs are also a potential source for human infections because they carry infected ticks into nonendemic environs or closer to people. Unattached ticks may move from the dogs and attach to people. More frequently, people expose their abraded skin or conjunctivae to an engorged tick's hemolymph or excreta during tick removal.¹²⁹ It is not the secretions from infected dogs but the effluents from engorged, infected ticks that pose the greatest danger. Aerosol exposure from an infected dog's secretions is unlikely under natural conditions because the organism does not survive outside host or tick cells. Aerosol exposure has only occurred in the laboratory, where inadvertent inoculation of infected tissues may also occur.

The clinical manifestations in affected people closely parallel the signs seen in dogs (see [Table 29-2](#)). Early signs in people are vague and may mimic an upper respiratory tract infection. Although the rash is considered typical of RMSF, it never develops in up to 12% of people and when it does develop, it is seen in less than 50% of the cases within the first 3 days of illness. Not all people develop all manifestations of RMSF, although fever and headache are most consistent. Neurologic signs usually develop later in the course of illness. Death appears to be more of a problem in people who develop severe hepatomegaly, jaundice, stupor, and azotemia (serum urea > 25 mg/dl). Cardiac arrhythmias from myocarditis, meningoencephalitis, and DIC often are detected in terminal patients. Subclinical infections in people have been suspected, but the role of nonpathogenic rickettsiae in causing the observed serologic responses has not been determined. Primary infection or coinfection with *Ehrlichia* organisms can confound the diagnosis of RMSF in people. Manifestations of RMSF and *Ehrlichia chaffeensis* or *Anaplasma phagocytophilum* infections (see [Chapter 28](#)) are clinically indistinguishable and occur in overlapping geographic locations. Broad serologic testing must be incorporated to determine the cause of illness in most instances.

Ticks should be removed by applying constant traction with curved forceps or (although less desirable) with tweezers or fingers protected with facial tissue placed as close as possible to the point of insertion. Ticks should not be squeezed or crushed with bare fingers because the organism can be transmitted via tick feces or hemolymph. Hands should be washed thoroughly with soap and water after removal of the tick.

The most effective measures to prevent tick-induced infections have been to wear permethrin-treated clothing and tuck trouser legs into boots when spending time in tick-infested areas.¹⁵⁶ Wearing clothing that is tight around the ankles and wrists when walking through wooded areas is advised. After outdoor activities the skin along the hairline and clothing around the cuffs and collars should be examined. Bathing in a tub of water with a cup of added bleach is recommended after leaving tick-infested areas (see [Chapter 45](#), Lyme Borreliosis, for additional information on tick control).

241

29.2 CAT-FLEA TYPHUSLIKE ILLNESS (*RICKETTSIA FELIS* INFECTION)

In North America a typhuslike illness caused by *Rickettsia felis* has been reported in people in southern Texas,³⁵ California,¹³⁸ and Mexico.¹⁵⁷ Opossums (*Didelphis virginiana*) have been implicated as reservoir hosts in these areas, and the vector is the cat flea (*Ctenocephalides felis*). The disease in southern Texas and California overlaps that of human murine typhus caused by *Rickettsia typhi*, and opossums and fleas have been found to be coinfecting with both rickettsiae in these areas.¹³ In these areas, cat flea infection with *R. felis* is more common than with *R. typhi*.^{124,125,155} An infection cycle in people with *R. felis* and *C. felis* has been found in France, Germany, and Brazil.^{113,118} *R. felis* has been found in *C. felis* on dogs and cats in France,¹¹⁹ Spain,⁸⁴ Mexico,¹⁵⁹ the United Kingdom,^{67a,69} and Brazil¹⁰² and in ticks from Japan.⁶¹ Affected people develop cutaneous flea bite reactions, fever, hyperesthesia, myalgia, and a maculopapular rash.^{118,157} The infection probably exists worldwide in areas where cat fleas are prevalent. The rickettsial agent *R. felis* (previously “ELB agent”)⁵⁴ is ultrastructurally and serologically indistinguishable from *R. typhi* and *Rickettsia prowazekii* and has been identified by PCR in infected fleas, opossums, and people in the same area of the United States reported to be endemic for *R. typhi*.^{124,125} Despite these morphologic and serologic similarities, genetic analysis with phylogenetic comparison has placed *R. felis* in the SFG rickettsiae.¹⁴ PCR and restriction fragment length polymorphism identified *R. typhi* in four of five people from Texas who had typhus, and *R. felis* was found in the remaining person.¹²⁴ In addition to opossums, cats (but not dogs or rats) have been seropositive to *R. typhi* antigen in these areas.^{125,138} The newly recognized *R. felis* agent is the predominant rickettsiae (rather than *R. typhi*) in cat fleas found feeding on opossums in these endemic regions.^{125,155} It has not been cultured, although molecular techniques have been used to demonstrate its presence. *R. felis* is transmitted transovarially and transstadially in successive generations of *C. felis*.^{6,55} Infection can be maintained in cat fleas for up to 12 generations without the fleas having fed on an infected host.¹⁵⁰ Infection has also been transmitted among cats by infected fleas.¹⁴⁹ Cats may be likely hosts that transport infected fleas into human habitats. The reservoir potential of cats for *R. felis* and its pathogenicity for cats has not been determined. Experimental infection of cats has produced subclinical infection with seroconversion between 2 to 4 months.¹⁴⁹ In the United States, *R. felis* has been detected in cat fleas from California, Florida, Georgia, Louisiana, New York, North Carolina, Oklahoma, Tennessee, and Texas and is probably even more widespread.⁵ Although *R. typhi* and *R. felis* have never been found in the same fleas in these regions, experimental infections have produced coinfecting fleas.⁹⁹

29.3 RICKETTSIALPOX

Rickettsialpox, a nonfatal febrile zoonotic illness caused by *Rickettsia akari*, predominantly affects people in urban areas. Serum antibodies to *R. akari* were found in dogs examined during routine veterinary care in New York City.²⁴ Approximately 7% of the results of an ELISA screening test for antibody to *R. rickettsii* were positive, and seroprevalence increased with advancing age and a history of tick infestation. The dogs also had seropositive results to *R. rickettsii*; however, cross-absorption studies indicated a stronger reaction to *R. akari*. The only possible source of exposure for a person in North Carolina developing rickettsialpox was to capture mice brought in by a pet cat.⁷³ The maintenance of *R. akari* involves horizontal transmission between the house mouse (*Mus musculus*) and its mite (*Liponyssoides sanguineus*). Transovarial and transstadial transmission occurs in the mite. Seropositivity in dogs indicates that an alternative form of this cycle must exist. It is presumed that mites

Infectious Diseases of the Dog and Cat, 3rd Edition

feed on dogs, *R. sanguineus* has a broader host range than dogs under some circumstances, or other as yet unknown tick vectors are responsible for infecting dogs.

29.4 TYPHUS

Humans are the primary reservoirs of *louseborne typhus*, or *epidemic typhus*, a sporadic illness caused by *Rickettsia prowazekii* (see [Table 29-1](#)). It occurs when events favor proliferation and spread of lice, such as unsanitary conditions and natural disasters. Human cases of recrudescence or recently introduced typhus are thought to initiate outbreaks. The organism infects the louse's alimentary tract and is excreted in its feces. Irritation from biting lice causes the person to scratch their skin, thereby contaminating the abraded site with infected louse feces. Infection can also occur after rubbing contaminated hands on mucosal surfaces. Lice affected by *R. prowazekii* die within 1 to 3 weeks after ingestion of infected blood. Lice do not transmit the infection transovarially to their progeny. Another reservoir for this infection in people in the United States appears to be the southern flying squirrel. The clinical signs of disease in people are generally similar to those of RMSF. Antibody reactivity to typhus group rickettsiae has been observed in the sera of dogs suspected of having rickettsial disease.¹⁷ Rabbits have been experimentally infected by inoculation in attempts to transmit infection to lice.⁵⁸ *R. prowazekii* caused no illness or sustained infection in experimentally inoculated immunocompetent dogs.¹⁷ No information clarifies whether this organism infects cats.

Murine typhus, or *endemic typhus*, has a more worldwide distribution and is caused by *Rickettsia typhi*, which is transmitted by fleas (see [Table 29-1](#)). It is most prevalent in the temperate and subtropical climates where the reservoir rodent hosts and their fleas are found. The disease is transmitted by scratching of infected flea feces into a pruritic bite wound. Some transovarial transmission occurs, so direct bites from fleas can also produce illness. The clinical signs in people are very similar to those of RMSF. In the United States, murine typhus is endemic in southern California and South Texas. The natural host and vector system is the opossum and cat flea. Dog and cat owners were no more seropositive than nonowners, indicating that pet contact is not a risk factor for exposure.¹⁵²

Scrub typhus is a rickettsial disease of people caused by *Orientia* (previously *Rickettsia*) *tsutsugamushi* in southeastern Asia, the South Pacific, and Australia. It is transmitted by the chigger mite, and wild rodents and birds are reservoir hosts. Clinical signs are similar to those of RMSF. Dogs have been experimentally infected with *O. tsutsugamushi* without signs of clinical illness. The organism has been susceptible to tetracyclines and chloramphenicol; however, resistant strains of infection have been treated with fluoroquinolones.

29.5 Q FEVER

29.5.1 Etiology and Epidemiology

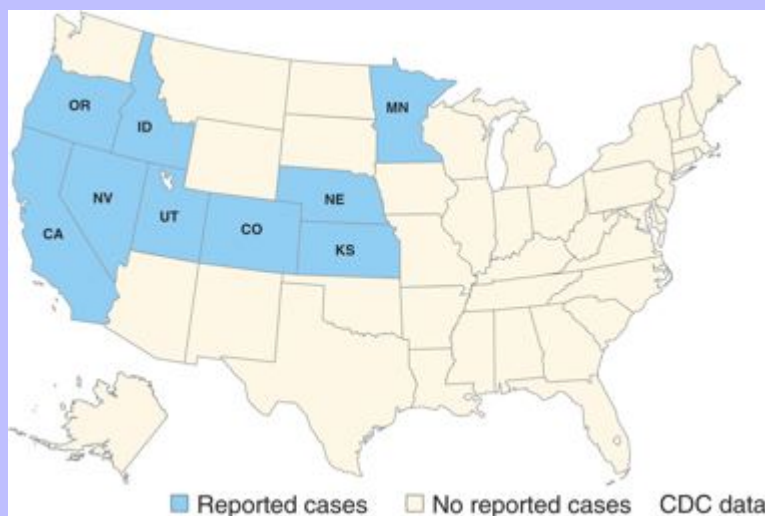

Query fever (Q fever) is caused by the obligate intracellular gram-negative bacteria *Coxiella burnetii* (see [Table 29-1](#)). The organism is not stained by the Gram technique, so the Gimenez method is used. It has been classified in the gamma subdivision of *Proteobacteria*, which also includes *Francisella*. The organism has two distinct life cycle stages that are morphologically and functionally different. The large-cell form is the metabolically active intracellular vegetative stage. The small-cell extracellular variant is thought to be metabolically inactive and is the environmentally resistant stage. Considerable genetic heterogeneity exists in geographically diverse isolates. Q fever is an endemic zoonosis worldwide except in geographically isolated countries such as Sweden, Norway, Iceland, and New Zealand, where reports of the disease are rare. In the United States, most of the reported cases are from the western region ([Fig. 29-10](#)). Reservoir hosts vary depending on the geographic location and include domestic and wild animals and their ectoparasites.

Infectious Diseases of the Dog and Cat, 3rd Edition

Approximately 40 species of ticks and many other arthropods are naturally infected with *C. burnetii*. The tick facilitates a sylvan cycle with reservoir animals. Resultant infection of people and domestic animals may occur when infected ticks feed on them. However, domestic animals and people are more commonly infected by inhalation or ingestion of environmentally resistant organisms. Cattle, sheep, and goats are the most common domestic animal reservoirs for human infection. Wildlife and farm animal species may be the reservoir hosts for domestic pets. Birds may also serve as reservoirs, and one outbreak was associated with exposure to aerosols of pigeon feces and bites from ticks feeding on these birds. Typically, animals are subclinically infected and shed environmentally resistant organisms in their urine, feces, milk, and parturient discharges. The female's uterus and mammary glands are the main sites of chronic infection and reactivation of infection occurs during pregnancy, so shedding mainly occurs during parturition. The placenta in late gestation may contain the greatest concentration of *C. burnetii* organisms (10^9 per g of tissue). Within the herd, infection is probably maintained by inhalation of infected dust and aerosols or by fomites.

C. burnetii sporulates and is highly resistant, maintaining viability in spite of elevated temperatures, desiccation, osmotic shock, ultraviolet light, and chemicals.¹²⁶ Hypochlorite (0.5%), phenolics (15%), formalin (5%), and quaternary ammonium compounds (2%) are not completely effective in killing the organism after 24 hours. After 30 minutes, solutions of alcohol (70%) or chloroform (5%) are effective in destroying *C. burnetii*.

Fig 29-10 Reported cases of Q fever in United States and U.S. territories in 2000. (Data from Centers for Disease Control and Prevention, Atlanta, Ga. Map courtesy University of Georgia, Athens, Ga.)

Serologic and organism isolation studies indicate that dogs and cats can be infected (Table 29-5). Dogs and cats may acquire infection under natural circumstances by tick bites or ingestion or inhalation of organisms while feeding on infected body tissues, milk, placentas, or carcasses. The prevalence of infection in dogs having contact with sheep is much higher than in those with no contact.¹² Inhalation of infected aerosols is also possible in contaminated environments. In one study, dogs had a higher prevalence of antibody (>50%) than cats (9%).¹⁵³ Data from seroprevalence studies in Japan show higher positive rates among stray cats than among pet cats.⁷¹ *C. burnetii* has been found in the blood of experimentally infected cats for 1 month and in

Infectious Diseases of the Dog and Cat, 3rd Edition

their urine for 2 months. It has been isolated from vaginal swabs of clinically healthy or ill cats at veterinary clinics⁹⁷ and from the uteri of postpartum cats and dogs.⁹¹ Bitches can shed coxiellae in their milk for 1 month and in urine for at least 70 days. Infected dogs and cats, especially those that are parturient, can be a source of infection for people. The organism was isolated from dogs on farms where human outbreaks of Q fever occurred and from *R. sanguineus* ticks that were feeding on the dogs. People have become infected via contact with pets that have acquired their infections from exposure to herbivores. Reports have described people becoming infected after exposure to aerosols from environments or fomites contaminated with parturient or aborted tissues from infected cats^{75,86-88,107} and a dog.²⁰

29.5.2 Pathogenesis

Studies of the time course and progression of illness have been established for people, and it is likely similar in animals. After inhaling organisms from infected fomites, the lungs appear to be the main portal of entry for the organism into the systemic circulation, and an atypical pneumonia develops. If the organism is ingested, the liver is prone to develop more severe lesions with resultant granulomatous hepatitis. The incubation period is shorter and severity of disease is greater when people are exposed to increasing numbers of organisms, after exposure to highly virulent strains, or when the organism is inhaled rather than ingested. This bacterium has a predilection for entry, replication, and persistence in macrophages; however, in the host, injured tissues include vascular endothelium and respiratory, renal tubular, and serosal epithelia. Widespread vasculitis causes focal necrotizing hemorrhagic pneumonitis and necrosis and hemorrhage of many other organs, including the liver, CNS, and mononuclear phagocyte system. After recovery, the virulent organism can persist in mononuclear phagocytes, and people can be latently infected with *C. burnetii* for extended periods. During chronic infection, immune complex phenomena can develop in many organs. During replication in the cell, highly resistant small-cell variants of the organism are produced. In chronically infected people and subclinically infected animals, the organism remains latent until parturition, at which time large numbers enter the placenta, parturient fluids, feces, urine, and milk. The highly resistant small-cell variants are dispersed in the environment. Chronically infected animals may continue to shed organisms in their urine and feces.

29.5.3 Clinical Findings

Infections in dogs and cats are usually subclinical. Splenomegaly is usually the only clinical finding in infected dogs. Fever, anorexia, and lethargy beginning 2 days after inoculation and lasting for 3 days occur in experimentally infected cats. Abortion has occurred in some of the cats and has also been associated with human outbreaks, but the organism has also been isolated from cats having normal parturition. A dog that transmitted the infection to people delivered pups that died within 24 hours of birth.²⁰ Animals do not usually develop the endocarditis and chronic infections found in people.

29.5.4 Diagnosis

Lymphocytosis and thrombocytopenia are the main nonspecific hematologic changes in infected people. Definitive diagnosis of Q fever is made by serologic testing or isolation of the organism. Isolation must be made in cell culture of macrophage or fibroblast lines, embryonated eggs, or laboratory rodents. All isolations must be made in biosafety level 3 laboratories. The Micro-IF test is the preferred method for measuring antibodies. Although information concerning human exposure can be obtained by examining a single serum sample, it is recommended that a second sample be submitted 4 weeks later. A fourfold increase in *C. burnetii*-specific IgG titer is diagnostic. Cross-reactions to organisms in closely related genera such as *Bartonella* occur. More than 50% of chronic Q fever patients have sera that cross-react at measurable but lower levels with *Bartonella henselae*, another zoonotic agent of cats (see [Chapter 54](#)).⁷⁶

Coxiella organisms undergo a phase variation in their outer surface proteins during the course of infection in people. Two separate phase antigens are used in detecting antibodies. Phase I antigens are isolated from organisms taken directly from animals or their parasites. This natural phase is highly infectious, contains large amounts of lipopolysaccharide (LPS), and forms smooth colonies in culture. Phase II antigens are found in organisms that have been passed serially in embryonated eggs, have a truncated LPS, and lack some cell surface antigens. During acute illness, antibody to phase II antigen increases, whereas antibody to phase I antigen is low. In chronic infections, antibody to phase I antigen equals or is greater than that of the phase II type.³⁷ Titers from cats involved in outbreaks have shown a similar pattern of reactivity to phase I and phase II antigens. Newer diagnostic tests that can provide a convincing diagnosis on a single sample involve measurement of specific IgM to phase II antigen or of IgA to phase I antigen using immunofluorescent or ELISA methods.^{26,137} Organism isolation is usually performed by inoculation of tissue samples into laboratory rodents whose serum and lymphoid tissues are examined for evidence of infection. PCR or immunohistochemical methods can be used for detection of *C. burnetii* in tissue culture or tissue specimens derived from patients.¹³⁹

Infectious Diseases of the Dog and Cat, 3rd Edition

29.5.5 Therapy

Rickettsiostatic drugs such as tetracyclines and chloramphenicol are as effective in the treatment of Q fever as in the treatment of RMSF; however, chronic infections in people are more difficult to resolve (see Table 29-4). Dosages that achieve higher serum concentrations (>5 ug/ml) of doxycycline are more effective in treating endocarditis.¹¹⁹ Use of erythromycin and trimethoprim-sulfonamide has been variably successful in treating infected people. Quinolones vary, with sparflaxacin being most effective in vitro;⁹¹ however, clinical use in people is accompanied by relapses. Newer erythromycin derivatives such as clarithromycin may be more effective.²⁰ Because many affected people recover spontaneously from their acute illness, interpretation of recovery is difficult without an untreated control population. The most successful in vitro combinations have included rifampin combined with doxycycline or trimethoprim. Chronic infections in people with endocarditis have been treated effectively with a combination of quinolones and doxycycline for 3 years⁷⁹; however, relapses are usual.

29.5.6 Prevention

Q fever vaccines are not available for animals or people. Experimentally, dogs have been vaccinated with formalin-inactivated phase I and phase II antigens and have developed humoral and cell-mediated immunity responses to *C. burnetii*.¹⁵⁴ Unfortunately, the vaccines or their adjuvants caused significant reactions at the inoculation sites.

29.5.7 Public Health Considerations

Human Q fever is usually contracted by inhalation of infected aerosols, such as after parturition or by ingestion of raw or poorly cooked food from livestock. Inhalation has been the suspected means of infection in outbreaks associated with parturient cats^{75,86-88} and a dog.²⁰ Because of occupational exposure, abattoir workers, wool sorters, tanners, farm workers (shepherds, dairy workers), and veterinary and laboratory personnel are particularly susceptible to infection from livestock. Investigational inactivated vaccines are available in the United States for such high-risk exposure groups. Acute infections in people are usually subclinical or are associated with a mild, flulike illness and spontaneous recovery. In some people, more persistent pneumonitis, myocarditis, hepatitis, meningitis, or other syndromes may develop from vasculitis throughout the body. People most at risk include those with previous cardiac valve defects, pregnancy, or immunosuppression. Chronic infections are associated with a delayed onset of endocarditis and include myocarditis or meningoencephalitis. Children, who are commonly infected after the ingestion of raw milk, are usually nonsymptomatic, regardless of the source of infection. Venereal transmission can occur among infected people, and females may transmit infection transplacentally.

Dogs have been reported to transmit infection to people on a few occasions. These have usually been rural exposures associated with farm dogs that have had exposure to sheep or their offal. Some of the previously reported outbreaks of Q fever in urban settings have related to exposure to environments contaminated by infected cats. In cat-associated Q fever, the incubation period, from time of contact until the first signs of illness, ranges from 4 to 30 days. The radiographic appearance of pneumonia in people infected from cats is more often associated with rounded pulmonary opacities.⁸⁸ Common source exposure is likely under such circumstances because the organism can be spread on clothing, dust, and other fomites to other people. Direct person-to-person transmission is uncommon but can occur because the organism is present in the body

Infectious Diseases of the Dog and Cat, 3rd Edition

secretions of infected people. Direct transmission between people has been most common in situations in which infected pregnant females deliver or abort their fetus.

After a prolonged incubation period (14 to 39 days), acute systemic manifestations consist of headache, fever ($\geq 40^{\circ}\text{C}$ [104°F]), chills, and myalgia. Less commonly, nausea, vomiting, diarrhea, arthralgia, or erythematous macules are noted. Although the respiratory tract is the usual source of infection and clinical or radiographic findings of interstitial pneumonitis may develop, respiratory signs occur infrequently. Signs of acute hepatitis may also occur. The acute illness generally lasts 15 days, and mortality rates are low, except in older or immunosuppressed individuals. A diagnosis is often made in infected people by measuring serum antibodies (see Diagnosis in this chapter).

Only a small number ($<1\%$) of patients with acute Q fever develop chronic illness. Chronic Q fever is a potentially fatal, multisystemic disorder that may develop up to 20 years after an acute episode. Signs of chronic endocarditis or hepatitis, such as fever, lethargy, dyspnea, cardiac murmurs, hepatomegaly, thrombocytopenia, and occasional thromboembolism or jaundice, occur.

29.5.8 Biohazard Potential

The environmental resistance, low infectious dose, spread by inhalation, and high environmental resistance of *C. burnetii* makes it a potential agent of bioterrorism.³

30 CHAPTER 30 Chlamydial Infections

Craig E. Greene

Jane E. Sykes

30.1 ETIOLOGY

The genus *Chlamydophila* is a member of the class *Microtobiotes*, order Chlamydiales, and family *Chlamydiaceae*. Chlamydophilae are obligate, generally gram-negative, intracellular parasites that, similar to bacteria, have a cell wall, DNA, and RNA but lack the metabolic machinery required for autonomous survival and replication. They multiply by binary fission within membrane-bound cytoplasmic vacuoles of host cells. They have an unusual developmental cycle that involves both extracellular (elementary body) and intracellular (reticulate body) forms (Fig. 30-1).

Elementary bodies are small (0.2 to 0.6 μm), resistant, metabolically inactive, infectious particles with rigid cell walls. They undergo a transient extracellular migration to infect new cells, where within vacuolar inclusions, they transform into larger vegetative replicating forms. These larger forms (0.5 to 1.5 μm), the reticulate bodies, lack cell walls and are noninfectious. The reticulate bodies proliferate by means of budding and fission within the cytoplasmic vesicle, or phagosome, of the host cell. This proliferation is followed by a phase of rapid division during which the initial bodies transform to become a large, membrane-bound population of elementary bodies. This cycle takes approximately 2 days. Elementary bodies are released from the cell after lysis and are able to infect new host cells.

Chlamydophilae persist on the ocular, respiratory, gastrointestinal (GI), and genitourinary mucosae. They produce inapparent-to-overt infections in a variety of hosts. The hosts provide a natural reservoir for these environmentally susceptible organisms. They spread directly between hosts via contact or aerosols, surviving only a few days in the environment at room temperature. Immunity to these organisms involves cellular and hormonal mechanisms. Their tendency to cause chronic, relapsing, or latent infections indicates that only a partial host immune response is evoked.

246

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 30-1 Sequential steps in the reproduction and development of *Chlamydia*. Two forms exist, the infectious elementary body (EB) and the replicative reticulate body (RB). In steps A-B, the EB transforms to the RB and replicates. Some RBs differentiate into EB (C), and the host cell lyses (E) resulting in infection of adjacent host cells and dissemination (rarely) to other tissues (F) via phagocytes. In cases when the body's immune response contains the infection, some RBs persist intercellularly (D) without replication. (Courtesy University of Georgia, Athens, Ga.)

Table 30-1 Comparison of Classification of Chlamydophila and Chlamydia

HOSTS	PREFERENTIAL TISSUES	BEFORE 1999	AFTER 1999
<i>Chlamydophila</i>			
Birds	Genital, lung, internal organs	<i>Chlamydia psittaci</i>	<i>psittaci</i>
Cattle, sheep	Brain, eye, joints	<i>Chlamydia pecorum</i>	<i>pecorum</i>
People, koala, horses	Lung, joints, endothelial	<i>Chlamydia pneumoniae</i>	<i>pneumoniae</i>
Sheep, mammals	Intestines, placenta	<i>Chlamydia psittaci</i>	<i>abortus</i>
Guinea pigs	Bladder, eye, spleen	<i>Chlamydia psittaci</i>	<i>caviae</i>
Cats	Eye, genital, joints, lung	<i>Chlamydia psittaci</i>	<i>felis</i>
<i>Chlamydia</i>			
People	Ocular and urogenital, neonatal lung	<i>Chlamydia trachomatis</i>	<i>trachomatis</i>
Rodents	Many internal organs	<i>Chlamydia trachomatis</i>	<i>muridarum</i>
Swine	Eye, intestines, lung	Novel species	<i>suis</i>

The genomic classification has undergone major revisions since 1999, and the family *Chlamydiaceae* has been divided into two genera, *Chlamydia* and *Chlamydophila* (Table 30-1).¹⁴ Previously, this family consisted only of the genus *Chlamydia*, composed of the species *C. trachomatis*, *C. pneumoniae*, *C. pecorum*, and *C. psittaci*.³² The genus *Chlamydia* now contains *C. trachomatis*, which causes ocular and urogenital disease in people, *C. muridarum*, which infects rodents, and *C. suis*, which infects swine. The genus *Chlamydophila* contains *C.*

Infectious Diseases of the Dog and Cat, 3rd Edition

percorum, previously *Chlamydia pecorum*, which infects cattle and sheep, *C. pneumoniae*, as well as four new species: *C. psittaci*, *C. abortus*, *C. caviae*, and *C. felis*, each derived from the formerly named species *Chlamydia psittaci*.¹⁴ *C. psittaci* is the type species for this genus and is the causative agent of psittacosis in birds. *C. felis* (previously *Chlamydia psittaci* var. *felis*) is the predominant organism of cats; *C. abortus* and *C. caviae* infect sheep and guinea pigs, respectively. *C. pneumoniae* is a human pathogen producing respiratory infections and has also been linked to coronary artery disease, asthma, cerebrovascular disease, sarcoidosis, and reactive arthritis.

In addition to genetic differences, the different species can be differentiated phenotypically by their monoclonal antibody (MABs) reactivity, and to a certain extent, morphologically and by their staining properties. The morphology of *C. psittaci* and *Chlamydia trachomatis* are virtually identical, but *C. pneumoniae* forms pear-shaped elementary bodies.¹⁶ *Chlamydia trachomatis* forms compact rigid cell wall inclusions, containing glycogen, that stain with iodine, a characteristic distinguishing it from *C. psittaci*. Generally, each *Chlamydomphila* species has a preferred host range, often of a few or single host animal species, sometimes producing respiratory, genital, and systemic illness. Isolates from cats worldwide are genetically similar with at least two subtypes.^{48,59} Serologic relationships may be more diverse.^{27,47} The following discussion concentrates on *Chlamydomphila* infections in dogs and cats.

30.2 EPIDEMIOLOGY

30.2.1 Dogs

Little information is available about the epidemiology of chlamydial infections in dogs.

30.2.2 Cats

Positive antibody titers to chlamydiae have been detected in as many as 9% of healthy, laboratory-reared cats and 45% of farm cats. Despite this high prevalence of seropositivity, *Chlamydomphila* were isolated from conjunctival or rectal swabs from only 6% and 4%, respectively, of clinically healthy cats. Isolation rates of up to 30% of household cats with conjunctivitis were reported.⁶⁸ Serologic studies in cats coupled with organism culture or genetic detection indicate that the chance of exposure and increasing immunity are greater with advancing age.^{49,58,68} Cats 2 to 6 months of age are likely to be infected with *C. felis*, as are cats up to 1 year of age. Thereafter, the prevalence of infection decreases, and cats older than 5 years of age are very unlikely to be infected with *C. felis*. Cats less than 8 weeks of age are less likely to be infected, presumably from passive immunity from nursing.

A primary mode of transmission of infection for neonatal kittens is thought to be from the genital mucosae of the dam during parturition. In older cats, transmission occurs from close direct or aerosol contact. Venereal transmission, as described in other hosts, has not yet been confirmed in cats. In epidemiologic surveys for respiratory disease, the prevalence of detection depends on the method used, geographic location, presence of clinical illness, and age of cats (Table 30-2). Cats over 1 year of age have progressively lower isolation rates as they continue to age, which likely relates to natural immunity and clearing of infection with advancing age. Conjunctivitis is more likely associated with *Chlamydomphila* infection, while sneezing is more likely in feline herpes virus type 1 (FHV-1) infections.⁵⁸ *Chlamydomphila* prevalence rates have been higher in the summer months.⁵⁸

Infectious Diseases of the Dog and Cat, 3rd Edition

Non-*C. felis* chlamydial DNA was detected in conjunctival specimens that was 99% homologous to the sequence of *Neochlamydia hartmannellae*, an amebic endosymbiont.⁶⁶ These chlamydiae were found in association with their obligate ameboid host, *Hartmannella vermiformis*. These organisms were not observed cytologically and such detection often involves tissue biopsy and confocal microscopy. This free-living amoeba has been identified as a cause of ocular surface infection in people and may have some role in feline ocular infections (see [Chapter 93](#)).

30.3 PATHOGENESIS

30.3.1 Dogs

Little is known about the course or genospecies of chlamydial infection in dogs. Presumably, it is similar to that of other host species; however, respiratory and genital infections have not been recognized and may be asymptomatic. Disease in the dog may reflect dissemination and persistence in deeper host tissues. Research in human infections, using polymerase chain reaction (PCR), shows that these organisms may enter a latent, noncultivable phase during which the host's immune reaction induces chronic immunopathologic lesions. Such has been shown with *C. trachomatis*, inducing Reiter's arthritis, and *C. pneumoniae*, causing atherosclerotic disease. Organisms likely spread to internal tissues during acute illness or immunosuppression. Using immunohistochemistry with MABs and PCR, chlamydiae have been detected in atheromatous lesions of the aorta, coronary, and splenic arteries of dogs.⁵²

30.3.2 Cats

Cats infected with *C. felis* develop upper respiratory signs, including fever, ocular discharge, and sneezing. The appearance of conjunctivitis parallels the ocular shedding of chlamydiae. The predominant feature is inflammation of the conjunctiva or nictitating membrane. A low dose produces unilateral signs, and higher doses produce bilateral illness.⁶¹ Organisms spread internally to colonize many tissues, including the tonsil, lung, liver, spleen, and kidney.³³ Infections often become chronic and insidious. Cats may become asymptomatic but harbor the organism in the conjunctiva for 2 months or longer. Organisms have been isolated from the conjunctiva for up to 215 days after experimental infection.^{45,67} Whether chronic disease is the result of repeated reinfection or the presence of persistent chlamydiae is unclear. Persistent chlamydiae in the form of atypical reticulate bodies have been identified in the joints of people with reactive arthritis. Localization of persistent chlamydiae to deeper tissues, such as the subsynovial layer in human patients with arthritis, may afford protection from the continual rapid turnover characteristic of epithelial tissues. Shedding from the reproductive tract has not been documented in kittens younger than 13 weeks, even though they shed organisms from the ocular discharges.⁶¹ When they are infected at 4 to 6 months or older, most of the animals shed organisms from the reproductive tract within a week after ocular inoculation. Reactivation of shedding may occur in late pregnancy. These factors suggest that the hormonal influence on reproductive tissues or immune system may be important for the replication of organisms in the reproductive tract. Long-term infections have been described as a sequel to some chlamydial infections in people and animals. The intestinal tract is a potential site of persistent infection in cats as has been seen in other species. Cell-mediated immune clearance is required to eliminate persistent intracellular pathogens. Co-infections with other agents such as feline coronavirus (FCV), FHV-1, *Bordetella*, or *Mycoplasma* may increase the clinical severity of infection and duration of shedding. Other bacteria, including those that normally colonize the healthy conjunctival sac, can also act as secondary invaders and worsen disease.

Infectious Diseases of the Dog and Cat, 3rd Edition

The febrile response in chlamydiosis is associated with chlamydemia, an acute phase reaction in which a release of interleukin (IL)-1, IL-6, tumor necrosis factor, and interferons occurs. Acute phase reactants and IL-6 are increased in plasma of experimentally infected cats.⁶¹

30.4 CLINICAL FINDINGS

30.4.1 Dogs

Chlamydiosis has not been well documented as a spontaneously occurring entity in dogs. Serologic surveys have detected antibodies to chlamydiae in up to 50% of healthy dogs. Chlamydiae have been suggested as a cause of chronic superficial keratitis in dogs; however, they can be found as ocular flora in clinically healthy animals. Although never established as the cause, chlamydiae were isolated from dogs with encephalitis and systemic illness. *Chlamydophila* isolated from a sheep with polyarthritis produced fever, anorexia, depression, pneumonia, joint pain, and diarrhea when experimentally inoculated into dogs.⁷² The organism has been reisolated from parenchymal tissues, the intestinal tract, and synovial fluid; lesions were focal hepatitis, lymphoid hyperplasia, fibrinopurulent polyarthritis, and meningitis. Chlamydiosis was diagnosed in a febrile dog with shifting leg lameness.¹ The organisms were demonstrated in the cytoplasm of macrophages in thoracic fluid, which had positive culture results for an avian strain, and the dog seroconverted. Systemic signs including lymphadenomegaly and arthritis were also described in a dog.²⁸ *Chlamydophila*-like organisms were detected by direct fluorescent antibody (FA) testing and PCR for *Chlamydophila* antigen in its joint fluid.

Table 30-2 Prevalence of Chlamydomphila Infection in Naturally Infected Domestic Cats Based on Culture or Genetic Detection Methods^a

COUNTRY/SAMPLES COLLECTED	CAT DEMOGRAPHICS	METHOD	NUMBER POSITIVE/NUMBER TESTED	PERCENT POSITIVE
Australia ⁵⁸ —conjunctival swabs	Conjunctivitis, rhinitis, keratitis	PCR	82/578	14.2%
	< 8 weeks of age		5/19	26.3%
	9 weeks to 6 months of age		22/79	27.8%
	1 to 11 months of age		6/22	27.3%
	1 to 5 years of age		21/142	14.8%
	5 to 10 years of age		4/87	4.6%
	> 10 years of age		3/46	6.5%
	Clinically healthy cats, various ages	PCR	1/95	1.1%
Japan ⁵ —conjunctival, some nasal swabs	Conjunctivitis, respiratory disease	PCR	39/66	59.1%
		Isolation-yolk sac	11/66	16.7%
Japan ⁴¹ —conjunctival swabs	Conjunctivitis, rhinitis	PCR	7/26	26.9%
Japan ²³ —conjunctival, nasal, oral swabs	Conjunctivitis, respiratory disease, stomatitis	PCR	7/52	13.5%
		Isolation-cell culture	6/52	11.6%
Italy ⁴⁹	Conjunctivitis	PCR	14/70	20%
	Clinically healthy cats	PCR	0/35	0%
Switzerland ⁶⁶	Conjunctivitis	PCR	114/226	50%
	Clinically healthy cats	PCR	7/30	23%
United Kingdom ⁶⁸	Conjunctivitis	Isolation-cell culture	226/753	30%
Scotland ³⁹ —conjunctival swabs	Clinical health status:	PCR		
	Ocular discharge		5/20	25%
	Recurrent or chronic conjunctivitis		7/39	18%
	Conjunctivitis and upper respiratory disease		6/33	18%
	Acute conjunctivitis		2/21	10%
	Upper respiratory tract signs only		3/43	7%
	Healthy in-contact cats		2/2	100%
	Healthy cats		0/6	0%
	Other disease		1/7	14%
	Unknown reason		5/45	11%
	Serologic indirect FA titer results:			
	< 1:20		0/24	0%
	1:20–1:40		0/10	0%
	1:80–1:160		3/15	20%
	> 1:320		9/22	41%

PCR, Polymerase chain reaction; FA, fluorescent antibody.

^a Numerous serosurveys show a higher prevalence of positive results, indicating that exposure to *Chlamydomphila* infection in cats is higher than the actual infection rate.

Infectious Diseases of the Dog and Cat, 3rd Edition

30.4.2 Cats

Chlamydiae have been recognized as a cause of ocular, nasal, and lower respiratory tract infections of cats (see [Chapters 16](#) and [93](#)); however, ocular signs are predominant. Typically acute, chronic, or recurrent conjunctivitis occur, and only sometimes are additional respiratory signs seen. Clinical signs are conjunctival hyperemia, chemosis, blepharospasm, and mucopurulent to serous ocular discharge ([Fig. 30-2](#)). Corneal disease is rare, and if present, is likely caused by other or co-infecting pathogens such as FHV-1 or bacteria. Most cats remain well and continue to eat. Pneumonia is generally subclinical; thus signs of coughing or dyspnea are rarely, if ever, seen. The strain and route of infection may influence the extent of respiratory involvement. Some cats develop nasal discharge and sneezing; however, signs of rhinitis such as sneezing or nasal discharge, without ocular involvement, are unlikely caused by *C. felis* infection.⁵⁸ *C. felis* has occasionally been isolated from neonatal conjunctivitis in kittens, although most kittens appear to be protected by maternal antibody.⁵⁶ Whether such cases are associated with genital infection in the queen, as occurs in people infected with *Chlamydia trachomatis*, is unclear.

Experimental infection of cats results in a systemic phase of disease that has been less commonly reported in natural infections. Following ocular inoculation, *C. felis* colonizes the GI and genital mucosae, resulting in persistent infection in some cats. In other studies, systemic signs of fever, lethargy, lameness, and weight loss have developed.⁶¹ These signs can develop within 2 weeks after those of conjunctivitis in cats infected by intraocular instillation of virulent organisms. Lameness has been observed in association with the febrile response in experimental infections of cats,⁶¹ and it may be similar to Reiter's syndrome, which follows human *Chlamydia trachomatis* infections. Although polyarthritis is the proposed mechanism, further study such as synovial fluid analysis is needed.

Fig 30-2 Marked chemosis and conjunctival inflammation in a cat with ocular *Chlamydophila* infection. (Courtesy University of Georgia, Athens, Ga.)

Chlamydiae were isolated from the superficial mucus-producing cells of the gastric mucosa in some cats.²⁰ No consistent association could be found of GI-infected cats with GI or respiratory signs, which may represent subclinical carrier infection. Chlamydiae were isolated from the gastric mucosa of young cats in research

Infectious Diseases of the Dog and Cat, 3rd Edition

colonies with signs of weight loss. Experimental inoculation of the gastric isolates into the respiratory tract produced upper respiratory tract infection similar to that caused by respiratory isolates and only mild gastritis in some cats.

Reproductive shedding of organisms and vaginal discharge occur following experimental conjunctival inoculation; however, clinical signs of reproductive dysfunction have not been substantiated with experimental or natural infections. Intravaginal and intraurethral inoculation has produced vaginal discharge and bleeding in female cats, urethritis and urethral discharge in male cats, and proctitis in both sexes. Instillation of organisms directly in the fallopian tubes resulted in 2 months of shedding, and suspected infertility from inflammation, resulting in scars and adhesions. Placental infection was documented in a cat experimentally infected by intraocular exposure during gestation. No histologic evidence of inflammation was found in the placental tissues or infection of the neonate; however, vaginal shedding commenced in the queen after parturition. Although the valvular structures in the feline reproductive tract may prevent chlamydial infection ascending from the vagina, hematogenous dissemination may allow the agent to relocate to the reproductive tract. Although *C. felis* DNA could not be detected using the PCR in serial blood samples collected from experimentally infected cats,⁶⁰ infection has been transmitted experimentally by blood transfusion, with subsequent development of systemic signs and conjunctivitis.⁶¹ Whether chlamydiae are responsible for reproductive disorders in cats is uncertain. Possibly, for *C. felis* to cause infertility or abortion, certain criteria may need to be met. The stage of pregnancy at which infection occurs, co-infection with other organisms, concurrent immunosuppression, route of infection, and the strain involved may be important. Genital infections are likely a means by which the organism is spread from queens to their kittens. FHV-1 may be responsible for a large number of suspected cases of *C. felis*-induced genital and perinatal disease.

Concurrent feline immunodeficiency virus (FIV) infection in cats prolonged the duration of conjunctivitis and clinical signs noted after ocular inoculation of *C. psittaci*.⁴⁵ Prolonged (270 days) excretion of *Chlamydophila* was noted in FIV infected cats compared with control cats (70 days). Peritonitis also was attributed to *Chlamydophila* infection in one cat.⁸

30.5 DIAGNOSIS

30.5.1 Cultivation

Culture of the organism is the most definitive diagnostic test. Isolations from cats are usually highest from conjunctival swabs, although nasal and pharyngeal isolations have been used. Culture of rectal and vaginal swabs may also yield organisms. The organism is occasionally isolated from aspirations or specimens of deeper tissues, such as the spleen, liver, or peritoneum. Vigorous swabbing of mucosal surfaces is essential to obtain enough epithelial cells that contain the organism. Cotton swabs are best; Dacron swabs or those with wooden sticks should not be used. To enhance organism survival, swabs should be placed immediately in a chlamydial transport medium such as 2SP (0.2 M sucrose and 0.02 M phosphate). Routine viral transport media containing antibiotics will inactivate the organisms. The sample should be refrigerated (4° C) if it is not immediately sent to the laboratory and ideally should reach the laboratory within 24 hours of sample collection. Specimens can also be frozen at -70° C, but this may result in the loss of some organisms and consequent false negatives.²⁹ Organisms can be cultured from swabs for up to 8 days at 22° C and 30 days when in tissues.³⁹ In the laboratory, organisms can be grown in the yolk sac of embryonating eggs or in monolayers of mouse, monkey, or human cells.¹³ Isolates are generally differentiated using genetic typing methods.

249

250

Infectious Diseases of the Dog and Cat, 3rd Edition

30.5.2 Microscopic and Enzyme-Linked Immunosorbent Assay Detection

For cytology, swabs or conjunctival spatulas are swiped across the inferior cul-de-sac, and cells are smeared on glass slides. The slides are air dried and fixed in acetone. Intracytoplasmic inclusions composed of clusters of coccoid (0.5- μm diameter) bodies are usually 10 μm in diameter in phagocytes or epithelial cells and stain basophilic (Fig. 30-3). Giemsa is the traditional stain for demonstrating *Chlamydiaceae*, but artifacts in the cytoplasm may stain similarly. Inclusions are generally visible only early, if at all, during the course of infection. Melanin granules in the cytoplasm of conjunctival epithelial cells can yield false-positive results. Direct FA techniques using MABs make identification more specific.

Enzyme-linked immunosorbent assay (ELISA) methodology can detect antigen directly in patient specimens. A variety of commercial antigen detection kits are available (see Appendix 6). Cross-reaction with all the members of the genera *Chlamydia* and *Chlamydophila* occurs with these tests as currently used commercially (Chlamydiazyme, Abbott Labs, Chicago, Ill.; IDEIA Chlamydia Test, Boots-Celltech Diagnostics Inc., East Hanover, N.J.). Unfortunately, these kits vary in their sensitivity and specificity. In general, ELISA methods have lower sensitivity and specificity as compared with cell culture or direct FA methods in detecting feline infections. See Appendix 6 for further information on test kits.

30.5.3 Genetic Detection

Until the development of DNA-based detection, the gold standard for diagnosis was cultivation as previously described. Currently, PCR and other DNA-based identification methods make speciation of isolates from culture or infected tissues routine. Furthermore, because the organism does not need to be viable for PCR testing, special transport conditions are not as critical as for culture. PCR followed by restriction digestion can distinguish all species of chlamydiae.¹³ *C. felis* strains worldwide appear similar to each other based on these restriction digests of the *ompA* gene.^{5,59} Real time quantitative PCR has been used to detect *C. felis* in cats.²² PCR has been used to detect *Chlamydophila* in atheromas of canine blood vessels.⁵² Variation in PCR methods can be traced to differences in nucleic acid extraction and primer selection. PCR methods are usually more sensitive compared with cultural isolation in which comparisons have been made in naturally infected cats (see Table 30-2). In experimental studies, PCR was more sensitive than was culture (PCR 85.7%, culture 72.9%) in untreated cats with or without clinical illness.⁶⁰ PCR and culture had equivalent sensitivity (100%) during the first month of infection in clinically ill cats; however, PCR was more sensitive during the second month (PCR 72.9%, culture 47.9%). During treatment of infected cats, culture results are positive for 1 day after treatment is initiated, and PCR results are positive for up to 5 days.⁶⁰ Presumably, this difference reflects the greater sensitivity of PCR and its ability to detect nonviable organisms. Discrepancy in viability occurs with death of organisms on transit to the laboratory or persistence of nucleic acid when organisms die in the host. Chlamydial DNA has been detected in samples placed in the environment up to 10 weeks at 22° C, well beyond its viability based on culture.³⁹ A multiplex PCR procedure has been developed to simultaneously detect three feline respiratory pathogens, chlamydiae, FCV, and FHV-1, in mucosal swabs.⁵⁷

30.5.4 Serologic Testing

Serologic testing can be used to distinguish the various species of chlamydiae. Unfortunately, testing for serum antibodies to chlamydiae is of limited diagnostic benefit in determining active infection because the IgG antibody titer increase is variable or prolonged, and IgM antibody titers are inconsistently elevated. However, the highest antibody titers are generally associated with symptomatic cats.⁶⁸ Chlamydial infections persist in the presence of high serum antibody levels; therefore serologic testing documents only exposure and cannot be used to evaluate protection afforded by vaccines. Higher indirect FA antibody titers correlate with recent infection and may correspond with the isolation of *Chlamydomphila* in the clinically healthy animal.³⁹ Seronegative animals are less likely to be carriers. Unfortunately, serologic tests are not widely available. Serial titers may be needed to document active infections, and recent vaccination may interfere with interpretation of positive titer results.

30.6 THERAPY

Treatment of chlamydial infections has involved primarily antimicrobial therapy. In evaluating the response to treatment, also important to consider is concurrent presence of the viral causes of feline upper respiratory tract disease (see [Chapter 16](#)). Treatment of co-infected cats may result only in temporary improvement caused by resolution of secondary bacterial and *Chlamydomphila* infections.

Recommended dosages for all drugs are in [Table 30-3](#). Most of the information on therapeutic efficacy involves cats. Oral administration of tetracycline is usually preferred at a dosage of 22 mg/kg three times daily for 3 to 4 weeks or doxycycline at 5 to 10 mg/kg twice daily for the same period. A dose of 10 to 15 mg/kg once daily can also be used.^{53,55} Higher dosage rates of doxycycline are used for cats to avoid giving partial tablets. Crushed or

250

Infectious Diseases of the Dog and Cat, 3rd Edition

251

broken tablets are not recommended because of the risk of causing esophagitis; administration of doxycycline suspension is least likely to be associated with this problem. Tetracyclines have also been associated with toxic hepatitis or dental staining. However, doxycycline is less likely to stain the teeth because of its reduced calcium-binding avidity (see Drug Formulary, [Appendix 8](#)). Ocular infections alone may respond to tetracycline eye ointment applied three times daily, although the likely systemic nature of the infection must be considered.

Table 30-3 Recommended Therapy for Chlamydiosis

DRUG ^a	SPECIES	DOSE ^b (mg/kg)	ROUTE	INTERVAL (HOURS)	DURATION (WEEKS)
Amoxicillin-clavulanate	B	12.5–25	PO, SC, IV	12	4
Doxycycline	B	5–10	PO, IV	12	3–4
	C	10–15 ^c	PO	24	3–4
Tetracycline	B	22	PO	8	4

B, Dog and cat; C, cat; PO, by mouth; SC, subcutaneous; IV, intravenous.

- a For additional information, see Drug Formulary, [Appendix 8](#).
- b Dose per administration at specified interval.
- c The dose should be rounded off to the nearest whole- or half-tablet size to help prevent esophagitis. In addition, small amounts of food or water should be administered after each dose to help rinse the tablet into the stomach.

Experimentally infected cats, treated with oral doxycycline, have shown clinical improvement beginning 24 to 48 hours after treatment was instituted compared with placebo-treated cats or those treated with topical antimicrobial therapy.^{53,60} Three weeks' duration has been effective.⁶⁰ In cat colonies with chlamydial infection, treatment may have to be continued for up to 6 to 8 weeks to ensure that all cats have been successfully treated. The entire population may have to be treated simultaneously. Treatment should always continue for at least 2 weeks after the resolution of clinical signs.

In other studies, experimentally infected cats were treated with amoxicillin-clavulanate, doxycycline, or placebo for 19 days.⁵⁵ Both treated groups had a reduction in isolation rates and improvement in clinical signs, with slightly better initial efficacy at 2 to 4 days with the amoxicillin-clavulanate. However, a majority of the cats treated with amoxicillin-clavulanate had a relapse of infection 14 to 20 days after treatment was discontinued. These cats had to be retreated for 4 weeks, and recovery was complete when monitored for 6 months. Treatment with amoxicillin-clavulanate has less risk of potential side effects as compared with tetracyclines. In addition, some cats will eat amoxicillin-clavulanate but not doxycycline tablets voluntarily.⁵⁵ Both doxycycline and amoxicillin-clavulanate can be considered as effective treatment for chlamydiosis. Drugs such as sulfonamides or chloramphenicol are ineffective, and penicillin is only inhibitory in vitro at higher doses.⁵⁶

Infections with *Chlamydia trachomatis* in people are susceptible to treatment with other drugs such as erythromycin and its newer derivative, azithromycin, and with fluoroquinolones and rifampin. Controlled studies have not been conducted in *C. felis*-infected cats with many of these other drugs; however, azithromycin has been recommended on an empirical basis to treat cats on a once-daily or once-weekly dosage regimen.⁵¹ In other studies with *C. felis*-experimentally infected, specific-pathogen-free cats, azithromycin suspension was given at 10 to 15 mg/kg, orally, daily for 3 days and then twice weekly thereafter for a total treatment period of 4 weeks.⁴⁶ This regimen produced rapid resolution of clinical signs, and organisms were no longer able to be isolated after 6 days. However, *C. felis* was subsequently isolated beginning 14 days after institution of treatment. Even daily administration of azithromycin for a similar period was ineffective in clearing the infection. In comparison, cats

Infectious Diseases of the Dog and Cat, 3rd Edition

receiving doxycycline tablets at 10 to 15 mg/kg once daily for 4 weeks had a clearing of their infection after 6 days for the duration of the observation period. Because of these findings, azithromycin is not recommended for treatment of *C. felis* infections.

Most of the treatment studies in infected cats have relied on culture to determine the efficacy of therapy in eliminating *C. felis*. In cats with natural disease that tested positive using PCR, recent treatment with antichlamydial drugs or glucocorticoids was not associated with a lower prevalence of infection.⁶⁰ This finding may indicate a lack of efficacy of currently used drugs or the increased sensitivity of PCR to detect latent infections. Nucleic acid detected using PCR may also be nonviable. Further studies may be needed using PCR to determine if the carrier state is eliminated.

30.7 PREVENTION

Kittens acquire maternal antibodies to *C. felis* that usually protect them from infection until 7 to 9 weeks of age. Both inactivated and modified live vaccines have been available to protect cats from chlamydial respiratory disease (see Prevention, [Chapter 16](#), and Feline Viral Respiratory Disease, [Chapter 100](#)). Even modified live vaccines, which provide the best protection, do not entirely prevent colonization of mucosae and shedding of chlamydiae after challenge. They minimize the replication of the organism and hence reduce the clinical signs in subsequently infected cats. A delayed postvaccinal reaction of transient fever, anorexia, lethargy, and occasional limb soreness 7 to 21 days after use of combined vaccines containing modified live *Chlamydophila* has been reported in a low percentage of cats (see Postvaccinal Complications, [Chapter 100](#)).⁵⁹ These vaccines are indicated only for cats with a high risk of acquiring infection, such as those in catteries with endemic chlamydiosis. Transmission of the organism will also be minimized by good hygiene, quarantine, and disinfection practices in cattery situations. The organism is readily inactivated by detergents.

30.8 PUBLIC HEALTH CONSIDERATIONS

Chlamydophila of feline origin has been suspected as the cause of human conjunctivitis on several occasions. Many of these associations have never been substantiated, because of the lack of valid scientific tests to identify specific species and isolates. Relatively crude methods, such as serologic similarities or biochemical features, have been used to characterize the isolates. Many of the reports of human chlamydiosis from cats before the advent of genetic typing cannot be substantiated. For example, *Chlamydophila* has been associated with cat scratch disease in people; but recent studies suggest that this association was inaccurate because of cross-reactivity between some species of *Chlamydophila* and *Bartonella* on serologic tests.^{35,36,64}

With the new focus on genetic detection, many of these concerns of identifying particular *Chlamydophila* species can be addressed. *C. felis* was isolated from the conjunctiva of a person with nontrachomatous *Chlamydia* infection.²¹ This organism was genetically indistinguishable from an isolate later recovered from the patient's cat. Although these associations have been difficult to document, people should take precautions in medicating cats with conjunctivitis, and infected cats may have to be treated with systemic antimicrobials simultaneously with people in households in which people develop chlamydial conjunctivitis.

The interspecies transmission of avian chlamydiosis (psittacosis, ornithosis, *C. psittaci*) from birds to people is a better-substantiated veterinary and public health problem.¹² *Chlamydophila* causing conjunctivitis in a cat was suspected to have been acquired from a pet macaw in the same household.³⁰ The *C. psittaci* strain causing infection in birds is known to cause human psittacosis. In another household, three humans and three dogs

Infectious Diseases of the Dog and Cat, 3rd Edition

developed infection attributed to psittacosis from a cockatiel.¹⁹ Although the bird was euthanized, the affected people and dogs had clinical recovery with treatment.

C. pneumoniae is a ubiquitous pathogen that causes acute respiratory disease in people and has been incriminated as a cause of coronary and cerebral vascular disease.^{6,17} People appear to be the reservoir host for this agent, and it is not known to infect dogs or cats. However, similar vascular lesions have been attributed to chlamydial infection in dogs (see previous discussion on Pathogenesis). Rabbits and mice can be experimentally infected with this organism. Veterinarians should have knowledge of this relationship because they may be questioned regarding the risk of pets for this infection in people. Virtually all people are infected with *C. pneumoniae*, and many become reinfected. Antibody prevalence to this organism increases with advancing age. Following treatment, the organism can be detected with PCR in tissues of people, even after it can no longer be cultured. The metabolically inactive elementary bodies are not affected by antibiotics and may persist in the body for indefinite periods. Morphologic studies have shown this organism in atheromatous plaques of coronary and large blood vessels. The definitive relationship between their presence and vascular disease remains to be established.

31 CHAPTER 31 Hemotropic Mycoplasmosis (Hemobartonellosis)

John W. Harvey

31.1 ETIOLOGY

Hemotropic mycoplasmas are gram-negative, nonacid-fast, epicellular parasites of erythrocytes. These organisms were classified as rickettsia in the genera *Haemobartonella* and *Eperythrozoon* for many years; however, results from recent sequencing of the 16S rRNA gene indicate that they are mycoplasmas.^{15,42,51} Consequently, *Haemobartonella* and *Eperythrozoon* genera are being discarded and these hemotropic parasites being moved to the genus *Mycoplasma*. Species names often include the prefix “haemo-” (e.g., *Mycoplasma haemofelis*) to identify these unique mycoplasmas that attach to erythrocytes. Haemoplasmas has been proposed as a general name for these hemotropic mycoplasmas.⁴⁷

Hemotropic mycoplasmas contain DNA and RNA and replicate by binary fission. These organisms have not been cultivated outside their hosts. Hemotropic mycoplasmas are distinctly different from *Bartonella* organisms, which are bacteria that can be cultured in cell-free media.

31.1.1 Hemotropic Mycoplasmas in Cats

Two distinctly different hemotropic mycoplasmas have been identified in cats based on 16S rRNA gene sequences. The similarities of gene sequences between these organisms is only about 83%.¹⁶ One organism was previously referred to as the *Haemobartonella felis* large (Hflg) variant because the organism appeared larger than the second organism, which was referred to as the *H. felis* small (Hfsm) variant.¹⁵ The Hflg organism is now classified as *M. haemofelis*,⁴⁸ and the Hfsm organism is now classified as *Mycoplasma haemominutum*.¹⁶ Organisms previously classified as Florida, Ohio, Oklahoma, and Illinois isolates of *H. felis* are now classified as *M. haemofelis* isolates, and organisms previously classified as California and Birmingham isolates of *H. felis* are now classified as isolates of *M. haemominutum* based on similarities in the sequence of the 16S rRNA gene (Table 31-1).⁵⁵ An Australian strain of *M. haemofelis* has been reported with a 16S rRNA gene sequence identical to the Ohio and Florida isolates.¹¹

253

In polychrome-stained blood films, hemotropic mycoplasmas appear as small (0.3 to 0.8 μ m), blue-staining cocci, rings, or rods that are usually attached to erythrocytes (Fig. 31-1). The genome size of *M. haemofelis* is about 1200 kb.² In thick blood films or thick areas of thin films, nearly all organisms appear as cocci. Ring- and rod-shape organisms are seen more readily in thin blood films or the feathered edges of thick blood films. *M. haemominutum* organisms are rarely observed in stained blood films from infected cats. When seen, *M. haemominutum* appear as small rods, rings, or coccoid organisms that are reported to stain less densely and measure about half the size of *M. haemofelis*.¹⁵⁻¹⁷ However, this reported size difference has been challenged by the finding of a *M. haemominutum* isolate in Great Britain that is about 0.6 μ m in diameter.⁵⁵ Morphologic appearance is not reliable in distinguishing isolates, and genetic analysis is needed for specific identification.

The epicellular nature of *M. haemofelis* on erythrocytes is readily apparent by scanning electron microscopy (EM) examinations (Fig. 31-2). Organisms appear to be partially buried in indented foci on the surface of the erythrocytes. Discoid, conical, coccoid, rod-shape, and doughnut-shape organisms have been observed.

Infectious Diseases of the Dog and Cat, 3rd Edition

Parasitized erythrocytes generally lose the normal biconcave shape and become spherocytes or stomatospherocytes.

The epicellular nature of *M. haemofelis* parasites is also readily apparent by transmission EM (Fig. 31-3).⁵³ A single membrane surrounds the organisms. The cytoplasm of organisms is composed of granules that vary in size and density. No cytoplasmic organelles have been recognized. Electron-lucent areas (vacuoles) appear to be present in some organisms. Organisms appear to adhere to the erythrocyte membrane by intermittent contact points. Although smudging of the erythrocytic membrane in association with organism attachment has been reported, complete erosion of the membrane has not been documented.

Table 31-1 Comparison of Hemotrophic Mycoplasmas of Cats

SPECIES	<i>MYCOPLASMA HAEMOFELIS</i>	<i>MYCOPLASMA HAEMOMINUTUM</i>
Synonyms	Large variant <i>Haemobartonella felis</i> Ohio strain Florida strain Oklahoma strain Illinois strain	Small variant <i>Haemobartonella felis</i> California strain Birmingham strain
Morphologic findings	Common in blood films Coccoid in thick smear Ring and rod in thin areas	Rare in blood films, stain lightly Small rods, rings, or coccoid
Clinical illness	Mental depression, fever, anemia, dehydration, hepatosplenomegaly, lymphadenomegaly, icterus, dyspnea	Minimal or absent

31.1.2 Hemotrophic *Mycoplasma* Organisms in Dogs

Mycoplasma haemocanis (formerly *Haemobartonella canis*)^{39,44} is considered to be the causative agent of hemotrophic mycoplasmosis in dogs; however, the sequence of the 16S rRNA gene of *M. haemocanis* was remarkably similar (99% homology) to that of *M. haemofelis*, suggesting that these agents might be different strains of the same organism.⁸ Other studies evaluating RNase P gene sequences demonstrated a lower degree of sequence homology between the two organisms (about 95%), indicating that the organisms may be different species.⁶

253

254

Fig 31-1 *M. haemofelis*(A) and *M. haemominutum* (B; arrow) in blood films from infected cats (Wright stain, $\times 1600$). (B, Courtesy Janet Foley, University of California, Davis, Calif.)

Fig 31-2 Scanning electron photomicrograph of erythrocytes from a cat infected with *M. haemofelis* ($\times 5000$). (Courtesy Dallas Hyde, University of California, Davis, Calif.)

M. haemocanis differs morphologically from *M. haemofelis* in that it more commonly forms chains that extend across the surface of affected erythrocytes (Fig. 31-4). However, individual organisms may also appear as small cocci, rods, or rings.

Results of scanning and transmission EM studies of *M. haemocanis* indicate that it is ultrastructurally similar to *M. haemofelis*. Although single organisms dimple the surface of host erythrocytes in a manner similar to that described previously for *M. haemofelis*, chains of organisms are frequently found in grooves or deep folds, which can markedly distort the erythrocyte shape.

A novel small haemoplasma, '*Candidatus mycoplasma Mycoplasma haematoparvum*,' which is genetically more closely related to *M. haemominutum* than *M. haemofelis*, was isolated from the blood of a splenectomized dog with hematopoietic neoplasia.^{53a} In a study involving PCR of blood from dogs in France, this novel organism was more prevalent than *M. haemocanis*.³⁰

Infectious Diseases of the Dog and Cat, 3rd Edition

31.2 EPIDEMIOLOGY AND PATHOGENESIS

31.2.1 Cats

Based on the morphologic appearance of the organisms, clinical signs, and laboratory findings, it appears that most publications concerning feline hemotropic mycoplasmal infections published before 1998 involved *M. haemofelis*. The Florida and Ohio strains of the organism used in experimental studies cited in this chapter were shown to be *M. haemofelis* by the polymerase chain reaction (PCR) and sequencing of the 16S rRNA gene.⁵¹ Reports to date indicate that *M. haemofelis* often produces anemia and clinical signs of disease, whereas *M. haemominutum* generally results in inapparent infections and a minimal change in hematocrit (HCT), unless complicated by feline leukemia virus (FeLV) infections.^{15-17,54,61} The following discussion focuses on the pathogenesis of disease associated with *M. haemofelis* infection.

Fig 31-3 Transmission electron photomicrograph of five *M. haemofelis* organisms in intermittent contact with the plasmalemma of a parasitized erythrocyte (×17,000). (From Simpson CF, et al. 1978. Ultrastructure of erythrocytes parasitized by *Haemobartonella felis*, *J Parasitol* 64:504-511.)

Fig 31-4 Two erythrocytes parasitized by *M. haemocanis* organisms.
(Wright-Giemsa stain, ×1800)

Experimentally, *M. haemofelis* infection has been transmitted by intraperitoneal and intravenous (IV) injection and oral (PO) administration of infected blood. Dissemination of infection by blood-sucking arthropods such as fleas is considered by many to be the primary mode of transmission, although such transmission has not been established experimentally in cats. *M. haemofelis* can be transmitted from queens with clinical disease to their newborn offspring in the absence of arthropod vectors. It is not known whether transmission occurs in utero, during parturition, or via nursing. Iatrogenic transmission of *M. haemofelis* can occur by the transfusion of blood from normal-appearing carrier cats.

254

255

The severity of disease produced by *M. haemofelis* varies, with some cats having mild anemia and no clinical signs and some cats having marked depression and severe anemia leading to death.

To facilitate the understanding of feline hemotropic mycoplasmosis caused by *M. haemofelis*, the disease has been divided into preparasitemic, acute, recovery, and carrier phases, or stages (Fig. 31-5).²⁶ The preparasitemic phase is generally about 1 to 3 weeks after IV injection. The acute phase of disease represents the time from the first to the last major parasitemia. This phase often lasts a month or more, but occasionally cats die quickly from massive parasitemias and precipitous decreases in HCT early in the course of the disease. Parasites generally appear in the blood in a cyclic manner within discrete parasitemic episodes (see Fig. 31-5). The number of parasites generally increases to a peak value over 1 to 5 days, followed by a rapid decline. The synchronized disappearance of organisms from the blood can occur in 2 hours or less. Few if any parasites are

Infectious Diseases of the Dog and Cat, 3rd Edition

seen in blood films for several days following parasitemic episodes, although low numbers of organisms can still be detected in blood using PCR.^{3,56}

In many instances a rapid decrease in HCT followed by a rapid increase occurs in association with the appearance and disappearance of large numbers of organisms from the blood. These fluctuations in HCT appear to be associated with splenic sequestration of parasitized erythrocytes and with later release of nonparasitized erythrocytes. In other instances the HCT remains lower or continues to decline for 1 or more days after a parasitemic episode, probably as a result of erythrocyte destruction.

Fig 31-5 Daily measurements of hematocrit (HCT, or packed cell volume [PCV]), rectal temperature, and blood parasite value in a cat after IV inoculation with *M. haemofelis*-infected blood on day 0. Closed arrows indicate intravenous administration of thiacetarsamide sodium (1 mg/kg). Open arrow at day 60 indicates a 25-ml IV whole blood transfusion. Phases of disease are indicated by letter and shading, with A being the preparasitemic phase, B the acute phase, C the recovery phase, and D the carrier phase. (From Harvey JW, Gaskin JM. 1977. Experimental feline haemobartonellosis, *J Am Anim Hosp Assoc* 13:28-38.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Repetitive parasitemic episodes appear to cause progressive erythrocyte damage and shortened erythrocyte life spans. Some damage to erythrocytes may be caused directly by the parasite, but immune-mediated injury appears to be more important. Coombs' (direct antiglobulin) tests (37° C) may have positive results within a week following the first parasitemia, and Coombs' test results generally remain positive during the acute stage of disease, regardless of whether parasites are present. It is postulated that the attachment of organisms to erythrocytes either exposes hidden erythrocyte antigens or results in altered erythrocyte antigens, and the host responds by producing antierythrocyte antibodies. Specific antibodies against *M. haemofelis* antigens have been detected in serum within 14 days after experimental infections.¹ Consequently, another possible mechanism of immune-mediated injury should also be considered. If antibody-mediated complement fixation occurs, the erythrocytic membrane may be damaged as an “innocent bystander.” However, minimal intravascular hemolysis occurs in this disorder. The anemia occurs primarily as a result of extravascular erythrophagocytosis by macrophages in the spleen, liver, lungs, and bone marrow.

As a lymphocyte- and macrophage-rich blood filter, the spleen is of primary importance in the clearance of bloodborne particulate antigens and the elaboration of specific immune responses to these antigens. In animals other than the cat, splenectomy is generally required before clinical disease is produced by the various species-specific hemotropic mycoplasmal organisms. *M. haemofelis* organisms are removed less readily in splenectomized cats, resulting in parasitemias that last about twice as long as those in intact cats. However, splenectomy performed before infection does not appear to affect the incubation period or severity of disease in cats. Splenectomy after cats have recovered results in transient reappearance of blood parasites, but in most animals the HCT does not drop to a clinically significant level. 255 256

Without therapy, up to one third of the cats with uncomplicated acute *M. haemofelis* infection die as a result of severe anemia. Cats that mount a sufficient immune response to the organism and a regenerative bone marrow response that compensates for the erythrocyte destruction recover from the disease. The recovery phase—the time from the last major parasitemia until the HCT has stabilized within or close to the reference range—often takes a month or more. In untreated cats, organisms are commonly observed in low numbers in the blood during the recovery phase but do not usually occur as discrete parasitemic episodes.

Cats that recover from acute infections with *M. haemofelis* remain chronically infected for months to years, if not for life. Although an extracellular parasite should be eliminated by immune mechanisms, intact organisms have been reported within phagocytic vacuoles of splenic and pulmonary macrophages. Some organisms may survive within these cells, which would account for the indefinite, chronically infected state (although in situ hybridization studies of an infected cat using a specific DNA probe only demonstrated organisms on erythrocytes).⁵ Carrier cats (those with latent infections) appear clinically normal. They may have a normal HCT or mild regenerative anemia. Low numbers of organisms are regularly observed in some cats, but in others no organisms are visible in blood films for weeks. Carrier cats appear to be in a balanced state in which replication of organisms is balanced by phagocytosis and removal of organisms.

M. haemofelis may be an opportunistic agent that exists commonly in healthy cats and produces disease when the cat is stressed by other diseases or surgical procedures; however, some cats with hemotropic mycoplasmosis do not have identifiable predisposing disease or stress conditions. Cat-bite abscesses appear to be the most frequent disorder recognized to precede hemotropic mycoplasmosis by a few weeks. Although an abscess is undoubtedly stressful, the possibility of transmission of the disease through a cat bite should be considered. Other factors associated with an increased likelihood of finding *M. haemofelis* organisms in stained blood films include male sex, lack of vaccinations, outdoor roaming, and positive FeLV and feline immunodeficiency virus (FIV) tests.^{18,21}

Infectious Diseases of the Dog and Cat, 3rd Edition

Of particular interest is the possible interrelationship between *M. haemofelis* and FeLV-produced disease. About 40% to 50% of cats with clinical hemotropic mycoplasmosis are FeLV positive.^{18,21,59} Because FeLV can suppress the normal immune response to unrelated antigens, this viral infection might increase the susceptibility of cats to hemotropic mycoplasmosis or convert a latent hemotropic mycoplasmal infection into a patent infection with clinical disease. However, experimental studies have demonstrated that the opposite can also occur (i.e., *M. haemofelis* infection can increase the susceptibility of cats to FeLV infection).³¹ Regardless of how the concurrent infections occur, infection with *M. haemofelis* and FeLV generally results in more severe anemia and clinical signs than occurs with infection by either agent alone.^{7,21,31} In contrast, concurrent infection with FIV and *M. haemofelis* does not appear to cause more severe anemia than does *M. haemofelis* infection alone.^{21,50}

Limited information is available concerning the pathogenesis of *M. haemominutum* infections. Substantial parasitemias can occur in blood with little change in HCT,^{55,56} a finding that has been reported in nonsplenectomized cattle infected with a similar hemotropic mycoplasma.⁵⁸ However, a mild regenerative anemia can occur in some cats infected only with *M. haemominutum*. As in *M. haemofelis*-infected cats discussed previously, cats co-infected with FeLV and *M. haemominutum* have more severe anemia than cats only infected with *M. haemominutum*.¹⁷ In addition, the stress of infection with *M. haemominutum* may induce the development of myeloproliferative disease in FeLV-infected cats.¹⁷

Although some investigators indicate that infection with *M. haemominutum* is protective against challenge with the virulent *M. haemofelis*,¹⁶ other investigators report that cats chronically infected with *M. haemominutum* are not protected against *M. haemofelis* infection.⁶¹ This latter group of investigators provides evidence that the anemia occurring with combined infections is more severe than the anemia occurring in cats only infected with *M. haemofelis*. Prior infection with one strain might predispose cats to having heightened immune-mediated responses when they become infected with a second strain.⁵⁷

31.2.2 Dogs

Transmission of *M. haemocanis* by the brown dog tick (*Rhipicephalus sanguineus*) has been demonstrated experimentally.⁵² Transstadial and transovarial transmission in ticks has also been described, indicating that the tick may be an important reservoir as well as a vector of infection. Iatrogenic transmission of *M. haemocanis* organisms by blood transfusions from clinically normal carrier dogs can also occur but is of less concern than it is in cats, because the recipient dog generally must be splenectomized before clinically significant disease occurs. Hemotropic mycoplasmosis resulting in the death of two animals from a litter of 4-week-old pups was reported.²⁴ Experimental studies to demonstrate transmission to puppies in utero or through nursing have not been successful, but indirect evidence for in utero transmission has been found.³⁴ Transmission by PO administration of infected blood has also been reported.³⁸

In contrast to *M. haemofelis* infection in cats, most nonsplenectomized dogs infected with *M. haemocanis* do not develop clinical evidence of disease. They probably do not become anemic or have sufficient numbers of organisms present in the blood to be recognized during routine blood film examination.

The prepatent period following IV injection of infected blood into splenectomized dogs has been reported to range from 1 or 2 days to 2 weeks or more. Some cases have been characterized by a rapidly progressive

Infectious Diseases of the Dog and Cat, 3rd Edition

anemia associated with nearly constant parasitemia. In these dogs, death generally occurs within a month following inoculation. In other dogs the development of anemia is more gradual, occurring as a result of repetitive parasitemic episodes. Parasites are generally observed in large numbers in the blood for a week or more, with a few intervening days when organisms are not observed. Approximately 1 to 2 months are generally required for the HCT and hemoglobin concentration to drop to minimum values, and an equal time is required for them to return to normal. Although immunologic evaluation of infected dogs has been limited, it appears that antibodies are produced against erythrocytes.

Although splenectomy is generally required before clinically significant hemotropic mycoplasmosis occurs in dogs,^{30a,b,33,37,46} cases have been described in nonsplenectomized dogs with concurrent *Ehrlichia*, *Babesia*, bacterial, and viral infections.²⁸ Hemotropic mycoplasmosis has also occurred in dogs given immunosuppressive drugs²⁰ and in dogs with pathologic splenic symptoms. Rare cases have occurred in spleen-intact dogs in which no evidence for immunosuppression was found.

256

257

31.3 CLINICAL FINDINGS

31.3.1 Cats

Acute hemotropic mycoplasmosis occurs in cats of all ages. Several studies have reported an increased incidence in adult males and attributed it to their increased roaming and fighting behavior, resulting in greater exposure to cats infected with *M. haemofelis*.^{18,21} Feline hemotropic mycoplasmosis is usually a disease of individual cats, although multiple infections in multicat households have been reported.⁴⁶

No clinical signs may be recognized in cats with subclinical infections and mild anemia.⁴⁶ The most common clinical signs in ill cats are tachypnea, depression, weakness, anorexia, weight loss, pale mucous membranes, dehydration, icterus, and splenomegaly.^{15,21} Clinical signs depend on the stage of disease and the rapidity with which anemia develops. If anemia develops gradually, a cat may exhibit weight loss but remain bright and alert. In contrast, a precipitous drop in HCT early in the disease in association with a severe parasitemia causes little weight loss, but marked mental depression and other clinical signs of anemia occur.

The rectal temperature generally is normal except during the acute phase of disease, when it is increased approximately 50% of the time. Subnormal temperatures may be present in moribund cats.

Clinical signs are mild or absent in cats experimentally infected only with *M. haemominutum*.¹⁵ Mild fever may occur at times.⁶¹ *M. haemominutum* infection has been demonstrated more often in sick cats than in healthy cats, but it is unclear whether the clinical signs present were related to the *M. haemominutum* infection or to other accompanying disease processes.⁵⁴

31.3.2 Dogs

Unless other diseases are also present, clinical signs are rarely apparent in nonsplenectomized dogs infected with *M. haemocanis*. Splenectomized experimental dogs infected with *M. haemocanis* become listless and develop pale mucous membranes as the anemia progresses but generally have normal rectal temperatures and appetites.

Infectious Diseases of the Dog and Cat, 3rd Edition

31.4 DIAGNOSIS

31.4.1 Clinical Laboratory Findings

31.4.1.1 Cats

M. haemofelis organisms are only present in sufficient numbers to be easily recognized in stained blood films about 50% of the time during the acute phase of disease. The HCT is usually below 20% and frequently below 10% before clinical signs of disease are apparent to the client. The HCT is not always a good indicator of total erythrocyte mass in cats with hemotropic mycoplasmosis. Parasitized erythrocytes that are primarily sequestered in the spleen and other organs may return to the general circulation following the removal of organisms from their surface.

If the HCT decreases rapidly, the mean cell volume (MCV) may be normal with few reticulocytes present. In most instances, by the time clinical signs of disease are apparent, the cat has a regenerative anemia with polychromasia and reticulocytosis. Erythrocytes are usually macrocytic, with an MCV greater than 50 fl, and frequently hypochromic, with a mean cell hemoglobin concentration (MCHC) less than 31 g/dl. Although anisocytosis, nucleated erythrocytes, and increased numbers of Howell-Jolly bodies are consistently observed in the circulation during the acute phase of feline hemotropic mycoplasmosis, these findings are not reliable indicators of a regenerative response to anemia in the cat. Howell-Jolly bodies are often observed in normal cats, nucleated erythrocytes may appear in a wide variety of feline diseases, and marked anisocytosis without polychromasia has been reported in cats with myeloproliferative disease. Cats with latent infections (carriers) occasionally have low numbers of parasites visible in the blood. Their HCT fluctuates over time; it may be normal or slightly to moderately decreased, although not below 20%. Slight reticulocytosis with polychromasia and increased MCV are present at times.

Because two morphologic forms of reticulocytes have been described in cats, it is important to know which criteria a reference laboratory uses to count reticulocytes. Aggregate reticulocytes occur as a low proportion (0 to 0.4%) of the erythrocytes in blood from normal cats. The percentage of this form correlates well with the percentage of polychromatophilic erythrocytes. A greater proportion (up to 10%) of circulating erythrocytes in normal cats are punctate reticulocytes, which contain punctate inclusions of precipitated ribosomes. Reticulocyte counts are not valid in blood heavily parasitized with *M. haemofelis*, because organisms also stain as blue inclusions with reticulocyte stains.

Total and differential leukocyte counts are quite variable and of limited diagnostic assistance, although increased monocyte reactivity may be observed.^{15,21,59} Erythrophagocytosis by monocytes or macrophages may be observed if blood films are scanned at low magnification. Platelet counts are usually normal.

Phagocytosis of erythrocytes by mononuclear cells in the circulation appears to occur as a result of antibodies, complement, or both on erythrocyte surfaces. Autoagglutination is frequently observed in refrigerated blood samples during early stages of acute hemotropic mycoplasmosis,⁶³ but the clinical significance of these IgM cold agglutinins is unclear.⁹ The Coombs' test (37° C) is often positive by the time a patient is presented for diagnostic evaluation.

Ratios of bone marrow myeloid to erythroid (M:E) are normal in the early stages of disease but are generally decreased later in the disease. Erythroid hyperplasia is manifested not only by an increase in the total number

Infectious Diseases of the Dog and Cat, 3rd Edition

of erythroid cells but also by an increased proportion of immature stages. Slight to marked erythrophagocytosis by macrophages is often present.

Icteric plasma is not consistently observed in feline hemotropic mycoplasmosis, but it may be present within 1 to 2 days after a rapid decrease in HCT. Icterus index values and plasma bilirubin concentration are not always increased subsequent to rapid decreases in HCT, probably because of the fact that erythrocytes can be sequestered in capillaries and vascular spaces within the spleen without being destroyed. Plasma protein concentrations are usually in the reference range (6 to 8 g) but may be increased in some cats. Serum alanine transferase and aspartate transferase activities are often mildly increased.²¹ These increases may be attributed to hepatic hypoxia secondary to anemia or hepatic lipidosis secondary to anorexia. Serum urea concentrations may be slightly to moderately increased without an accompanying increase in serum creatinine concentration.²¹ Increased serum urea concentrations are believed to be prerenal secondary to dehydration. Moribund cats may be hypoglycemic.

Cats infected with *M. haemominutum* may have a slight regenerative anemia or have normal hematologic findings.

31.4.1.2

Dogs

M. haemocanis organisms are usually present when clinical evidence of anemia caused by hemotropic mycoplasmosis is recognized in dogs. Although the anemia has varied from mild to severe in studies of splenectomized experimental dogs, the HCT has generally been below 20% before clinical signs of hemotropic mycoplasmosis were observed. Organisms may be found incidentally during hematologic screening, when an animal is examined early in the disease because of clinical signs attributable to other concurrent disorders.

257

258

In most cases, sufficient time has elapsed between the development of anemia and initial recognition of the disease for there to be peripheral blood evidence of a regenerative bone marrow response to the anemia. Hematologic findings include reticulocytosis with increased polychromasia and anisocytosis, circulating nucleated erythrocytes, and frequent Howell-Jolly bodies. Macrocytosis takes more time to develop and therefore may not be present when animals are initially seen by a veterinarian.

No consistent leukogram abnormalities are recognized in canine hemotropic mycoplasmosis. Neither icteric plasma nor hemoglobinemia is generally recognized in uncomplicated cases, but substantial bilirubinuria may occur.⁴⁶ Spherocytosis and positive Coombs' test results occur in some animals. Dogs with latent infections generally have normal hemograms.

31.4.2

Organism and Nucleic Acid Detection

31.4.2.1

Cats

Thin, well-stained blood films, without artifacts caused by improper drying or fixation or by precipitated stain, are required to identify hemotropic mycoplasmas. Numerous Romanowsky-type blood stains (e.g., Wright-Giemsa) may be used, although low numbers of organisms are difficult to recognize using the Diff-Quik stain (Dade Behring, Deerfield, Ill.). Blood films must be examined before therapy begins because organisms are absent while cats are being treated with tetracycline antibiotics. Organisms may detach from erythrocytes during storage in ethylenediaminetetraacetic acid (EDTA), so it is advisable to make blood

Infectious Diseases of the Dog and Cat, 3rd Edition

smears as soon as possible after sample collection.¹ The clinician must be able to differentiate hemotrophic mycoplasmas from stain precipitate, drying artifacts, Howell-Jolly bodies, basophilic stippling, siderotic inclusions, and *Cytauxzoon* parasites, which are small protozoa with a nucleus and cytoplasm (Table 31-2; see Chapter 76).²⁵ New methylene blue wet preparations and reticulocyte stains should not be used to diagnose hemotrophic mycoplasmal infections, because even normal cats have up to 10% punctate reticulocytes, and precipitated ribosomal material in reticulocytes cannot be accurately differentiated from hemotrophic mycoplasmas.

Because of the cyclic nature of the parasitemias, the absence of *M. haemofelis* organisms in blood films does not rule out a diagnosis of hemotrophic mycoplasmosis. A regenerative anemia with a positive Coombs' test result, the presence of autoagglutination in refrigerated blood samples, or erythrophagocytosis by blood monocytes is suggestive of hemotrophic mycoplasmosis. However, other diseases such as primary autoimmune hemolytic anemia or FeLV-induced hemolytic anemia should also be considered.

Table 31-2 Cytologic Inaccuracies for Detection of Hemotrophic Mycoplasmas of Cats

REASONS	APPEARANCE	REMEDY
False Positive		
Stain precipitate	Above focal plane, larger and denser-staining consistency, variable size	Use fresh-filtered stains
Drying artifacts	Irregular borders, refractile on focusing	Make thin smears, dry rapidly
Howell-Jolly bodies	Larger size (1–2µm) nuclear remnants	None
Siderotic inclusions	Focal fine, blue-staining granules	Positive with Prussian blue stain
False Negative		
Transient parasitemia	No organisms seen despite regenerative anemia	PCR assay
Excess amount or exposure time to EDTA	No organisms seen despite regenerative anemia	New blood specimen, fresh smears, heparin or no anticoagulant

M. haemominutum organisms are rarely seen in blood and when present are difficult to identify with certainty because they are so small.^{17,61}

Highly sensitive feline PCR-based assays have been developed that can detect hemotrophic mycoplasmas in blood when too few organisms are present to make a diagnosis using stained blood films.^{29,42,58}

Using competitive, quantitative PCR, it has been determined that about 50 *M. haemofelis* organisms can be detected by PCR.¹² Specific PCR primers have been developed to differentiate between *M. haemofelis* and *M. haemominutum* infections in cats based on amplified DNA products.^{15,29,61} PCR results were positive 4 to 15 days after experimental infections with hemotrophic mycoplasmas, and results remained positive until appropriate antibiotic therapy was initiated.^{14,15,61} PCR results were generally negative during antibiotic therapy, but most cats showed positive results again between 3 days and 5 weeks after therapy was discontinued, although low numbers of animals had negative results up to 6 months after treatment.^{3,7a,14,15} Using quantitative PCR, the concentration of *M. haemofelis* DNA in blood was found to be inversely proportional to the hematocrit of infected cats.^{54a,37a}

Whether diagnosed by identification of parasites in blood films or PCR-based assays, the significance of hemotrophic mycoplasmal infections must be interpreted in light of hematologic and clinical findings. The

Infectious Diseases of the Dog and Cat, 3rd Edition

mere presence of hemotropic mycoplasmas in the blood does not necessarily indicate that the clinical illness present was produced by this agent, because parasites may be incidentally observed in carrier cats with other diseases. On the other hand, even if the anemia appears nonregenerative the clinician should not automatically discount the significance of organisms in cats. If the HCT drops precipitously after infection, a cat can be depressed and anemic for several days before a substantial regenerative bone marrow response is evident in the peripheral blood. However, a persistent nonregenerative anemia should make the clinician investigate other causes of anemia, such as FeLV infection.

PCR testing has been beneficial in testing clinically healthy cats being screened as blood donors or for entry into specific pathogen-free colonies. It has also been valuable in epidemiologic studies evaluating the variety and prevalence of infection in cat populations. Community shelter-source cats, outside cats, and those with flea exposure, which were screened for blood donation by PCR, had the highest prevalence of infection.¹⁹

31.4.2.2

Dogs

Based on current information, it appears that *M. haemocanis* can generally be identified in blood of dogs with clinically significant hemotropic mycoplasmosis, although organisms may be few and difficult to find. As in cats, the clinician must be able to differentiate between organisms and staining artifacts, basophilic stippling, and Howell-Jolly bodies. The most useful criterion is the tendency of *M. haemocanis* to form chains of organisms across the erythrocyte surface. Blood films should be inspected closely if an anemia develops or becomes worse in a dog after splenectomy.

PCR-based assays have been developed to identify *M. haemocanis* infections.^{6,8} Although not evaluated, it is assumed that these assays are sensitive enough to identify animals with subclinical infections.

31.4.3

Prevalence of Infections

Using PCR-based assays, investigators in the United States²⁹ and Spain¹³ reported finding about 30% of anemic cats suspected of having hemotropic mycoplasmosis to be positive for hemotropic mycoplasmas by PCR, with a majority of cats being positive for *M. haemofelis* alone or in combination with *M. haemominutum*. Additionally, about 14% of healthy control cats in the United States study were PCR positive for hemotropic mycoplasmas. Of these PCR-positive healthy cats, 19 were infected only with *M. haemominutum* and 1 was infected with both variants.²⁹ Some caution is needed in interpreting these results, because only one variant was subsequently identified by PCR in some cats experimentally infected with both variants.⁶¹

A lower prevalence of *M. haemofelis* infections was found in a survey of British cats.⁵⁴ Less than 2% of ill cats (anemic or nonanemic) and less than 2% of healthy cats were infected with *M. haemofelis*. In contrast, about 20% of ill cats (anemic or nonanemic) and 8% of healthy cats were infected with *M. haemominutum*. A survey of feral cats in northern Florida revealed that 8% were PCR positive for *M. haemofelis* and 12% were PCR positive for *M. haemominutum*.⁴⁰ As in other reports, males were more commonly infected than females, and a positive correlation was found between hemotropic mycoplasma infections and FeLV and FIV infections.⁴⁰ In a survey identifying infected domestic cats in Japan, 67% had positive PCR results for *M. haemofelis*, 22% were positive for *M. haemominutum*, and 11% were coinfecting.⁶⁰

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 31-3 Drug Dosages for Canine and Feline Hemotropic Mycoplasmosis

DRUG ^a	SPECIES	DOSE ^b (mg/kg)	ROUTE	INTERVAL (HOURS)	DURATION (DAYS)
Tetracycline	Dog, cat	20	PO, IV	8	21
Oxytetracycline	Dog, cat	20	PO, IV	8	21
Doxycycline	Dog, cat	10	PO	24	21
Doxycycline	Dog, cat	5	PO	12	21
Enrofloxacin	Cat	5–10 ^c	PO	24	14
Prednisolone ^d	Dog, cat	1–2	PO	12	prn

PO, By mouth; IV, intravenous; prn, as needed.

- a See Drug Formulary, [Appendix 8](#), for additional information on these drugs.
- b Dose per administration at specified interval.
- c Recommendation based on efficacy study of *Mycoplasma haemofelis* infection in cats.^{36,56a} However, dosages at a level of > 5 mg/kg/day may cause retinotoxicity in cats and should be used with caution or substituted with other drugs.
- d Value of glucocorticoids is not substantiated. Cats with experimental disease have responded to therapy with tetracyclines alone.

31.5 PATHOLOGIC FINDINGS

Gross necropsy findings in cats include pale tissue in all cases, emaciation in approximately 75% of the cats, slight to marked splenomegaly in approximately 50%, and slight to moderate icterus in some cats.

Abnormal histologic findings are variable and include erythroid and at times myeloid hyperplasia of bone marrow and passive congestion, extramedullary hematopoiesis, follicular hyperplasia, erythrophagocytosis, and increased hemosiderin in the spleen. In some cases, fatty degeneration and centrilobular necrosis of the liver is recognized.

Necropsy findings in canine hemotropic mycoplasmosis have not been thoroughly reported. The blood appears watery and tissues appear pale. The bone marrow is red and gelatinous. Hyperplasia of the mononuclear phagocyte system may be present.

31.6 THERAPY

31.6.1 Cats

Doxycycline or tetracycline/oxytetracycline antibiotics should be given for 3 weeks ([Table 31-3](#)).

Unfortunately, tetracycline antibiotics may produce fever, evidence of GI disease (e.g., esophageal stricture), or both in cats.⁴¹ Preliminary findings indicate that enrofloxacin (10 mg/kg, PO, once daily) may be an efficacious alternative for cats that do not tolerate tetracycline antibiotics.^{14,56a,62} Glucocorticoids, such as prednisolone (1 to 2 mg/kg, PO, every 12 hours), may be given to severely anemic animals to decrease erythrophagocytosis. The glucocorticoid dosage should be gradually decreased as the HCT increases. Blood transfusions are required when the anemia is considered life-threatening. IV fluid containing glucose is recommended for moribund animals.

Infectious Diseases of the Dog and Cat, 3rd Edition

Treated and untreated animals that recover from *M. haemofelis* infections generally remain carriers but seldom relapse with clinical disease once the HCT returns to normal.^{3,17,27} Following immunosuppression with glucocorticoids, organisms can still be detected by PCR.³ Azithromycin or imidocarb dipropionate are not effective in treating hemotrophic mycoplasmal infections in cats.^{35,61} Chloramphenicol has previously been recommended for the treatment of *M. haemofelis* infections, but it should not be used for this purpose, because it causes dose-dependent erythroid hypoplasia in the bone marrow of cats.²⁵ Antimicrobial treatment reduces or eliminates visible parasitemia, but it does not clear the parasite from the body.

259

31.6.2 Dogs

260

Experimental studies evaluating therapy for canine hemotrophic mycoplasmosis have been limited. Blood transfusions should be administered when the anemia is considered life-threatening. Orally administered oxytetracycline is reported to be effective in treating *M. haemocanis* infections (see Table 31-3). Dogs that recover from hemotrophic mycoplasmosis probably have latent infections. Data is not available for the need or efficacy of treatment of ‘*Candidatus M. haematoparvum*’ infection in dogs.

31.7 PREVENTION

Elimination of blood-sucking arthropods from dogs and cats is recommended because they may transmit infectious diseases, including hemotrophic mycoplasmosis. Iatrogenic transmission of *M. haemocanis* in dogs is usually of concern only if the recipient has been splenectomized. Iatrogenic transmission can likely be prevented in cats and dogs by testing blood donors using PCR-based tests.

³²CHAPTER 32 Mycoplasmal, Ureaplasmal, and L-Form Infections

Craig E. Greene

32.1 MYCOPLASMAL AND UREAPLASMAL INFECTIONS

32.1.1 Etiology

Mycoplasmas, the smallest free-living microorganisms, are prokaryotes within the class Mollicutes. Mycoplasmas are currently divided into hemotrophic and nonhemotrophic types. Only the nonhemotrophic types will be described here; hemotrophic organisms are discussed in [Chapter 31](#), Hemotrophic Mycoplasmosis. Mycoplasmas have the smallest of genomes, with replicating cells as small as 300 nm and a DNA molecule expressing as few as 700 genes ([Fig. 32-1](#)). Although this molecule is large enough for an extracellular existence, its size restricts its metabolic capacity. Mycoplasmas therefore depend on nourishment from a rich environment, which they find on mucosal membranes of the respiratory and urogenital tracts of their warm-blooded hosts. The lack of a rigid, protective cell wall makes mycoplasmas rather fragile outside the host but resistant to lysozyme and cell wall-inhibiting antibiotics such as penicillin, cephalosporin, vancomycin, and bacitracin. Animal mycoplasmas survive for variable time periods outside the host, depending on the species, amount of moisture, and temperature.⁵³ Under dry conditions, most mycoplasmas are stable at 4° C, but many are unstable at higher temperatures. Stability is influenced by pH, being more stable at 7.5 than 6.5. The presence of organic material such as host tissues or body fluids helps their preservation. Survival times vary between species but generally range from 50 to 150 days at 4° C in liquid media to 7 to 14 days under dry conditions at 30° C.⁵³

Despite their limited genome, mycoplasmas have marked genetic alterability, which allows them to vary the expression of major surface antigenic proteins as a means of avoiding host immune surveillance. Genetic studies of mycoplasmas of animals and people have shown that host preference does not derive from bacterial phylogenetic closeness.⁷ This finding suggests that switching to new hosts from genetic alterations may have occurred at several times during their evolution.

Mycoplasmas of the genera *Mycoplasma*, *Ureaplasma*, and *Acholeplasma* are represented in the natural mucosal flora of dogs and cats ([Table 32-1](#)). The term *Mycoplasma* in this chapter refers to any of these organisms. Ureaplasmas are organisms with an adaptive preference for the genitourinary mucosae. Many species may have a role in diseases by virtue of being isolated from disease processes, but few have been conclusively proved to be pathogenic. [Table 32-1](#) also contains a list of diseases of dogs and cats in which mycoplasmas may be causal factors. These diseases most often involve inflammation of mucosal or serosal surfaces of the respiratory tract, urogenital tract, joints, mammary glands, and conjunctiva.

Studies in experimental mycoplasmal infections of mice have shown that IgA response is a primary factor in resistance to respiratory tract infections.²⁸ Generation of this response was best induced by intraspiratory, but not parenteral, administration of *Mycoplasma* antigen. Addition of cholera toxin as an adjuvant was beneficial in producing a protective immunity. *Mycoplasma* may also induce T-cell responses, which cause both beneficial and adverse immunologic consequences. Increased cytokines promote antimicrobial clearance and increased tissue injury. Mycoplasmal products may act as superantigens, which may stimulate chronic immune-mediated diseases such as rheumatoid arthritis. In addition, some mycoplasmas may become intracellular, resulting in chronic persistent infections.

NR, Not reported.

^a These may represent L-form infections.

Mycoplasma DNA has been identified by polymerase chain reaction (PCR) methods in live virus veterinary vaccines; however, no viable organisms could be cultivated.⁴⁰ Presumably, contamination during their production was the cause. Further work is needed to clarify this finding.

32.1.2 Clinical Findings

32.1.2.1 Ocular

Mycoplasma felis is considered to be a significant pathogen in conjunctivitis of cats. Experimental inoculation of *Mycoplasma* has produced conjunctivitis only when cats are young or when a large amount of inoculum is used. Spontaneously observed conjunctivitis usually occurs when infected cats are housed in groups and develops soon after weaning with loss of maternal immunity. The incidence of *M. felis* in cats with conjunctivitis is 25%; it is not isolated from clinically healthy cats, although it may be present in levels below the sensitivity of culture.²⁵ The clinical signs of mycoplasmal conjunctivitis have been described as serous discharge followed by mucoid and sticky exudate. The conjunctiva is initially hyperemic and edematous and later becomes indurated. Untreated cats may show signs as long as 60 days, but the cornea is usually not involved.

Infectious Diseases of the Dog and Cat, 3rd Edition

32.1.2.2 Respiratory

Most *Mycoplasma* spp. normally appear in the upper respiratory tract. They have also been isolated at necropsy from lungs of dogs and cats with various types of pneumonia but are not generally present in the lungs of healthy animals, especially cats.^{56,58} Isolation of *Mycoplasma* from tracheobronchial lavage specimens of clinically healthy animals was 0% for cats and 25% for dogs, whereas animals with pulmonary disease had a 21% isolation rate.^{58,59} Ureaplasmas are rarely, if ever, isolated from the respiratory tract of healthy or diseased animals.^{58,59} In animals with impaired pulmonary clearance resulting from viral infection, mycoplasmas inhaled from the upper respiratory tract may establish an infection in the lung or pleural cavity, or both, as a secondary opportunistic pathogen.^{17,52}

Chronic pulmonary mycoplasmosis has been observed in dogs with primary ciliary dyskinesia.³ These bacteria have the tendency to produce prolonged suppurative infection of the conducting airways.³ Histopathologic features consist of purulent bronchitis and bronchiolitis with bronchiectasis early, followed by bronchial and bronchiolar epithelial hyperplasia, mononuclear infiltration, lymphoid hyperplasia, interstitial pneumonia, and bronchiolitis obliterans.³⁹ When a large number of mycoplasmal species isolated from lungs of dogs with distemper pneumonia were evaluated for virulence by experimental exposure of healthy puppies, only one strain of *Mycoplasma cynos* induced pulmonary disease. Although it is not likely to play a primary role, *M. cynos* undoubtedly contributes to the multifactorial cause of canine pneumonia.^{12a} For example, mycoplasmas have been isolated, alone and in combination with other bacteria, from the airway washings of dogs with lower respiratory diseases.¹³ Common but variable anatomic changes in these dogs included collapsing trachea and interstitial, bronchointerstitial, and alveolar pulmonary disease. Whether these isolations represent contamination of upper airway microflora during retrograde collection methods is uncertain because these organisms have been isolated from the respiratory tract of clinically healthy dogs.

Because isolation of *Mycoplasma* from the respiratory tract washings of clinically healthy cats is uncommon, culturing these organisms may have clinical significance. *M. felis* is likely a primary pathogen in the cat because pneumonia has developed after experimental challenge of kittens. A kitten with congenital mitral valve dysplasia developed pneumonia and pyothorax associated with *M. felis* infection.⁴⁶ *Mycoplasma* spp. were isolated in pure culture from bronchoalveolar lavage specimens from three cats with either suppurative bronchitis or bronchopneumonia.²¹ *Mycoplasma* and *Arcanobacterium* (*Corynebacterium*) *pyogenes* were isolated from pyothorax in a kitten.²⁴ Cats with pleural effusion show minimal signs of dyspnea compared with dogs. Nonodorous fluid is expected with uncomplicated mycoplasma pyothorax.

32.1.2.3 Genitourinary

Isolating mycoplasmas in large numbers from the urine of dogs with urinary tract infection (UTI) is not uncommon. Although in most situations the mycoplasmas are in mixed culture with bacteria, they are also occasionally isolated.^{32,42} The same conditions such as tumors and urinary calculi, predisposing the animal to bacterial infection, may promote *Mycoplasma* infection. The source of the mycoplasmas in the urinary tract is undoubtedly the abundant microflora in the distal urogenital tract. More credibility exists for their role in infection when urine is collected by cystocentesis and no other bacteria are isolated. Collection of urine by voiding or catheterization will result in contamination of the urine specimen. Conditions causing

Infectious Diseases of the Dog and Cat, 3rd Edition

obstruction and urine stasis of the urethra will allow ascending contamination of the urinary system so that they may be isolated with cystocentesis. *M. felis* and *Mycoplasma gateae* have not been able to survive under osmotic conditions present in normal feline urine,⁹ indicating that mycoplasmas are unlikely candidates for urinary disorders of cats. *Ureaplasma* spp. are more resistant to osmotic damage by urine and are more likely candidates for UTIs in dogs and cats.⁹ No features can be used to distinguish mycoplasmal UTI from other bacterial urinary infections. Studies in cats with feline lower urinary tract disease have not implicated either mycoplasmas or ureaplasmas.⁶⁴

Mycoplasmas of the reproductive tract are currently considered to be opportunistic. *M. canis* has been isolated from dogs with endometritis. The assumed opportunistic role of mycoplasmas in endometritis is probably overlooked in many cases of mixed infection when conventional bacteria are cultured. Alternatively, opportunistic bacterial infections may be responsible for the reproductive disorders in kennels where both mycoplasmas and bacteria are found. Vaginal and preputial swabs and semen samples are often submitted for mycoplasmal culture in dogs with infertility problems. Very often, these samples give positive results; however, their significance as pathogens is uncertain. Weighing the culture results in relation to other diagnostic findings and judging whether antibiotic treatment for mycoplasmas will solve the infertility problem are important. Deep vaginal or semen cultures are the most accurate means of determining the presence of the organisms.

A survey showed that infertile dogs had ureaplasmas in vaginal and preputial samples more often than fertile dogs. This difference was statistically significant in male dogs but not in female dogs.¹⁸ Because ureaplasmas are associated with infertility in other animals, research work is urgently needed to evaluate the role of these organisms in dogs and cats. The percentages of dogs with positive culture results for *Mycoplasma* from the vagina or semen have not been statistically different between fertile and infertile dogs.¹⁹

32.1.2.4 Systemic

The general assumption holds that microorganisms from the natural flora cross the mucosal barrier with regularity, but healthy individuals eliminate these invaders by specific and nonspecific defense reactions. Mycoplasmas originating from the natural flora may therefore occasionally be isolated from parenchymatous organs of dogs and cats with debilitating diseases such as malignancies and immunosuppression.

32.1.2.5 Musculoskeletal

Dysgammaglobulinemia has been a predisposing cause of mycoplasmal polyarthritis and sepsis in people.⁴³ Naturally occurring mycoplasmal arthritis has occurred in cats.²⁰ Cats injected intravenously with *M. gateae* developed polyarthritis, thus confirming the potential virulence of this organism. Predisposing conditions were not identified in a young greyhound with polyarthritis caused by *Mycoplasma spumans*.²

32.1.2.6 Gastrointestinal

Mycoplasmas are occasionally isolated from rectum and colon biopsy samples of dogs with colitis, but conclusive evidence for their etiologic role in the inflammatory condition has not been found.

Infectious Diseases of the Dog and Cat, 3rd Edition

32.1.2.7 Abscesses

Organisms with the characteristics of mycoplasmas have been isolated from cats with abscesses, most likely introduced by bite-inflicted wounds.³⁶ Unfortunately, the isolates have been difficult to adapt to in vitro conditions and therefore have been impossible to classify. In some cases, these isolates may represent L-form infections (see later discussion). In one cat with multiple abscess wounds from a dog bite, *M. canis* and *M. spumans* were isolated.⁶⁹ In one report, three cats had mycoplasmal abscesses in subcutaneous and muscle tissue, and another cat was diagnosed with a cervical and a pulmonary abscess. Mycoplasmal abscesses are characterized by nonodorous, nondegenerate, neutrophilic exudates in which bacteria cannot be visualized with gram-stained smears. In all situations, the abscesses did not respond to surgical débridement or to cell wall-inhibiting antibacterials, but they did respond to treatment with tetracycline or tylosin (see also L-Form Infections).

32.1.3 Diagnosis

Mycoplasmas are often recovered as commensals from mucosal surfaces. To determine whether mycoplasmas are causative agents, they should be isolated from animals with disease in greater frequency than in healthy animals. Antibody responses should also be more prevalent in diseased animals, and clinical improvement should occur with *Mycoplasma*-susceptible antibiotics.

Exudates from draining lesions, inflamed mucosae, or body cavity effusions usually contain intact nondegenerate neutrophils, but no bacteria are noted. Organisms can be visualized by examining exudate or colony cultures by negative staining with transmission electron microscopy (EM). The clinician should be aware of the fragile nature of mycoplasmas. Special requests should be made of the laboratory if mycoplasmosis is suspected. Cotton swabs placed in Hayflicks broth medium or commercially available swabs with either Amies medium (without charcoal) or modified Stuart bacterial-transport medium can be submitted to the diagnostic laboratory for *Mycoplasma* culture. The specimens should be cooled and shipped with an ice pack if transport time is less than 24 hours but must be frozen and shipped with dry ice if longer transport time is expected. Urine sediment is cultured following centrifugation at $3000 \times g$ for 10 minutes. Mycoplasmas from dogs and cats grow best on special media prepared according to Hayflicks formula and can be identified quite easily, provided specific reference antisera are available. Incubation at 37° C in 5% carbon dioxide is followed by anaerobic conditions for 48 hours.

Table 32-2 Therapy for Mycoplasma and L-Form Infections

DRUG ^a	SPECIES	DOSE ^b (mg/kg)	ROUTE PREFERRED (ALTERNATE)	INTERVAL (HOURS)	DURATION (WEEKS)
Doxycycline	B	10–20	PO (IV)	12	1
Tetracycline	B	22–30	PO	8	1
Chloramphenicol	D	25–50	PO (IV, SC, IM)	8	1
	C	25	PO	12	1
Clindamycin	B	5–11	PO	12	1
Enrofloxacin	B	5	PO (SC)	24	1

D, Dog; C, cat; B, both dog and cat; PO, by mouth; IV, intravenous; SC, subcutaneous; IM, intramuscular.

a See [Appendix 8](#) for additional information.

b Dose per administration at specified interval.

Infectious Diseases of the Dog and Cat, 3rd Edition

Colonies have a characteristic “fried egg” appearance. They do not revert to parent cell wall-containing bacteria when they are grown on antibiotic-free media.

Mycoplasmas can be characterized by their biochemical features⁴⁸; however, this does not always follow consistent patterns among species. An immunobinding assay using polyclonal antisera has been used to distinguish *M. felis* and *M. gateae* isolated from cats and from other species.^{4,8} Mycoplasmas have also been identified by dot immunobinding and direct fluorescent antibody (FA) techniques. Molecular methods have included nucleic acid hybridization and random amplified polymorphic methods. PCR methods can help detect and differentiate *Mycoplasma* in cell culture⁷⁰ and clinical specimens.^{22,34,12a} Bacteria such as *Fusobacterium necrophorum* cross-react with certain PCR reactions intended to detect a wide range of *Mycoplasma* species.³³

32.1.4 Therapy and Prevention

Susceptibility testing to antimicrobial agents is not available for mycoplasmas on a routine basis. They are generally susceptible to the macrolides (tylosin, erythromycin, azithromycin, clarithromycin), pleuromutilins (valnemulin, tiamulin), tetracyclines, chloramphenicol, spiramycin, lincomycin, clindamycin, fluoroquinolones, nitrofurantoin, and aminoglycoside in vitro. Given that no agents are bactericidal, animals must be treated for an extended period (Table 32-2; also refer to the Drug Formulary, Appendix 8, for dosages). The immune system must be competent to eradicate the infection. Because tetracycline and chloramphenicol should not be used in pregnant animals, erythromycin and lincomycin, although less effective, are safer. Azithromycin causes less gastrointestinal side effects compared with erythromycin. The fluoroquinolones have been shown to be effective against mycoplasmas in vitro and in vivo.^{15,35,71} Drug-resistant systemic mycoplasmal meningitis and arthritis in immunocompromised people have been treated successfully with pleuromutilins, a new class of antibiotic.²⁶

No vaccines are available to prevent mycoplasmal infections in dogs and cats or other species. Attempts to protect animals against challenge with these agents have been discouraging. Studies in the respiratory tract indicate IgA is critical in providing immunity against these agents. Intranasal immunization has been most effective in experimental studies; however, inclusion of mucosal adjuvants such as cholera toxin was required.²⁸

32.1.5 Public Health Considerations

Mycoplasma infections of dogs and cats have not been considered as major public health risks. A veterinarian developed suppurative tenosynovitis 1 week after being scratched on a finger by a cat being treated for colitis.⁴⁷ The infection was resistant to erythromycin, cloxacillin, and penicillin but was cured with doxycycline. This report was the first of mycoplasma infection as a zoonosis and of *Mycoplasma* producing an abscess in people. Subsequently, *M. felis* has produced septic arthritis of the hip and knee in a person with common variable immunodeficiency syndrome who was receiving glucocorticoid therapy.⁵

Infectious Diseases of the Dog and Cat, 3rd Edition

32.2 L-FORM INFECTIONS

32.2.1 Etiology

L forms of bacteria represent cell wall–deficient forms and are morphologically similar to *Mycoplasma*. They are distinguishable from the latter by their variable size (1- to 4- μ m diameter), their greater pleomorphism, and their penicillin-binding affinities. Cell wall deficiencies can be induced in vitro or in vivo in many bacteria by exposing them to cell wall–damaging chemicals or antimicrobials (e.g., β -lactam drugs) or host immune responses.

32.2.2 Clinical Findings

Cell wall–deficient bacteria have been isolated from cats with a syndrome of fever and persistently draining, spreading cellulitis and synovitis that often involve the extremities.^{12,36,57} The usual source of infection has been contamination of penetrating bite wounds or surgical incisions. Cats have also presumably been infected from wound exudates from other cats. Infection begins at the point of inoculation, and lesions spread, drain, dehisce, and do not permanently heal (Fig. 32-2). Bacteremic spread of infection can occur, and polyarthritis or distant abscess formation may develop as a sequela. Progressive polyarthritis, unresponsive to antibiotics and glucocorticoids, occurred in a dog infected with an L form of *Nocardia asteroides*.¹⁰

32.2.3 Diagnosis

32.2.3.1 Laboratory Findings

Clinical laboratory abnormalities in cats with polyarthritis may include leukocytosis (over 25,000 cells/ μ l) with a mature neutrophilia and monocytosis, lymphocytosis, and eosinophilia.¹² Hyperfibrinogenemia and hyperglobulinemia may be found. The exudates contain predominantly macrophages and neutrophils with a few lymphocytes. Erythrophagia may be present; organisms *cannot* be detected by numerous cytologic stains. Radiographic abnormalities include periarticular soft tissue swelling and periosteal proliferation.¹² In severe cases, damage occurs to the articular cartilage and subchondral bone.

32.2.3.2 Organism Isolation

Diagnosis is difficult because these organisms are difficult to demonstrate by light microscopy. The organisms are also difficult to culture on bacterial or mycoplasmal media. Infection has been transmitted experimentally by subcutaneous inoculation with cell-free material from tissues or exudates of affected cats. EM evaluation of tissues may show the characteristically pleomorphic, cell wall–deficient organisms in phagocytes (Fig. 32-3).⁵⁷

Fig 32-2 Distal pelvic limb from a cat with L-form infection with multiple fistulas draining purulent exudates. (Courtesy University of Georgia, Athens, Ga.)

Fig 32-3 Transmission electron microphotograph of cell wall-deficient bacteria from draining lesions of the cat in [Fig. 32-2](#). (Courtesy University of Georgia, Athens, Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

32.2.4 Therapy

Cell wall–deficient organisms found in cats have been most responsive to tetracyclines. (For dosages, see [Table 32-2](#).) Erythromycin and chloramphenicol have been used in canine infections, but these infections do not respond to most antimicrobials. They are characteristically resistant to cell wall–synthesis inhibitors such as the β -lactam antibiotics or many other broad-spectrum antimicrobials often chosen for persistent multifocal infections. Response to therapy should occur within 2 days, and therapy should continue for at least 1 week after discharges have stopped.^{12,36,57}

264

32.2.5 Public Health Considerations

The public health risk of L-form infections in dogs and cats is uncertain because all of the cell wall–deficient organisms have not been adequately characterized. Instances of L-form infections in people are rare. In one report, a person developed an L-form infection at the site of a permanent indwelling catheter used for hemodialysis.¹⁴ The L-form isolate was characterized as *Streptococcus sanguis* of animal origin. The same strain of this organism was also isolated from the person's pet dog.

33 CHAPTER 33 Laboratory Diagnosis of Bacterial Infections

Robert L. Jones

The purpose of clinical bacteriology is to provide information rapidly and accurately concerning the presence or absence of a bacterial agent in an infectious disease process. It usually requires at least 24 to 72 hours for bacteria to be isolated, but the clinician can seldom wait that long to institute therapy. Knowledge of the prevalence of specific pathogens responsible for defined clinical syndromes and trends in antimicrobial susceptibility patterns provides the basis for making early rational treatment decisions and selecting the antimicrobial agent most likely to be effective. This knowledge can only be developed and updated by submission of specimens to the laboratory for isolation, identification, and antimicrobial susceptibility testing. Therefore the use of the laboratory builds a database that can guide the design of treatment plans for future as well as current patients.

Use of the microbiology laboratory is subject to unique pitfalls posed by the diversity of bacterial agents, each with unique requirements for identification: multiple and often poorly accessible sites for collection of specimens, contamination of specimens with indigenous flora, and the necessity for subjective interpretation of results. Problems in communication may occur between the microbiology laboratory and the clinician regarding the suitability of the specimen for laboratory examination, uncertainty of the significance of bacterial isolates, interpretation of reports, and length of delay between the submission of the specimen and the production of needed information. Special efforts by the clinician to provide history and signalment information along with the specimen assist the laboratory in recognizing and reporting significant results.

Major technologic advances have changed the way microbiology laboratories function. Bacterial identification is now achieved largely through the use of miniaturized packaged systems, many of which are automated. Antimicrobial susceptibility testing is commonly accomplished with a commercial microdilution system or some form of instrumentation. Immunodiagnostic methods for antigen and antibody detection have benefited greatly from radioimmunoassay, direct and indirect fluorescent antibody (FA) testing, enzyme-linked immunosorbent assay, latex agglutination, and immunoblotting, as well as the development of monoclonal antibody technology. Nucleic acid technology is leading the clinical microbiology laboratory into a new era of molecular diagnostics for detecting and identifying microorganisms. Cost constraints for all this new technology increasingly limit the scope of services that can reasonably be provided by any one laboratory. Therefore it is unreasonable to expect equal diagnostic capabilities from all microbiology laboratories for all microorganisms. With increasing frequency, specimens must be sent to reference laboratories that perform specialized diagnostic tests. [Appendix 5](#) lists commercial, state, and federal diagnostic laboratories that provide specific microbiologic testing for infectious diseases of dogs and cats.

33.1 DIAGNOSTIC METHODS

Microbiologic tests complement clinical judgment, enhance the clinician's ability to select specific antimicrobial drugs, and ultimately improve patient care through detection and identification of the etiologic agents.

33.1.1 Direct Microscopic Examination

Direct microscopic examination of exudates or infected body fluids is the single most important and cost-effective laboratory procedure that can be done for diagnosis and management of bacterial infections. Evaluations can be done in various clinical settings to obtain immediate information on the number, morphologic characteristics, and Gram-staining properties of microorganisms ([Table 33-1](#)) and the host cellular response. Purulent inflammatory responses are most suggestive of bacterial infection. Microscopic examination

Infectious Diseases of the Dog and Cat, 3rd Edition

also gives an indication of the suitability of the specimen for culture, the likelihood of the presence of infection, the likely pathogens, and the predominant organisms in a mixed infection. This information may be used as a basis for interpretation of the significance of subsequent culture results.

Bacteria are readily observed in a smear from a specimen when they occur in a concentration of about 10^4 to 10^5 per ml. Examination of specimens such as blood or cerebrospinal fluid (CSF) for bacteria is usually unrewarding because even when present, the bacteria are too few in number to be detected. Some bacteria, such as spirochetes and mycoplasmas, do not stain well with Gram stain. Dark-field microscopy allows visualization of spirochetes, but mycoplasmas are too small for observation by light microscopy. Background material and artifacts can interfere with interpretation. Mucus or other proteinaceous matter that stains gram negative may cause slender, weakly staining bacilli to blend into the background, making them difficult to visualize. Differential staining techniques that enhance visualization of gram-negative bacteria include methylene blue, Giemsa, and Wright stains.

33.1.2 Isolation and Identification

Whether isolation and identification are attempted depend on many factors—the most important of which are the source of the specimen and whether or not a presumptive diagnosis can be made microscopically. Most commonly encountered pyogenic bacteria readily grow on routinely inoculated blood agar plates. Liquid media provide enrichment for recovery of organisms present in small numbers and facilitate isolation of fastidious organisms. In some cases, selective media must be used to suppress growth of contaminants and normal flora while allowing growth of the pathogen.

267

268

Certain infectious diseases may be more efficiently diagnosed by direct detection of antigens, nucleic acids, or toxins. For diagnosis of some clostridial diseases, such as botulism (see [Chapter 42](#)), tetanus (see [Chapter 43](#)), and enterocolitis (see [Chapter 39](#)), it is imperative to identify the toxin rather than rely solely on isolation of the bacteria. Direct or indirect FA stains are extremely helpful for the rapid presumptive diagnosis of infection with some bacteria. Because *Yersinia pestis* (see [Chapter 47](#)) and *Francisella tularensis* (see [Chapter 48](#)) are hazardous to laboratory personnel, antigen detection by direct FA staining of exudate or tissue is the best tool for their rapid and specific identification. DNA probes and nucleic acid amplification techniques are useful for identification of microorganisms for which culture and serologic methods are difficult, extremely expensive, or unavailable.

Table 33-1 Appearance of Clinical Material in Gram-Stained Preparations

COMPONENT	STAINING REACTION
Gram-positive bacteria	Organisms retain the crystal-violet iodine complex and appear dark blue or purple.
Gram-negative bacteria	Organisms lose the primary complex, take up the secondary dye safranin, and appear red.
Fungi (yeasts)	Organisms appear gram positive.
Inflammatory cells	Organisms appear gram negative. Epithelial cells may appear gram positive, gram negative, or both depending on the thickness of the smear.
Backgrounds	Organisms usually appear gram negative but may appear gram positive. Fibrin, mucus, and erythrocytes often stain gram negative.

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 33-1 Collection of bacterial culture specimens from various sites, illustrating approaches used to prevent excessive contamination of specimen and probable sources of contamination. (From Jones RL 1985 Laboratory diagnosis of bacterial infections, pp 110-147. In McCurnin DM (ed), *Clinical textbook for veterinary technicians*. WB Saunders, Philadelphia, PA.)

33.1.3 Specimen Collection

Specimens must be collected from the actual site of infection with a minimum of contamination from adjacent tissues, organs, or secretions (Fig. 33-1). They must then be transported to the laboratory without further contamination or change in the relative numbers of bacteria. Some specimens are likely to become contaminated with indigenous flora during the collection process. Great care must be taken to use aseptic technique when collecting specimens to reduce the amount and likelihood of contamination. Some specimens are simply inaccessible except by aspiration or biopsy of deeper tissues. For all specimens obtained by biopsy or fine-needle aspiration, skin decontamination should be performed as it is before surgery. Specimens should be collected as early in the course of the disease process as possible. As the disease progresses and necrosis of tissue occurs, some microorganisms may die or be overgrown by other bacteria.

Whenever possible, specimens should be obtained before the administration of antimicrobials. However, their use does not necessarily preclude the recovery of bacteria from selected tissues in which low antimicrobial concentrations are achieved or from those animals infected with antimicrobial-resistant bacteria. If it is not possible to collect the specimen before any antimicrobials are administered, the specimen should be collected just before the next dose is given. If antimicrobials are concentrated at the sampling site, such as during urine collection, it is best to wait 48 hours after the last dose before collecting a specimen.

An adequate (several millimeters or grams) quantity of material should be obtained for appropriate laboratory tests. All too frequently, an inadequate amount of material is obtained with a swab, making it nearly impossible for the laboratory to make appropriate smears and inoculate adequate culture media. A swab should *never* be submitted in lieu of curettings, biopsy material, fluid (especially urine), or surgically removed tissue.

Multiple specimens should be submitted when lesions are present at several sites or when more than one laboratory procedure is requested. Multiple blood samples are necessary for detection of bacteremia. Multiple fecal samples are also indicated for detection of enteric pathogens such as salmonellae.

268

269

Infectious Diseases of the Dog and Cat, 3rd Edition

33.1.3.1 Collection Devices and Transport

Appropriate collection devices and specimen transport systems are needed to ensure survival of the microorganism without overgrowth and for optimal isolation and identification. Various containers are commercially available, ranging from simple swab and plastic tube combinations to complicated specimen collection devices (Fig. 33-2). Swabs must be made of noninhibitory materials and transported in a sterile container. Many bacteria are susceptible to desiccation during transport. Swabs are only acceptable for transport of specimens when provided with a humidified transporting chamber or placed in transport medium. Several swab-transport medium systems exist and are often available from the clinical laboratory. Tissue, exudate, feces, or fluid should be submitted in an appropriate closed (leak-proof), sterile container. Self-sealing plastic food storage bags and blood collection tubes that do not contain anticoagulants or preservatives are examples of recommended specimen containers. Each tissue or specimen must be placed in a separate container. Direct aspiration into a syringe is often a convenient and satisfactory means for of tissue and fluid collection. However, the needle must be removed for transport to avoid injuries, and the syringe should be capped.

Various types of media may be used for transporting specimens to the laboratory. Transport media such as Stuart's, Cary-Blair, Amies, and anaerobic devices (frequently available from the microbiology laboratory) are buffered non-nutritive formulations that preserve the viability of fastidious organisms in the specimen as well as minimize overgrowth by rapid-growing bacteria that may be present. Use of transport media eliminates the need to refrigerate or chill most specimens for shipment to the laboratory. The ordinary nutrient type of broth such as that in blood culture bottles may be used only when swabs or aspirates are collected from normally sterile body sites (e.g., CSF, synovia) and when great care has been taken to avoid any contamination. Special anaerobic transport devices must be used to prevent exposure of obligate anaerobes to lethal concentrations of oxygen (see Chapter 41). Because reduced oxygen is not lethal for the aerobes and facultative anaerobes, they can be transported in the same anaerobic transport devices. Tissue in formalin, dry swabs, urine collected several hours earlier and not refrigerated, and selective swabs for isolation of mycobacteria are unsuitable for bacterial culture.

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 33-2 Specimen collection devices include fecal cups, blood culture bottles, transport media and swabs, tubes, and syringes. Fecal specimens should be transported in screw-top cups (A). Blood and aseptically drawn body fluids such as joint taps should be collected and transported in blood culture bottles (B). Swabbed specimens can be transported in anaerobic transport media (C) or special chambers (D). Fluid specimens can be transported in tubes (E) or capped syringes (F). (Courtesy Robert L. Jones, Colorado State University, Fort Collins, Colo.)

33.1.3.2 Blood

Successful isolation of microorganisms from blood requires an understanding of the intermittence and low order of magnitude of most bacteremias (see Blood Culture, [Chapter 87](#), for the appropriate technique). Several specimens must be collected for culture over a period of time. If possible the first blood culture specimen should be drawn at the onset of fever. Another suggestion is to take three or four cultures within 1.5 to 3 hours; if more than one culture yields the same organism, it is probably significant.

33.1.3.3 Urine

The collection, transport, and storage of urine specimens are important adjuncts to the reliability of culture results. Urine is an excellent growth medium for some organisms; unless proper precautions are taken, urine

Infectious Diseases of the Dog and Cat, 3rd Edition

allows small, insignificant numbers of bacteria to multiply rapidly. Culture results from a voided specimen taken without cleansing the genitalia are useful only if no bacterial growth exists; for example, growth may be from urethral contamination, infection, or both. Contamination of a midstream-voided sample must be considered when less than 10^5 colony-forming units (CFU) per milliliter are isolated, although total counts of viable bacteria may be reduced in some infections. Gram staining of a drop (allowed to dry without spreading) of well-mixed urine not only provides a means of determining the adequacy of collection but also provides the findings for the diagnosis of significant bacteriuria ($>10^5$ CFU/ml) when at least two bacteria per oil immersion ($\times 1000$) field are found. Gram-positive bacteria are much more readily observed in smears than gram-negative bacteria, so caution must be exercised to avoid overlooking gram-negative bacilli.

Urine collection for culture by urethral catheterization is seldom indicated except in those animals in which catheterization must otherwise be performed for diagnostic or therapeutic reasons. Urine contamination by urethral flora is best prevented by cystocentesis, a relatively safe and simple procedure if performed by an experienced technician (see [Chapter 91](#)). This procedure solves the problem of equivocal counts and the risk of nosocomial urinary tract infections associated with catheterization. 269
270

Urine must be collected and stored in a sterile capped syringe or a capped container or tube, not collected merely by a “clean” cup or swab. If urine cannot be cultured within 1 to 2 hours after its collection, it must be refrigerated for a maximum of 8 hours. For longer storage or transport and storage, a urine preservation tube (VACUTAINER Brand Urine Transport System, Becton-Dickinson, Franklin Lakes, N.J.) allows for analysis and culture of specimens held for up to 48 hours at room temperature and for quantitative culture for up to 72 hours at refrigerated (4°C) temperatures.

33.1.3.4 Transudates and Exudates

A sterile syringe and needle should be used to collect a generous quantity of liquid material from unopened abscesses and body cavities after an antiseptic has been applied to the surface. After aspiration, air remaining in the syringe should be expelled and the end capped or the specimen transferred immediately into an anaerobic transport device. When a wash solution is used to aid in collection of a specimen such as a tracheal aspirate, it is imperative to have a solution that does not contain a bacteriostatic preservative. Best results can be expected when a buffered solution such as lactated Ringer's solution is used instead of isotonic saline solutions, which tend to be acidic.

33.1.3.5 Feces

Proper collection and preservation of feces are frequently neglected but important requirements for the isolation of pathogenic bacteria contributing to intestinal disease. Unless the specimen can be taken immediately to the laboratory and properly handled on delivery, salmonellae may not survive because of the pH changes that occur with a reduction from body temperature. A small quantity of feces (2 to 3 g) is the preferred specimen; a rectal swab specimen is less satisfactory, yielding fewer positive results. Portions of the feces containing mucus and blood may harbor a larger number of the pathogenic organisms than the customary-appearing samples. Fecal specimens should be collected in clean, sealed, leak-proof containers for transport to the laboratory.

Repeated cultures are often required for screening fecal specimens, because some pathogens may be shed only several days after onset of diarrhea, whereas other organisms may be few or absent later in the disease. Although performing three cultures is not absolutely required, repeated cultures are indicated if the clinical

Infectious Diseases of the Dog and Cat, 3rd Edition

picture suggests gastrointestinal (GI) infection by pathogenic bacteria and the first cultures are unrewarding. For some enteropathogenic strains, toxin analysis may be more beneficial than culture.³

33.1.3.6 Tissue Samples

Surgical biopsy specimens are of considerable importance for culture and may represent the entire pathologic process. They are usually obtained at considerable expense and some risk to the patient. Therefore they should be handled carefully to avoid contamination or desiccation, which would reduce their diagnostic value. A portion of the tissue rather than a swabbed specimen should be submitted. When the lesion is large or the individual has several lesions, multiple specimens from different sites should be collected. Samples from an abscess should include pus and a portion of the abscess wall. When collecting necropsy specimens, it is best to anticipate which specimens will be needed for microbiologic analysis before starting the necropsy and then to collect these first, before excessive tissue handling and exposure cause additional contamination. Samples from the GI tract should be taken last to avoid contaminating other tissues. When collecting fluid from a body compartment (e.g., joints, CSF, pericardial fluid), a syringe and needle should be used rather than a swab. The fluid sample should be aseptically aspirated. Tissue specimens should be placed (unfixed and without preservative) in sealed, leak-proof sterile containers to prevent contamination or desiccation. If the delivery of specimens to the laboratory is delayed, they should be refrigerated.

33.1.4 Specimen Submission, History, and Signalment

Specimen management is the one process in clinical microbiology that has the most influence on accurate laboratory results. Specimens that are improperly selected, collected, transported, or stored will very likely provide information that is misleading and could result in inaccurate diagnosis and inappropriate treatment. Ideally, the microbiology laboratory should provide the clinician with directions for collecting and transporting specimens and guidance in ordering tests. In turn, the clinician should provide the laboratory with sufficient history and signalment from the animal and description of the specimen source for proper processing of the specimen and interpretation of the results. Information about the animal aids in the selection of appropriate media to be inoculated and additional tests to be performed and increases the probability of significant results being recognized, properly interpreted, and reported to the clinician. Spending extra time and effort to submit adequate information to the laboratory is the best way to ensure better quality results and prevent the necessity for repeat specimen collection.

In most cases of infection with an unknown cause that do not yield results after initial culturing attempts, consultation between the microbiologist and clinician is recommended. Simply repeating culture after culture is expensive and often unsuccessful.

33.2 INTERPRETATION OF CULTURE RESULTS

Specimens that have been properly collected, carefully transported to the laboratory, and processed for bacteriologic culture and antimicrobial susceptibility testing frequently yield important information about the cause of the infection and the antimicrobials expected to be most effective. However, laboratory identification of a bacterium is not necessarily indisputable evidence of disease. The findings must be interpreted by evaluating the clinical signs or lesion, the collection site of the specimen, the presence of normal flora or other contaminants, the method of handling and transporting the specimen to the laboratory, and the number of different bacteria isolated and quantitative recovery of the agents.

Infectious Diseases of the Dog and Cat, 3rd Edition

33.2.1 Normal Flora

All mucous membranes and external body surfaces can be colonized with bacteria as part of the normal flora. These bacteria may be pathogenic if they are invading the tissue and causing inflammation, or they may be just colonizing the surfaces. Therefore culture results must be correlated with clinical signs. Quantitation of culture results is often an aid to evaluating the significance of the findings. Isolation of a mixture of four or more aerobic microorganisms in light or moderate numbers is typical of normal flora. Frequently, the number of species of bacteria isolated from a specimen is indirectly proportional to the patient care value of the report.

33.2.2 Quantitation of Growth

The amount of bacterial growth can aid in interpreting the significance of isolates, although the number of bacteria can be related to the vigor of swabbing to collect the specimen and subsequent handling. The laboratory report should indicate whether growth is light, moderate, or heavy. Finding large numbers of a single microorganism in nearly pure culture is a strong indication of significance. Light growth, including growth from broth enrichment alone, is often typical of normal flora, insignificant contaminants, or suppression of growth by antimicrobials. Such culture results usually have limited significance unless the sample was taken from a normally sterile body site and knowledge exists that the specimen was properly collected.

33.2.3 Absence of Specified Pathogens

Sometimes it is more important to know that the laboratory sought to isolate specific pathogens but was unable to find them rather than to receive a report identifying the microorganisms that were present. For example, a culture report on a fecal sample stating that no *Salmonella* or *Campylobacter* organisms were isolated is much more useful than a report naming several species of normal fecal flora, because it indicates that a specifically directed effort was made to identify particular pathogens in the specimen.

33.2.4 No-Growth Cultures

Failure to isolate bacteria may be a false-negative result for numerous reasons, including sampling and transporting mistakes, such as desiccation or inappropriate transport media; previous antimicrobial therapy; and infections caused by fastidious microorganisms for which proper culture procedures were not performed, such as mycoplasmas, obligate anaerobes, spirochetes, and rickettsias. If microscopic examination of the specimen reveals microorganisms but comparable microorganisms are not isolated, transporting and culturing procedures should be evaluated during a consultation with the clinical microbiologist. Innovative techniques of molecular detection and immunochemistry are now being developed for direct application to specimens to identify microorganisms that are difficult to cultivate.

33.3 MOLECULAR DETECTION AND IDENTIFICATION

Direct nucleic acid hybridization probe and gene amplification protocols have a tremendous potential for detecting microbial pathogens, and significant progress has been made in the development of these assays.^{9,12} Many improvements have occurred in specificity and sensitivity as well as in protocols for processing samples. DNA probe assays are particularly well suited for in situ hybridization in tissue in which the location and distribution of the organisms must be ascertained, for identification of slow-growing bacterial cultures (e.g., *Mycobacterium* sp. and *Leptospira* sp.), and for identification of toxigenic strains of bacteria that cannot be differentiated from

Infectious Diseases of the Dog and Cat, 3rd Edition

nontoxicogenic strains by conventional methods (e.g., enteropathogenic genotypes of *Escherichia coli* and *Clostridium perfringens*.⁴) Nucleic acid amplification assays that can be performed in situ or on specimens employ primers and the polymerase chain reaction (PCR) to provide enough specificity and sensitivity to detect even a single organism or up to 10 copies of a specific gene sequence (see [Chapter 1](#)). In addition to being specific enough to detect a single genotype based on the selection of the primer, strategies are now emerging for using universal primers for large groups of related infectious agents or multiplex assays using a selected set of primers. Microarrays of synthetic nucleotides (detection probes) placed on a silicon matrix (chip) enable automated searching of hundreds to thousands of sequences for identification of specific genotypes (strains) through amplification of a single specimen.

Ultimately, the goal of these molecular techniques is the direct determination of identities of microorganisms in clinical specimens and prediction of their antimicrobial susceptibility patterns. As the technology for nucleic acid amplification currently stands, application of the procedure is limited to referral and research laboratories. Partial or full automation and improved technology are reducing costs and increasing access to these assays. Specimen handling and preparation remain the most critical limiting steps. Specimen preparation must release the nucleic acids from the target organism, prevent degradation of the free nucleic acids, remove any substances inhibitory to nucleic acid amplification or hybridization, concentrate the nucleic acids into a small volume, place the nucleic acids in amplification or hybridization buffer, and prevent false-positive results caused by contaminating nucleic acids. Various samples have to be processed differently to extract the nucleic acids from their matrix. Therefore to obtain useful results, clinicians must consult with the laboratory when collecting specimens.

Despite their sensitivity and specificity, molecular detection procedures will never totally replace conventional cultural and serologic procedures because the results of nucleic acid amplification procedures and the results of culture or serology have different purposes. Nucleic acid detection procedures determine whether DNA or RNA from a particular organism is present in the specimen. They cannot determine whether the organism is involved in an infectious process, and they reveal nothing about the viability of the organism because they can detect DNA from dead organisms. Culture, by comparison, clearly demonstrates the viability of the organism, and a rise in titer of antibody to a specific organism strongly suggests active infection. Undoubtedly, the greatest asset of molecular diagnostics is the sensitivity to detect very small amounts of signal. However, the author (RLJ) must continue to recognize the potential for contamination of samples and asymptomatic carriage of small numbers of microorganisms, perhaps in sites previously considered sterile by conventional cultural procedures. These tools hold the power to enhance detection of new agents and enable clinicians to recognize new disease associations, but they require continued vigilance in evaluating disease causation. In some cases, epidemiologic characterization of disease may require different approaches. For example, the serovars of *Leptospira* organisms do not correlate precisely with genotypes that can be identified by nucleic acid analysis, yet serovars continue to be the best correlate of epidemiologic patterns of disease (see [Chapter 44](#)). See [Chapter 1](#) for additional discussion on molecular diagnostic methods.

33.4 ANTIMICROBIAL SUSCEPTIBILITY TESTS

Testing bacteria for their susceptibility to antimicrobials is one of laboratory procedures that has a significant impact on the prescribing of antimicrobials. To improve the predictive value of susceptibility tests, the indications for these tests and their limitations must be understood. *Susceptible* and *resistant* are relative terms (and somewhat arbitrarily defined) because a microorganism within the animal may be susceptible in one location as a result of attainable antimicrobial concentrations but resistant in another. Susceptibility tests measure the lowest concentration of antimicrobial required to macroscopically inhibit growth of the microorganism, a level called the *minimum inhibitory concentration* (MIC). The concentration of antimicrobial that inhibits the infectious agent, either by killing it outright or by slowing its growth sufficiently so that normal body defense mechanisms can take

Infectious Diseases of the Dog and Cat, 3rd Edition

over, is assumed to be similar to the in vitro MIC. Comparison of the MIC with the concentration of antimicrobial that can be attained in various body compartments allows prediction of the susceptibility or resistance of the organism to the drug at the infection site.

271

33.4.1 Indications

272

Some microorganisms are known to be susceptible to a particular highly effective antimicrobial, so testing is unnecessary. Susceptibility testing is indicated for any microorganism contributing to an infectious process if its susceptibility cannot be reliably predicted or resistance is anticipated based on knowledge of the organism's identity. Generally, isolates from normally sterile body sites should be tested, although questions have been raised about the cost effectiveness of routine testing of all urinary tract isolates. Susceptibility testing of multiple bacterial isolates from abscesses and wounds or normal flora is meaningless. Testing the susceptibility of anaerobes remains a technical problem and an unsettled issue; most anaerobes except those that produce β -lactamases are predictably susceptible.

33.4.2 Test Methods

The reference method of antimicrobial susceptibility testing measures the MIC in micrograms per ml by incorporating serial twofold dilutions of antimicrobials in a bacteriologic growth medium (Fig. 33-3). These dilutions can be made in microdilution wells, a procedure used by many larger laboratories. The clinical significance is determined by interpreting the results according to the criteria in Table 33-2.

In contrast to the dilution method, the most common antimicrobial susceptibility test performed in small laboratories and veterinary practices is the agar diffusion test. This method uses antimicrobial-impregnated paper disks applied to the surface of agar that have been inoculated with pure cultures of the test organism (Fig. 33-4). The diameter of the zone of inhibition of growth around the disk correlates inversely with the MIC. The disk diffusion technique is not difficult to perform; however, strict guidelines must be followed to use the standard zone size interpretive chart for each drug. Any variation in technique changes the relationship between the zone size and the MIC, leading to possible misinterpretation of the test result.

Conventional susceptibility testing methods assess the in vitro effects of antimicrobial agents on the growth of microorganisms under laboratory-defined conditions. In some cases, clinical response is better predicted by directly determining the production of antimicrobial-modifying enzymes even at very low levels (e.g., β -lactamases by *Staphylococcus* sp. and *Bacteroides fragilis*).

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 33-3 Antimicrobial susceptibility testing by the microdilution method. Each row of microwells contains serial twofold dilutions of an antimicrobial. The lowest concentration of drug that inhibits growth of the bacteria is defined as the MIC. For example, the first row contains ampicillin (256 $\mu\text{g/ml}$ in well A1, decreasing to 0.25 $\mu\text{g/ml}$ in well A11). The pellet of bacteria in the lower four wells (A8 to A11) indicates that 4 $\mu\text{g/ml}$ (well A7) is the MIC. Susceptibility to seven other drugs has also been tested in this microwell plate. (Courtesy Robert L. Jones, Colorado State University, Fort Collins, Colo.)

Genetic susceptibility test methods that have the potential to provide more rapid and reliable assessment of antimicrobial resistance in comparison with growth (phenotypic) methods have emerged in the past decade.

272

Genetic tests can be performed directly on clinical specimens, eliminating the need to isolate an organism when it is not readily cultivatable. Most genotypic methods include amplification of the resistance gene through the use of PCR and subsequent confirmation methods similar to those used for microbial identification. The genetic presence of resistance can now be detected for vancomycin-resistant *Enterococcus*, methicillin-resistant *Staphylococcus aureus*, extended-spectrum β -lactamase resistance in the Enterobacteriaceae family, and resistance genotypes of *Helicobacter* sp. and *Mycobacterium* sp. that are difficult or slow growing.

273

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 33-2 Interpretation Categories for Antimicrobial Susceptibility Tests

CATEGORY	DEFINITION
Susceptible	Infection caused by a strain that can be appropriately treated with the standard dosage of antimicrobial recommended for that type of infection and infecting species unless otherwise contraindicated.
Intermediate	Infection caused by a strain with antimicrobial MICs approaching blood and tissue levels that are usually attainable; therapeutic response rates may be lower than for susceptible isolates; selected drugs should be physiologically concentrated (e.g., quinolones and β -lactams in urine) or given at a high dosage without toxicity (e.g., β -lactams).
Resistant	Infection caused by a strain not inhibited by the usually achievable systemic concentrations of the antimicrobial at usual dosages; specific microbial resistance mechanisms are likely, and clinical efficacy has not been reliable in treatment studies.

MIC, Minimum inhibitory concentration.

Fig 33-4 Antimicrobial susceptibility testing by the agar diffusion method using disks containing antimicrobials. The diameter of the zone of inhibited microbial growth correlates inversely with the susceptibility of the microorganism. (Courtesy Robert L. Jones, Colorado State University, Fort Collins, Colo.)

33.4.3 Interpretations

In general, in vitro susceptibility testing is useful and reliably applied only to common, rapidly growing microorganisms such as staphylococci, enterococci, Enterobacteriaceae, and *Pseudomonas aeruginosa*. Infections caused by fastidious bacteria are usually treated more reliably on the basis of published guidelines. A

Infectious Diseases of the Dog and Cat, 3rd Edition

helpful guide to empiric therapy can be compiled by monitoring susceptibility trends of microorganisms recently isolated from animals within the practice region.

Susceptibility test results are a prediction of the expected response to treatment, not a guarantee. Most susceptibility tests use class-representative drugs rather than each possible antimicrobial. Furthermore, the interpretative criteria are based on the average blood levels of antimicrobials that can be achieved with a standard, fixed dose. Extralabel drug use in patients of other species, ages, and body sizes or modified dosages (flexible-label dosages) may significantly alter drug distribution. Levels of drug in tissues usually differ from levels in serum (e.g., low levels in CSF, high levels in urine). Although in vitro susceptibility testing predicts effectiveness, the drug may not be able to penetrate to the site of infection. In addition the pharmacodynamics of bacterial killing (time dependent versus concentration dependent) must be considered in the interpretation of susceptibility tests and subsequent dosage design. Therefore the predictive value of susceptibility tests for a favorable response is moderate at best. The MIC's value in predicting failure is much better but still not totally accurate. For example, a technician who interprets an MIC result as resistant according to blood levels may not have taken into account that the organism was recovered from urine, where the drug is concentrated, or that a topical treatment is being applied with drug concentrations of milligrams per milliliter rather than micrograms per milliliter.

33.5 SEROLOGIC TESTING

Detection of specific antibodies in the serum of an animal can be an indication of previous exposure, ongoing infection, vaccination, or passively acquired antibody. It is not always easy to discern the origin of these antibodies. Therefore serology is most effective as a diagnostic tool when the prevalence of antibodies in a population is low or when paired serum samples are collected to evaluate changes in antibody titers. The more common bacterial infections for which serologic tests are useful include brucellosis (see [Chapter 40](#)), leptospirosis (see [Chapter 44](#)), borreliosis (see [Chapter 45](#)), and rickettsial and ehrlichial infections (see [Chapters 27 to 29](#)).

For best results from serologic tests, serum should be transferred to a sterile tube as soon as possible after complete clotting and centrifugation to separate it from cellular elements. Excessive hemolysis interferes with some tests. Bacterial growth in serum may alter the immunoglobulin molecules. Once separated, serum samples should be refrigerated until testing begins if it starts within 72 hours. For longer periods of storage, serum may be preserved for extended periods by storage in a freezer (−20°C). Frozen serum samples should be packaged and shipped with adequate insulation and ice to prevent thawing before arrival at the laboratory.

34 CHAPTER 34 Antibacterial Chemotherapy

Craig E. Greene

A.D.J. Watson

Antibacterials, among the most widely used drugs in veterinary practice, are often administered without adequate documentation that an infection exists. Although this practice may not immediately harm the patient, routine and irrational use of antimicrobials may have several undesirable consequences. Unrestricted use encourages the selection of resistant strains of bacteria, which subsequently limits the choice of effective agents. Long-term treatment with antimicrobials may suppress the animal's resident microflora, thereby allowing overgrowth of more resistant microorganisms.

The increase in antimicrobial resistance worldwide has paralleled the use of drugs to combat microbial infections in people and animals.²⁸⁴ For example, increases in multiresistant *Enterobacter*, *Enterococcus*, and *Pseudomonas* spp. were observed in canine urinary tract infections (UTIs) from 1994 to 1998.³⁰⁵ However, other studies have not shown this trend.²⁷⁷ Once resistance emerges, selection pressure forces it to remain if antimicrobial usage is continued. Therefore veterinary hospitals must develop protocols that minimize inappropriate and indiscriminate antibacterial usage.

Selection of bacterial subpopulations with greater antimicrobial resistance than the original population is an inevitable consequence of antibacterial treatment. Selection pressures are highest when bacteria are exposed to suboptimal dosage regimens (i.e., concentrations of drug below the minimum inhibitory concentration [MIC]).

Antibiotics can be divided into two groups based on their patterns of bactericidal activity: concentration-dependent drugs and time-dependent drugs.⁸⁰ For the *concentration-dependent drugs*, optimal activity is achieved with high peak-drug concentration and area under the concentration time (AUC) curve; this group comprises aminoglycosides, fluoroquinolones, azithromycin, tetracyclines, vancomycin, quinupristin-dalfopristin, and metronidazole. The highest safe, achievable drug concentration is the most important factor for aminoglycosides and quinolones. Pulse infusion or once-daily dosing is likely to maximize the efficacy of these agents and induce the least amount of bacterial resistance. Most of the remaining antimicrobials are the *time-dependent drugs*, which show optimal activity when plasma concentrations of approximately four times the MIC are maintained for 50% to 80% of the dosage interval.³⁷⁷ Drugs of this type are the β -lactams (penicillins, cephalosporins, monobactams, carbapenems), clindamycin, and most macrolides. Administration of these drugs by continuous infusion or multiple daily doses would be most efficacious.

A postantibacterial effect (PAE) refers to persistent suppression of bacterial growth following exposure to an antimicrobial agent. All antibacterials appear to have this effect with susceptible gram-positive bacteria. With gram-negative bacteria, this effect is noted only with inhibitors of protein or nucleic acid synthesis, such as aminoglycosides, quinolones, tetracyclines, macrolides, chloramphenicol, and rifampin. In some instances, as with quinolones and aminoglycosides, the PAE is longer in vivo because they achieve higher concentration in leukocytes at sites of inflammation.

Antimicrobial combinations are used widely in veterinary practice, but few instances have occurred in which a synergistic outcome is documented; in many cases, combined use might reduce efficacy or enhance toxicity. However, several potentially effective combinations exist. β -Lactams act on bacterial cell walls and increase the uptake of aminoglycosides. Cell wall-active agents such as penicillins, cephalosporins, imipenem, and vancomycin

Infectious Diseases of the Dog and Cat, 3rd Edition

have been synergistic with the aminoglycosides streptomycin, gentamicin, and amikacin.² Agents acting sequentially in a pathway, for example, sulfonamides and diaminopyrimidines (see later discussion), have also been effective and more bactericidal than either drug by itself. Combinations of agents acting on the cell wall, such as aminopenicillin (ampicillin, amoxicillin) together with a cephalosporin (cefotaxime, ceftriaxone) have been more effective against bacteria in vitro and in vivo, presumably because they attach to different binding proteins on the bacterial cell wall. The streptogramins (see later discussion) consist of two components that act synergistically to inhibit protein synthesis in bacteria. β -lactamase inhibitors (see later discussion) increase the activity and spectrum of β -lactams against various bacteria. Other synergistic antimicrobial combinations include quinolones, macrolides, or tetracyclines with rifampin, especially against persistent intracellular microorganisms in difficult to reach areas such as pyogranulomatous lesions or meninges. Presumably rifampin facilitates intracellular penetration of the other drugs. Combinations of quinolones with β -lactams or aminoglycosides may also be beneficial.³³⁵ Clinical applications that justify combination therapy include bacterial endocarditis, resistant *Pseudomonas* infections, meningitis, febrile neutropenia, and *Brucella*, *Helicobacter*, and *Mycobacterium* infections.

Antimicrobial antagonism that is possible in certain circumstances can be avoided. The general advice is that cell wall-inhibiting drugs such as the β -lactams should not be used with bacteriostatic agents such as tetracyclines or chloramphenicol because rapid replication is needed for the cell wall-acting drugs to be effective. Macrolides should not be combined with lincosamides because complete antibacterial cross-resistance develops.

The prophylactic use of antimicrobials to prevent anticipated infections is controversial because of the increased risk of selecting for resistant microorganisms. Indiscriminant use of antibacterials may alter the patient's microbial flora and allow colonization by resistant bacteria. Several instances have occurred in which prophylactic administration were beneficial, as when infection is anticipated from contamination of otherwise sterile tissues. These cases include contaminated wounds following trauma, surgical procedures when contamination is expected, surgery in immunosuppressed patients, and during surgical procedures involving prolonged exposure of healthy tissue to air. Antibiotics may also be indicated prophylactically before major dental procedures and high-risk medical conditions, including diabetes mellitus, hyperadrenocorticism, immunosuppressive or cancer chemotherapy, and chronic bronchopulmonary disease. For further discussion of antimicrobials in traumatic and surgical wounds, see Traumatic and Surgical Infections, [Chapter 55](#).

274

275

This chapter presents a review of the general properties of antibacterial drugs by pharmacologic groups. Information on specific antibacterial drugs used in dogs and cats can be found in the Drug Formulary ([Appendix 8](#)) at the end of this book. Because of space limitations, a discussion of general principles of antibacterial chemotherapy has been omitted here. Antibacterial drug resistance and prophylaxis are discussed in [Chapter 94](#). The administration of antibacterial drugs in treating bacterial infections of various organ systems is covered in [Chapters 85](#) through [93](#). Dosage charts are listed in each of these chapters. In addition, [Appendix 8](#) also contains a list of appropriate antibacterial drugs for particular infection types and locations.

34.1 β -LACTAM DRUGS

This group of drugs, which includes penicillins, cephalosporins, monobactams, and carbapenems, acts by disrupting bacterial cell wall synthesis. These drugs are most effective when organisms are reproducing rapidly because of the high rate of cell wall formation. The most common mechanism of bacterial resistance to β -lactams is production of β -lactamase, which damages the β -lactam ring of these compounds. Genes for β -lactamase, encoded on chromosomes or plasmids, may spread within and among populations of bacteria. An increasing number of staphylococci have a modified penicillin-binding protein in their cell wall with a reduced affinity for all β -lactam drugs. These organisms have been classified as methicillin-resistant types and comprise a majority of nosocomial isolates from human hospitals. β -Lactam drugs act synergistically with aminoglycosides by facilitating

Infectious Diseases of the Dog and Cat, 3rd Edition

their entry into bacterial cells; however, they should never be premixed before administration because the aminoglycoside can damage the β -lactam ring. Synergism has been noted when a β -lactam such as ticarcillin has been combined with a quinolone for treating *Pseudomonas* infections.

34.1.1 Penicillins

34.1.1.1 Natural Penicillins

Penicillin G (benzyl penicillin) is a naturally occurring bactericidal antibiotic produced by certain molds of the genus *Penicillium*. It primarily inhibits synthesis of the gram-positive bacterial cell wall, causing osmotic fragility of susceptible bacteria. Penicillin G has three significant therapeutic limitations: it is degraded by gastric acid, which reduces systemic availability after oral administration; it is inactivated by β -lactamases produced by certain staphylococci and many gram-negative organisms; and at usual therapeutic dosages, it is active mainly against gram-positive aerobic and facultative anaerobic organisms (Table 34-1). Newer semisynthetic penicillins have been produced to overcome these disadvantages. Penicillins are believed generally to work synergistically with aminoglycosides in vivo.

Despite the production of newer derivatives, penicillin G remains the most active drug against many gram-positive aerobic bacteria. Most streptococci, except for enterococci (see Chapter 35), are susceptible. Many gram-positive bacilli and anaerobic bacteria, with the exception of β -lactamase-producing *Bacteroides fragilis*, are susceptible. Staphylococci are frequently resistant because of β -lactamase production. Procaine penicillin and benzathine penicillin are poorly soluble compounds that slowly dissolve at the site of injection, liberating penicillin G.

Penicillin V (phenoxymethyl penicillin) is an acid-stable derivative that is better absorbed from the alimentary tract, although resulting blood concentrations are much lower than that produced by parenteral administration of the same dose of penicillin G. Therapeutic effects equivalent to those obtained with penicillin V may be achieved at less expense by giving oral penicillin G to fasting animals at four times the usual parenteral dosage.

34.1.1.2 β -Lactamase-Resistant Penicillins

Methicillin, the first semisynthetic penicillin developed, resists β -lactamase but is inactivated by gastric acid and must be administered parenterally, limiting its clinical usefulness. Similarly, nafcillin has poor systemic availability after oral administration and is usually administered parenterally. The isoxazolyl derivatives (cloxacillin, dicloxacillin, flucloxacillin, oxacillin) can be administered orally with reasonable absorption from the gut and are resistant to staphylococcal β -lactamase but are less active compared with penicillin G against other penicillin G-sensitive organisms. These substances are highly protein-bound drugs, which delays their elimination and maintains high plasma-drug concentrations. However, this protein binding limits penetration of the drug into tissues. Possible indications for these drugs include infections caused by β -lactamase-producing staphylococci, as in pyoderma or osteomyelitis.

34.1.1.3 Aminopenicillins

Although ampicillin, amoxicillin, and hetacillin are susceptible to β -lactamase, they can be given orally or parenterally. They are slightly less active than penicillin G against gram-positive and anaerobic pathogens but have wider activity against gram-negative aerobic bacteria such as *Escherichia*, *Proteus*, and *Salmonella*.

Infectious Diseases of the Dog and Cat, 3rd Edition

Amoxicillin has antibacterial spectrum identical to ampicillin but is better absorbed orally and has more rapid and longer action compared with ampicillin. Hetacillin is an inactive derivative of ampicillin, is more stable in gastric acid than ampicillin, and is hydrolyzed rapidly to ampicillin in vivo. Bacampicillin, pivampicillin, and talampicillin are similar derivatives.

34.1.1.4

Carboxypenicillins

Carbenicillin and ticarcillin have increased activity against gram-negative aerobes, including *Acinetobacter*, *Proteus*, *Enterobacter*, some *Klebsiella*, and some anaerobes. Ticarcillin is especially active against *Pseudomonas*. Carboxypenicillins are destroyed by β -lactamase and are less effective against gram-positive organisms. These drugs are generally not well absorbed orally and must be given parenterally for systemic activity, but carindacillin and carfecillin are two esters of carbenicillin that are available for oral administration. The MICs for susceptible organisms are relatively high; therefore large doses must be administered. Co-administration with an aminoglycoside improves efficacy against *Pseudomonas* and reduces development of drug resistance. Ticarcillin and ticarcillin-clavulanate have been used successfully in managing canine otitis externa caused by *Pseudomonas aeruginosa* (see Drug Formulary, [Appendix 8](#), and [Chapter 85](#), Otitis Externa).²⁸⁰ Expense generally limits systemic use of carboxypenicillins.

34.1.1.5

Ureidopenicillins

Azlocillin, mezlocillin, and piperacillin have acid instability and β -lactamase resistance similar to those of the carboxypenicillins but have greater activity against gram-negative aerobes, including *Pseudomonas*, and less activity against some anaerobes. The main area of interest is their antipseudomonal activity, but piperacillin is one of few drugs consistently effective against enterococci and *B. fragilis*. Cost is a limiting factor with these drugs, but co-administration with a cephalosporin or quinolone might be considered when managing difficult-to-treat gram-negative aerobic bacterial infections.

- d Also includes azlocillin (Azlin).
- e Susceptibility data indicate efficacy of inhibitor alone, although the drug is not available by itself.

34.1.2 Pharmacokinetics

Absorption and duration of activity of penicillins depend on the dose administered, the vehicle containing the drug, and the solubility of the salt formulation. The potassium and sodium salts are soluble and can be given by the oral (PO), intramuscular (IM), subcutaneous (SC), intravenous (IV), and topical routes, whereas insoluble trihydrates are absorbed less rapidly by PO, IM, and SC routes. Soluble penicillin derivatives are absorbed from serous and mucosal surfaces but not through unbroken skin. Food in the stomach can adversely affect bioavailability of orally administered penicillins. All penicillins are eliminated by the kidney through active tubular secretion. As a result, soluble penicillin derivatives must be given at least every 4 hours to maintain therapeutic blood concentrations. Probenecid inhibits this rapid elimination. Activity can also be prolonged by delaying release of penicillins from injection sites by placing them in water-insoluble vehicles or combining them with organic salts. Examples are procaine penicillin and benzathine penicillin.

In general, penicillins are widely distributed into most highly perfused tissues, body fluids, and bone. Brain and cerebrospinal fluid (CSF) are exceptions, but concentrations in CSF are higher when meninges are inflamed. Penetration of body fluids and tissues by the highly protein-bound isoxazolyl derivatives is more limited. Dose reduction may not be necessary in patients with renal failure, despite impaired elimination, because of low inherent toxicity and the increased biliary secretion obtained with the semisynthetic penicillins. Potassium-containing penicillins should not be given IV to oliguric patients because of the risk of hyperkalemia.

277

278

Most aqueous solutions of penicillins are unstable, especially at higher temperatures. They should be maintained at a pH of 5.5 to 7.5 and not added to solutions containing bicarbonate or other alkalinizing ingredients. Oral suspensions of penicillins must be kept refrigerated after reconstitution. They generally remain stable for only 1 week. IV solutions should be used within 24 hours of preparation.

Penicillins should never be mixed with blood, plasma, or other proteinaceous fluids or with other antibiotics before administration. They might display in vivo antagonism with tetracycline and chloramphenicol; variable interactions with erythromycin, novobiocin, and lincomycin; no antagonism with sulfonamides; and possible synergism with aminoglycosides, cephalosporins, and polymyxins. Penicillins should not be mixed in the same syringe with aminoglycosides because of potential inactivation of both drugs.

Infectious Diseases of the Dog and Cat, 3rd Edition

34.1.3 Pharmacodynamics

Dosing schedules for β -lactams have been based on maintenance of blood levels above MIC for all or most of the dosing interval.³⁸⁶ Unlike the aminoglycosides and quinolones, β -lactams do not exhibit concentration-dependent killing. Their efficacy is time dependent; and for optimal effect, plasma drug concentrations should exceed the MIC for 50% to, at, or above 80% of the treatment interval so that bacterial cell walls can be disrupted as they form. A bactericidal effect is usually achieved at between one and four times the MIC. Higher doses of β -lactams have often been used for more severe infections, but reaching the MIC may be all that is necessary, and impairment of excretory mechanisms in septic animals may permit use of lower doses.²³⁷ Because of their low toxicity, β -lactams may have been given in overdoses. Additional studies on bioactivity and pharmacokinetics in ill and organ-impaired animals will be needed to resolve the dosing schedules for these drugs. Unlike aminoglycosides and quinolones, penicillins and cephalosporins have no PAE on gram-negative bacteria at clinically achievable concentrations. A PAE for certain gram-positive organisms, such as some staphylococci, has occurred. The PAE allows antibiotic concentrations to fall below the MIC for a portion of the treatment interval without impairing efficacy. Nevertheless, for most infections, β -lactams should be administered at a dose and interval sufficient to maintain plasma concentrations high enough to affect the target organism in the tissues of concern. In severe infections with resistant organisms, this action may necessitate constant IV infusions.

34.1.4 Toxicity

Toxic reactions are relatively rare with penicillins, and they generally have a high margin of safety. Rapid IV infusion or occasional IM injections may cause neurologic signs and convulsions. Hypersensitivity reactions such as hives, fever, joint pain, and acute anaphylaxis have been noted immediately after administration to dogs and cats. Administration of any penicillin derivatives should be avoided in known sensitized animals because of cross-reactivity.

Bleeding has been an important side effect in human patients treated with antipseudomonal and extended-spectrum penicillins. This effect has been attributed to various factors, including delayed fibrin polymerization, suppression of vitamin K-dependent procoagulants, and platelet dysfunction. Acute postoperative (within 5 days) azotemia has been ascribed to administration of nafcillin to dogs during surgery.²⁹⁶

34.1.5 Other β -Lactam Drugs

34.1.5.1 Monobactams

Aztreonam, the only clinically available member of this group, is resistant to β -lactamase and active against a wide range of aerobic and facultative gram-negative bacteria, including many strains resistant to other drugs. However, it has no useful activity against gram-positive or anaerobic pathogens. Aztreonam is given parenterally and enters many body tissues and fluids of dogs, including the CSF. Adverse effects are minimal and include diarrhea and vomiting. Primary use has been to treat patients with serious gram-negative infections in which resistance or toxicity to aminoglycosides is anticipated.

Infectious Diseases of the Dog and Cat, 3rd Edition

34.1.5.2 Carbapenems

This group includes imipenem, panipenem, biapenem, meropenem, and ertapenem. Imipenem is active against very many gram-positive and gram-negative aerobes and anaerobes. It is primarily indicated for treatment of infections caused by cephalosporin-resistant members of the family Enterobacteriaceae and some anaerobes. Resistant *Pseudomonas* isolates have emerged during therapy. Breakdown of imipenem by dehydropeptidase-1 in the kidney and other tissues produces nephrotoxic metabolites and decreases urine concentrations of active drug. Co-administration of cilastatin, a metabolic inhibitor of dehydropeptidase-1, increases urine drug concentrations and decreases potential nephrotoxicity. Panipenem is combined with betamipron for the same reason. Biapenem and meropenem are more stable and do not require any inhibitor be given concurrently. Meropenem pharmacokinetics have been studied in dogs.²⁷ The protein binding of meropenem is such that plasma concentrations parallel those in interstitial fluid.²⁸ Ertapenem has a narrower spectrum of activity than others in this class. Parenteral administration of imipenem-cilastatin is necessary because neither is absorbed orally. The dose should be reduced in renal failure. Adverse effects include nausea, vomiting, diarrhea, phlebitis at the infusion site, fever, and seizures. See Drug Formulary ([Appendix 8](#)) for further information on each of these drugs.

34.1.6 β -Lactamase Inhibitors

Some naturally occurring β -lactam drugs have low antibacterial activity by themselves but bind irreversibly to and inactivate bacterial β -lactamase. Concurrent administration of these agents increases the activity of penicillins and decreases the in vitro MIC required to inactivate many β -lactamase-producing organisms, such as staphylococci, *Escherichia*, *Capnocytophaga canimorsus*, some *Proteus* and *Klebsiella*, *B. fragilis*, *Salmonella*, and *Campylobacter* ([Table 34-2](#)). Organisms such as *Enterobacter*, *Serratia*, *Citrobacter*, and *Pseudomonas* remain resistant.

34.1.6.1 Clavulanate

Clavulanate has weak antibacterial activity against a wide range of organisms but is a potent inhibitor of β -lactamase. It is rapidly absorbed, unaffected by food, and widely distributed in extravascular sites with the exception of the central nervous system (CNS). Clavulanate is excreted rapidly in unchanged form in urine.

An orally administered product combining amoxicillin with potassium clavulanate is licensed for small animal use. A parenteral formulation of ticarcillin with potassium clavulanate is licensed for human and equine use. This combination is best suited to treat resistant infections caused by members of the family Enterobacteriaceae (except some *Pseudomonas* spp.) and anaerobes. It is given commonly to treat infections of the skin, lower respiratory tract, soft tissue, middle ear, and sinuses. The primary side effect has been diarrhea. Studies over a 9-year period on bacteria isolated from dogs and cats showed little decrease in relative susceptibility to this drug combination.³⁹³

279

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 34-2 Comparison of Antibacterial Activity of Selected β -Lactam and β -Lactamase Inhibitor Combinations^a

PENICILLIN	INHIBITOR	BACTERIAL SUSCEPTIBILITY			
		GRAM POSITIVE	GRAM NEGATIVE	ANAEROBES	PSEUDOMONAS
Amoxicillin	Clavulanate	+	+	+	—
Ticarcillin	Clavulanate	++	++	+++	+
Ampicillin	Sulbactam	+	+	+	—
Piperacillin	Tazobactam	++	+++	++	++

+++ , Excellent; ++, very good; +, good; —, poor.

a See [Appendix 8](#) for further drug information and dosages.

Table 34-3 Comparison of Antimicrobial Activity of Cephalosporins

GENERATION	BACTERIAL SUSCEPTIBILITY				
	GRAM POSITIVE	GRAM NEGATIVE	ANAEROBES	β -LACTAMASE RESISTANT	SELECTED SUSCEPTIBLE ORGANISMS
First ^a	+++	+	++	+	<i>Staphylococcus</i>
Second ^b	++	++	++	+	<i>Proteus</i>
Third ^c	+	+++	+	++	<i>Pseudomonas</i>
Fourth ^d	+	+++	+	+++	Enterobacteriaceae

+++ , Excellent; ++, very good; +, good; —, poor.

- a **First generation:** primarily active against gram-positive aerobes and facultative anaerobes; resistant to staphylococcal β -lactamase, which is responsible for penicillin ineffectiveness, but is less effective on a weight basis than penicillin G against obligate anaerobes.
- b **Second generation:** similar attributes to first generation but (as with aminopenicillins) is also active against some gram-negative aerobes and facultative anaerobes; second best cephalosporin group against anaerobes.
- c **Third generation:** enhanced activity against gram-negative aerobes and facultative anaerobes, low activity against obligate anaerobes, but less active against gram-positive aerobes and facultative anaerobes; variable activity against *Pseudomonas*; see [Table 34-4](#) for antipseudomonal efficacy of selected cephalosporins.
- d **Fourth generation:** very active against Enterobacteriaceae and *Staphylococcus* (including methicillin-resistant strains); moderate antipseudomonal activity.

34.1.6.2 Sulbactam

This drug, an irreversible β -lactamase inhibitor, has weak intrinsic antibacterial activity against most gram-positive and some gram-negative organisms, with best activity against *Neisseria* and *Bacteroides*. It extends the bacterial spectrum of ampicillin to include *Staphylococcus*, *Bacteroides*, and most *Escherichia*.

Infectious Diseases of the Dog and Cat, 3rd Edition

Sulbactam has been given with ampicillin to treat resistant bacterial meningitis in people and to treat those with intraabdominal, pelvic, skin, soft-tissue, bone, and joint infections.

34.1.6.3

Tazobactam

This β -lactamase inhibitor has been added to enhance the antibacterial spectrum of piperacillin. It is active against many resistant Enterobacteriaceae, *Staphylococcus*, and *Bacteroides*.

34.2

CEPHALOSPORINS

The cephalosporins are a group of antibiotics derived chemically from a substance produced by the fungus *Cephalosporium acremonium*. Several related compounds can also be considered in the cephalosporin group because they have similar antibacterial activity, pharmacology, and indications. This group includes cefoxitin and cefotetan (both cephamycins), loracarbef (a carbacephem), and latamoxef (an oxacephem).

Similar to penicillins, cephalosporins are bactericidal β -lactam antibiotics that inhibit bacterial cell wall synthesis, resulting in osmotic fragility. These drugs are generally more effective than penicillin in penetrating the outer cell wall of gram-negative bacteria and are less susceptible to inactivation by bacterial β -lactamases.

Cephalosporins have been separated into four generations or classes, based on the chronology of discovery, chemical structure, and therapeutic activity. The characteristics of the classes are compared in [Table 34-3](#), and important features of common cephalosporins are presented in [Table 34-4](#). For further information on specific drugs and dosage, see the Drug Formulary ([Appendix 8](#)).

34.2.1

First Generation

The first-generation cephalosporins are primarily active against gram-positive bacteria, with the exception of some resistant *Staphylococcus*, and some gram-negative aerobes, such as *Escherichia*, *Klebsiella*, and *Proteus mirabilis*. The activity of these drugs against susceptible aerobes and facultative anaerobes is not as strong as that of penicillin G. They are not as effective against anaerobes, including *Bacteroides*. First-generation cephalosporins can be administered orally or parenterally, depending on the drug, and they have variable protein binding with wide distribution into pleural, pericardial, peritoneal, and synovial fluids and most soft tissues. They enter the CSF only in the presence of meningeal inflammation. Most are excreted unchanged in the urine. Cephalosporins may give atypical or false-positive reactions with copper reduction methods for determining urine glucose (e.g., Clinitest tablets).

279

281

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 34-4 Properties of Cephalosporins^a

GENERIC NAME (TRADE NAME)	ROUTE OF ADMINISTRATION	COMMENTS
First Generation^b		
Cephalexin (Keflex)	PO	Less active against <i>Staphylococcus</i>
Cefazolin (Ancef, Kefzol)	IV, IM	Achieves greatest blood concentration; longest half-life; most protein-bound; more active against <i>Escherichia</i> , <i>Klebsiella</i> , <i>Enterobacter</i> than others in its class
Cephapirin (Cefadyl)	IV, IM	Resists β -lactamase; high doses for life-threatening infections when causative organism shows susceptibility to first-generation drugs
Cefadroxil (Duricef, Cefa-Tabs)	PO	Rapid and complete oral absorption even with food; enters prostate
Cephadrine (Velosef, Anspor)	IV, IM, PO	Spectrum similar to cephalexin; less active against some gram-negative organisms
Second Generation^c		
Cefaclor (Ceclor)	PO	Similar spectrum but more active than first generation against <i>Proteus</i> , <i>Escherichia</i> , <i>Enterobacter</i> , and <i>Klebsiella</i> ; adequate soft-tissue concentrations; minor amount excreted in urine unchanged
Cefotetan (Cefotan) ^d	IV, IM	Similar indications to cefoxitin, but may be less expensive
Cefoxitin (Mefoxin) ^d	IV, IM	Pain on IM injection; active against <i>Bacteroides fragilis</i> and <i>Serratia</i> ; particularly effective against most anaerobes
Cefuroxime (Zinacef, Kefurox)	IV, IM	Crosses blood-brain barrier; good for lower respiratory tract and central nervous system infections
Third Generation^e		
Cefixime (Suprax)	PO	High bioavailability and long half-life in dogs; for urinary tract and respiratory infections caused by resistant bacteria; not active against <i>Pseudomonas</i> or <i>Bordetella</i>
Ceftiofur (Naxcel)	IV, IM	Licensed for treatment of bovine respiratory disease; good for broad-spectrum treatment of systemic infections; low activity against <i>Staphylococcus</i>
Cefotaxime (Claforan)	IV	Active against <i>Leptospira</i> and gram-negative aerobes except <i>Pseudomonas</i> ; metabolized in liver to active drug; good central nervous system penetration
Ceftriaxone (Recephin)	IV, IM	Longest duration for once-daily dosing; active against resistant gram negatives except <i>Pseudomonas</i> ; good against <i>Borrelia</i>
Antipseudomonal Third Generation^f		
Ceftazidime (Fortaz, Tazidime, Tazicef)	IV	Primarily active against gram-negative aerobes and best of cephalosporins against <i>Pseudomonas</i>
Cefoperazone (Cefobid)	IV	Less active than other third-generation drugs against gram-positive and -negative aerobes; second best of its class against <i>Pseudomonas</i> ; can produce coagulation deficiencies; erratic central nervous system penetration; predominant (80%) biliary excretion
Fourth Generation^g		
Cefepime (Maxipime)	IV	High blood levels and widely distributed in tissues; good against <i>Pseudomonas</i> and <i>Mycobacterium avium-intracellulare</i> ; variable activity against gram positives and anaerobes

IM, Intramuscular; IV, intravenous; PO, by mouth.

Infectious Diseases of the Dog and Cat, 3rd Edition

- a See Drug Formulary ([Appendix 8](#)) for further information on pharmacokinetics and appropriate dosages for each drug.
- b Also includes cephaloglycin, cephalothin, and cephaloridine.
- c Also includes cefuroxime axetil (Ceftin), cefmetazole, cefonicid (Monocid), and three more (given orally): cefprozil, cefpodoxime (Vantin), and loracarbef.
- d Cefoxitin and cefotetan are cephamycins.
- e Also includes ceftriaxone (Rocephin), ceftizoxime (Cefizox), flomoxef, ceftibuten (Cedax), cefmenoxime, and latamoxef (Moxam, Latoxacef [an oxacephem]).
- f Also includes cefsulodin and cefpiramide.
- g Also includes cefpirome.

Two members of this group are of historic significance but are no longer used. Cephalothin is found in susceptibility disks, but it is of limited use because of pain and sterile abscesses produced on IM injection. Cephaloridine produces similar complications and is nephrotoxic. Cephalothin is the only first-generation drug to penetrate CSF well. First-generation agents available for parenteral use include cefazolin, cepapirin, and cephradine. Oral drugs include cefadroxil and cephalexin, which have both been marketed for veterinary use. These two oral drugs have uses for treating gram-negative urinary and gram-positive skin infections in dogs and skin and soft-tissue infections in cats. Both agents reach effective blood plasma concentrations after oral dosing of dogs and cats.

34.2.2 Second Generation

Second-generation cephalosporins have a broader spectrum of antibacterial activity and greater efficacy against gram-negative aerobic bacteria and anaerobes than does the first generation (see [Table 34-3](#)). This activity is largely the result of the greater resistance of these drugs to β -lactamases. They are more effective than first-generation drugs against *Proteus* (other than *P. mirabilis*), *Escherichia*, *Klebsiella*, *Enterobacter*, and anaerobic bacteria. As with first-generation drugs, second- and third-generation cephalosporins are relatively ineffective against *Bacteroides*. Exceptions are cefoxitin, and cefotetan, which are effective against most obligate anaerobes. Cefoxitin is also effective against *Serratia*. Second-generation drugs are generally given parenterally, but drugs effective orally include cefaclor, cefuroxime axetil (a pro-drug), cefprozil, cefpodoxime, and loracarbef.

34.2.3 Third Generation

The third-generation cephalosporins have longer duration of activity compared with the other two classes. Excretion in either urine or bile is variable, depending on the drug, although most undergo some inactivation and excretion by the liver. Third-generation drugs—except for latamoxef, ceftriaxone, and cefotaxime—do not penetrate CSF well in the absence of inflammation. Third-generation cephalosporins have marked activity against aerobic gram-negative organisms and less effectiveness against aerobic gram-positive organisms and anaerobes than the preceding classes (see [Table 34-3](#)). They are more active than second-generation drugs against *Citrobacter*, *Acinetobacter*, *Pseudomonas*, and *Serratia*. Most third-generation drugs are given parenterally, but a few oral drugs such as cefixime and cefpodoxime proxetil (a pro-drug) are available. Unfortunately, these oral preparations are not always as effective as the other members of this class against difficult organisms. Third-generation cephalosporins have been recommended for IV use in septicemia, bacteremia, intraabdominal infection, and endocarditis. Second- and third-generation drugs have had good efficacy against drug-resistant *Salmonella* isolated from people.

Infectious Diseases of the Dog and Cat, 3rd Edition

34.2.4 Antipseudomonal Cephalosporins

Unlike other cephalosporins, cefoperazone and ceftazidime are among the most effective drugs against *P. aeruginosa*. However, most third-generation cephalosporins are not as effective against *Pseudomonas* as are the newer extended-spectrum penicillins.

34.2.5 Fourth Generation

Fourth-generation cephalosporins are not affected by some chromosome-mediated and many plasmid-mediated β -lactamases. Cefepime and cefpirome are members of this class. They have good activity against *Staphylococcus*, Enterobacteriaceae, and *Pseudomonas* but, as with third-generation drugs, are not reliable against anaerobes (see [Table 34-3](#)).

34.2.6 Indications

The varied indications for use of cephalosporins include treatment of bacterial infections of respiratory, urinary, and genital tracts, as well as soft tissues, bones and joints, and skin. Cephalosporins are effective when given prophylactically for polymicrobial intraabdominal infections after bowel surgery. In addition, cephalosporins have also been recommended for prophylactic purposes in biliary surgery and for treating biliary infections because many are excreted unchanged in bile. However, they do not enter the biliary tract when complete biliary obstruction and jaundice are present. Failure of cephalosporins to prevent postoperative staphylococcal infections has been associated with strains that hydrolyze cephalosporins.¹⁹² Cefotaxime, latamoxef, and ceftriaxone are effective for meningitis caused by drug-resistant bacteria. None of the cephalosporins are effective against methicillin-resistant staphylococci or enterococci.

Most oral cephalosporins administered in small animal practice are first-generation drugs but oral second- and third-generation products are available (see [Table 34-4](#)). Cefazolin and cephapirin are the most commonly used parenteral first-generation cephalosporins. The second-generation drugs, such as cefoxitin, have increased efficacy against anaerobic infections. Of the second-generation drugs, cefuroxime has a high degree of penetration into the CNS and CSF for treatment of meningitis. Some concern has surfaced of the increasing use of third-generation drugs in animal patients.²⁰ This concern stems from the risk of producing antimicrobial-resistant strains that might spread to people.

34.2.7 Toxicity

The toxicity of cephalosporins is minimal compared with that of other antibiotics. In this regard, the cephalosporins are similar to the penicillin derivatives.²⁷² Allergic skin reactions have been reported with cephalosporins in dogs. A greater prevalence of diarrhea is associated with agents undergoing biliary excretion. Cephaloridine is nephrotoxic, but this is not characteristic of the newer drugs. Because the kidney excretes most cephalosporins, plasma concentrations are increased and half-lives prolonged in renal failure or when probenecid, loop diuretics, or aminoglycosides are used. All parenteral formulations of cephalosporins may cause phlebitis and myositis after IV and IM administration, respectively. Gut irritation may cause vomiting and diarrhea with oral administration. Bleeding disorders in people resulting from vitamin K antagonism, platelet dysfunction, and immune-mediated thrombocytopenia have been associated with third-generation cephalosporins, most frequently cefamandole, cefoperazone, and latamoxef. Cephalosporin-induced blood dyscrasias, a result of immune-mediated destruction of blood cells and direct marrow toxicity, have occurred in

Infectious Diseases of the Dog and Cat, 3rd Edition

dogs given high-dose, long-term cephalosporins.⁸⁹ Myelosuppression resolves when therapy is withdrawn. For individual drug characteristics, consult the Drug Formulary ([Appendix 8](#)).

34.3 AMINOGLYCOSIDES

These bactericidal antibiotics interfere with the synthesis of bacterial protein. Aminoglycosides (AGs) are relatively small, primarily basic, water-soluble molecules that are active against certain gram-negative and gram-positive aerobic and facultative anaerobic bacteria, including many staphylococci and some mycobacteria. They are particularly effective against aerobic gram-negative bacilli such as *Escherichia*, *Klebsiella*, *Proteus*, and *Enterobacter*, and some are effective against *Pseudomonas*. AGs are not active against fungi or obligate anaerobic bacteria and should not be used to treat abscesses or granulomatous infections. Their uptake across bacterial cell membranes requires the presence of oxygen. For this reason, AGs demonstrate poor activity against anaerobes and have decreased ability to penetrate bacteria within abscesses with limited oxygen tension. When used alone, AGs are relatively ineffective against *Streptococcus* but are effective against *Staphylococcus intermedius*. Co-administration with β -lactams increases their activity against some gram-positive aerobes including *Enterococcus* spp. In serious systemic infections, in which mixed organisms are anticipated, an aminoglycoside given with a β -lactam plus a β -lactamase-inhibitor combination acts against a broad spectrum of organisms. The properties and indications for various AGs are summarized in [Table 34-5](#).

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 34-5 Properties of Aminoglycosides^a

GENERIC NAME (TRADE NAME)	ROUTE OF ADMINISTRATION	COMMENTS
Streptomycin (many)	IM, SC	Occasional IM use for bacteremias, <i>Brucella canis</i> , <i>Leptospira</i> carriers; limited availability
Dihydrostreptomycin (many)	IM, SC	Same as streptomycin; many resistant strains; limited availability
Neomycin (Biosol, Mycifradin)	PO, topical	PO for local gastrointestinal effect; topical use in solutions, ointments, and so forth; spectrum similar to kanamycin; absorbed and toxic if bowel wall damaged
Kanamycin (Kantrex, Kantrix, Klebcil)	PO, IM, SC	PO for local gastrointestinal effect; useful in urinary tract infection, injections, and superficial and systemic infections; spectrum similar to gentamicin but resistant strains much more common; effective against <i>Staphylococcus</i>
Gentamicin (Gentocin, Garamycin, Apogen, Bristagen, U-Gencin)	IM, SC, IV, aerosol, topical	For bacteremia; in aerosol for respiratory infections caused by <i>Escherichia</i> , <i>Pasteurella</i> , <i>Pseudomonas</i> , <i>Proteus</i> , <i>Staphylococcus</i> , <i>Enterobacter</i> , <i>Serratia</i> , <i>Klebsiella</i> , <i>Bordetella</i>
Paromomycin (Humatin)	PO	PO for local gastrointestinal effect; for susceptible <i>Staphylococcus</i> , <i>Escherichia</i> , <i>Salmonella</i> , and protozoa (<i>Entamoeba</i> , <i>Balantidium</i> , <i>Cryptosporidium</i>)
Tobramycin (Nebcin)	IM, SC	Gram-negative spectrum similar to gentamicin; effective against some <i>Pseudomonas</i> resistant to gentamicin; less nephrotoxic than gentamicin
Amikacin (Amikin, Amiglyde)	IM, SC	Widest antibacterial spectrum aminoglycoside; effective against <i>Pseudomonas</i> and many gram-negative bacilli resistant to gentamicin and tobramycin (e.g., <i>Klebsiella</i>)
Sisomicin (Sisomin)	IM, SC	More active than gentamicin against many bacteria, especially <i>Pseudomonas</i> and <i>Escherichia</i> ; not effective against organisms resistant to gentamicin; toxicity parallels gentamicin
Netilmicin (Netromycin)	IM, SC	<i>Staphylococcus</i> highly susceptible; active against some organisms resistant to gentamicin; more active than sisomicin or tobramycin; slightly less active than amikacin against <i>Pseudomonas</i> ; less toxic than tobramycin
Framycetin (Soframycin, Neomycin B)	PO, topical	PO for local gastrointestinal effect; topical in ointment, drops, and so forth; gram-negative spectrum similar to neomycin
Dactinomycin ^b	IM, SC	Intraabdominal infections; wide activity against gram-positive and gram-negative aerobes; may be combined with metronidazole for anaerobic spectrum; most active aminoglycoside against <i>Acinetobacter</i> and <i>Staphylococcus</i>
Isepamicin ^b	IV, IM, SC	Exceptional activity against Enterobacteriaceae and <i>Pseudomonas</i>

IM, Intramuscular; SC, subcutaneous; PO, by mouth; IV, intravenous.

^a See Drug Formulary, [Appendix 8](#), for appropriate dosages.

^b Not available commercially.

Dihydrostreptomycin, streptomycin, neomycin, and kanamycin have been used extensively for many years. However, with such frequency of use, extensive bacterial resistance has developed. The first two drugs listed are no longer commercially available in many countries. Amikacin and gentamicin are more effective and routinely given. Amikacin is generally more effective compared with gentamicin against resistant strains. Tobramycin and netilmicin have been developed to increase antibacterial activity and reduce toxicity. Sisomicin, isepamicin, and dactimicin are newer AGs being evaluated for clinical purposes. The latter two drugs have broad-spectrum activity against gram-positive and gram-negative aerobes.

282

283

Infectious Diseases of the Dog and Cat, 3rd Edition

Antimicrobial synergy is often observed when AGs are combined with β -lactam drugs. The β -lactams may also enhance AG activity under conditions of reduced oxygen tension. β -Lactams are indicated to treat gram-negative bacterial infections but must be given parenterally for systemic infections. β -Lactams are used in combination with other antibiotics to treat difficult infections, such as enterococcal endocarditis.

34.3.1 Pharmacokinetics

The pharmacokinetics of many AGs have been studied in dogs and cats. AGs are poorly absorbed from the gastrointestinal (GI) tract and must be administered parenterally to achieve therapeutic plasma concentrations; however, some AGs such as neomycin and paromomycin are administered orally for local treatment of bacterial or protozoal enteritis or to suppress enteric microflora in hepatic coma. They are poorly absorbed through intact skin but may cross-damage squamous, mucosal, or visceral epithelium, resulting in potential toxicity. Topical AG creams and solutions can help control bacterial growth and facilitate healing of open wounds. They are absorbed following IM or SC administration,⁴²⁴ although more slowly with the latter. IV administration is best for immediate effects. Following intraoperative IV administration, AGs enter surgical wounds on a time course that parallels plasma concentrations. They are minimally bound to plasma proteins but are poorly lipid soluble and highly ionized; thus they penetrate little beyond extracellular fluid compartments, including synovial, peritoneal, and pleural spaces. They also diffuse poorly into the CNS, prostate, amniotic fluid, and eyes, even in the presence of inflammation. Obese cats have smaller volumes of distribution of AGs than lean cats, warranting dose reductions in obese animals.⁴²⁹ Little excretion into bile and feces occurs, but unchanged AG is eliminated rapidly in urine by glomerular filtration and tubular excretion. Within 1 hour after administration, urine AG concentrations are 25 to 100 times greater than peak blood plasma concentrations and remain above therapeutic levels for several days. These drugs may accumulate in renal tubular cells and are eliminated slowly from renal tissue; once-daily dosing produces less renal accumulation than thrice-daily dosing with higher peak tissue concentrations. The pH at which optimal antibacterial activity occurs is 7.5 to 8.0. AGs such as gentamicin have been effective in treating canine bronchopulmonary infections when administered as aerosols: drug concentration in airways is increased and toxicity is reduced because of poor absorption from this site.

Individual variability in distribution and elimination of AGs accounts for unpredictable variability in blood and tissue concentrations. Consequently, the monitoring of blood plasma concentration is common in human medicine. Liposomal encapsulation of AGs has been used in an attempt to increase therapeutic efficacy and decrease toxicity.³⁶³

34.3.2 Pharmacodynamics

AGs, in contrast to some other antibiotics, show marked concentration-dependent killing of bacteria, after which a distinct PAE, a bacteriostatic phase without regrowth, is observed. With concentration-dependent antibacterial activity, the rate and efficacy of bacterial killing increases with higher drug concentrations: all the organisms may die if concentrations are sufficiently high. When the peak blood plasma concentration is less than approximately 10 times the MIC, the time of exposure to the antibiotic concentration may still be important, and the entire AUC must be considered in these cases. Because of the peak concentration requirement, once-daily AG therapy has been considered superior to multidosing in producing higher concentrations and, incidentally, lower toxicity. Nevertheless, a reduction in toxicity by less frequent administration has not been well substantiated.²¹⁰ Gentamicin has been given to dogs once daily for 5 days with minimal or no nephrotoxicity.⁴ AGs are thought to have a PAE after exposure of some gram-negative or

Infectious Diseases of the Dog and Cat, 3rd Edition

gram-positive organisms to an antibiotic. Drug-induced nonlethal damage from bacteriostatic suppression of infecting strains has been seen against both gram-positive and gram-negative bacterial strains.

Bacteria are likely to develop resistance to AGs by one of three mechanisms: alteration of receptor sites on bacterial ribosomes, decreased bacterial cell penetrability, or plasmid-associated production of enzymes that inactivate AGs. Bacterial resistance to AGs is greater with the older drugs and less with newer compounds. Cross-resistance is not uniform among all members of the class. For example, although many *Klebsiella* are resistant to kanamycin and gentamicin, they are susceptible to amikacin, a derivative of kanamycin. In general, the degree of cross-resistance between gentamicin and other AGs is high, except for amikacin and tobramycin.

34.3.3 Toxicity

Toxicities with AG antibiotics are relatively common and depend on the individual drug and dosage, duration of therapy, state of patient hydration, presence of upper UTI, and pretreatment of renal function. Nephrotoxicity can be attributed to the uptake of AGs by proximal renal tubular cells and drug retention in lysosomes of these cells in the cortex. Above a certain concentration, cell necrosis occurs. Although species differences exist, nephrotoxicity in decreasing order is as follows: neomycin, kanamycin, gentamicin, tobramycin, amikacin, and streptomycin. Nephrotoxicity has been associated with high trough plasma concentrations (greater than 2.0 µg/ml for gentamicin and 5.0 µg/ml for amikacin). Frequent administration of small doses to maintain constant plasma AG concentrations is considered more toxic than less frequent administration of larger dosages. Frequent (three to four times daily) dosing has been recommended for treatment of systemic infections in animals, but renal function must be monitored closely with such protocols. AGs may be given at higher doses and less frequent intervals than commonly recommended. Pulse administration of large (10 mg/kg) doses of gentamicin at 5-day intervals has been shown to maintain effective tissue concentrations in dogs. Pulse administration should be less nephrotoxic than frequent dosing because plasma concentrations decrease sufficiently between administrations; however, further documentation of the efficacy of such regimens is needed.¹²⁷ Renal proximal tubular dysfunction is the most common and serious side effect of AG administration. Higher protein diets have protected dogs against development of gentamicin-induced nephrotoxicity.¹³⁶ Inadvertent absorption of gentamicin administered topically when lavaging an abscess produced nephrotoxicity in a cat.²⁵¹ Use of AGs should be restricted in puppies and kittens because these animals may be more prone to develop renal failure than older animals.

The best method of detecting early renal tubular dysfunction in practice is to examine the urine for casts and proteinuria. Although mainly a research tool, the most sensitive way to detect AG toxicity in dogs and cats is to measure urinary concentrating ability and urinary enzyme activities.¹³⁷ Serum urea and creatinine concentrations are primarily measures of glomerular filtration and are less sensitive indications of AG nephrotoxicity. Acute renal failure typically develops several days after therapy is initiated but may develop several days after the drug is discontinued. Because AGs accumulate in renal tubular cells, the insult persists after administration ceases. The prognosis for recovery from AG-induced renal failure is poor in dogs and cats. In human patients, AG concentrations are monitored to avoid toxicity; dosages are modified so that plasma concentrations are high enough 1 hour after administration to be bactericidal but are below toxic threshold levels 30 minutes later.

Clinical reports from human hospitals have noted increased nephrotoxicity when AGs are given with cephalosporins, although studies in rats indicated the combination may actually be protective. Similarly, combinations of piperacillin with gentamicin or cephaloridine were shown to have reduced nephrotoxicity. Furosemide may enhance nephrotoxicity and ototoxicity of AGs, probably because of decreased extracellular fluid volume and decreased drug excretion causing increased plasma AG concentration. Other diuretics may

Infectious Diseases of the Dog and Cat, 3rd Edition

have similar effects and should be avoided in combination with AGs. Cats and dogs should be well hydrated whenever AG therapy is instituted. Other nephrotoxic drugs such as amphotericin B and cisplatin should be avoided because they may potentiate nephrotoxicity.

Gentamicin-impregnated methyl methacrylate beads and methyl methacrylate cement have been applied successfully for prophylaxis in orthopedic surgery.³⁶² Local release of the gentamicin into surrounding bone, soft tissue, and synovial fluid allowed for long-term therapy, effective cure, and no side effects. AGs have also been incorporated into liposomes to reduce systemic toxicity.

Irreversible ototoxicity has been a problem with AG therapy; both vestibular and auditory impairment from damage to sensory end-organs have been reported. High concentrations of AGs remain in the perilymph fluid of the ear for extended periods compared with plasma. AGs are potentially ototoxic when instilled directly into the external ear canal of dogs and cats, especially if the tympanic membrane has been ruptured. However, ototoxicity has not been found at concentrations present in commercial otic preparations.³⁵⁶ Table 34-6 summarizes relative otic and renal toxicities of AGs for dogs and cats. In cats, the ototoxicity of AGs in decreasing order is streptomycin, dihydrostreptomycin, gentamicin, tobramycin, and netilmicin, with vestibular damage more likely than auditory damage. As with nephrotoxicity, ototoxicity is more likely with higher doses, with longer treatment durations, and with animals that are dehydrated or have poor renal perfusion.

Table 34-6 Relative Toxicity of Aminoglycosides

DRUG ^a	RENAL	VESTIBULAR	AUDITORY
Streptomycin	—	+	—
Dihydrostreptomycin	?	—	+

Ototoxicity in dogs and cats, *Semin Vet Med Surg Small Anim* 8:42–49.

^a See Drug Formulary, [Appendix 8](#), for appropriate dosages.

AGs, associated with underlying risk factors, may produce neuromuscular blockade by competitive antagonism of acetylcholine at the myoneural junction. In addition to their own neuromuscular blocking effects, they enhance the actions of other neuromuscular blocking agents and general anesthetics.¹¹⁶ Therefore irrigation of body cavities or parenteral administration of AGs should be avoided during surgery that requires general anesthesia.

Circulatory depression, exhibited by decreased systemic blood pressure and heart rate, has been found in cats, dogs, and nonhuman primates given AGs during pentobarbital anesthesia. Cardiac arrest has been reported in people overdosed with kanamycin. If possible, AG administration should be avoided in animals in shock or with cardiovascular insufficiency. Calcium gluconate, given IV, may reverse AG-induced neuromuscular blockade or myocardial depression and restore blood pressure.

Infectious Diseases of the Dog and Cat, 3rd Edition

Prolonged high oral doses of neomycin or paromomycin may produce diarrhea and malabsorption caused by overgrowth of resistant indigenous intestinal flora. Hypersensitivity and allergic reactions have been reported rarely in people receiving AGs. AGs should not be administered to pregnant animals because they can cross the placenta and may produce fetal intoxication. Penicillins and AGs should never be mixed in the same solution before administration—depending on the type and concentration of penicillin, mixing can inactivate the AGs. They should not be administered IV with solutions containing calcium, other antimicrobials, heparin, or sodium bicarbonate. For individual drug characteristics and dosages, consult the Drug Formulary ([Appendix 8](#)).

34.4 SPECTINOMYCIN

Aminocyclitol antibiotics, composed of a basic cyclic structure with an amino group, include the AGs along with spectinomycin and its derivatives. Spectinomycin shares many properties with the AGs, including low plasma protein binding, high water solubility, poor GI absorption, primary renal excretion, inhibition of bacterial ribosomal protein synthesis, and optimal antibacterial activity at pH 8.

Spectinomycin has bacteriostatic activity, mainly against gram-negative aerobic pathogens such as *Escherichia*, *Klebsiella*, *Salmonella*, *Enterobacter*, and *Proteus*, as well as mycoplasmas. Efficacy is low against gram-positive aerobes, most pseudomonads, and chlamydiae. Obligate anaerobes are resistant. Parenteral administration of spectinomycin may be useful to treat bacteremia associated with infectious gastroenteritis caused by susceptible enteropathogenic bacteria and for intraabdominal sepsis (see Intraabdominal Infections, [Chapter 89](#)). As with some AGs, development of resistant bacteria is a problem with spectinomycin. Trospsectomycin is an analog with similar activity against enterobacteria but increased activity against gram-positive aerobes.

34.5 PEPTIDES

34.5.1 Vancomycin

This complex glycopeptide molecule has bactericidal activity, inhibits cell wall formation and RNA production, and alters cytoplasmic membranes in susceptible replicating bacteria. Vancomycin is active primarily against gram-positive organisms, mainly *Staphylococcus* (including methicillin-resistant strains), *Streptococcus*, and *Clostridium*. Most gram-negative bacteria are resistant.

284

Vancomycin can be administered orally to treat enteric infections. It is absorbed poorly from the GI tract and must be given IV for systemic infections. The drug is distributed well into body cavities and across inflamed meninges. Excretion is largely by glomerular filtration, with small amounts entering the bile.⁴³⁶

285

The most frequent side effects with vancomycin in people have been fever, chills, and phlebitis at injection sites. These effects can be reduced if the drug is administered slowly in a large volume of fluid. Leukopenia and eosinopenia have been reported.

Possible uses for vancomycin in animals are limited but may be considered for treating severe, persistent staphylococcal infections and colitis associated with overgrowth of *Clostridium difficile*. At present, antimicrobial resistance to vancomycin does not appear to be as much a problem in fecal microflora of dogs and cats as to other more routinely used antimicrobials.³¹⁵ This status might change subsequent to indiscriminate use of this drug. See the Drug Formulary ([Appendix 8](#)) for further information. In some countries, such as the United States, restrictions have been placed on the use of glycopeptides in food-producing animals.¹¹

Infectious Diseases of the Dog and Cat, 3rd Edition

34.5.2 Teicoplanin and Dalbavancin

Teicoplanin is a complex glycopeptide whose structure, activity, and other properties are similar to those of vancomycin. It is primarily active against aerobic and some anaerobic gram-positive organisms. Teicoplanin is more protein bound and lipophilic than vancomycin. The half-life in plasma is much longer, which may allow once daily administration. Possible indications for veterinary use are as for vancomycin. Further information is given in the Drug Formulary ([Appendix 8](#)). Dalbavancin is a novel glycopeptide under clinical development with a long elimination half-life but minimal cross-resistance with other compounds in this group. It has a similar spectrum and is generally more bactericidal as compared with vancomycin or teicoplanin.³⁴²

34.6 POLYMYXINS

These agents form a group of closely related, cationic, cyclic peptides. Of the types A through E, polymyxin B and polymyxin E (colistin) are therapeutically most important. Polymyxins appear to exert their bactericidal effects as cationic detergents by binding to cell membrane phospholipids and increasing cell permeability of gram-negative bacteria. Most gram-negative organisms such as *Pasteurella*, *Escherichia*, *Shigella*, *Salmonella*, *Bordetella*, and some *Klebsiella* and *Pseudomonas* are susceptible, whereas *Brucella* and *Proteus* are frequently resistant. Resistance is also a factor of increased usage, and although emergent strains develop during usage, they become susceptible again once polymyxin therapy is stopped.

Polymyxins are poorly absorbed when given orally and topically. They do not produce high plasma concentrations after parenteral administration, presumably because of high affinity for host cell membranes. Polymyxins diffuse poorly through biologic membranes and are excreted unchanged in urine.

These drugs are provided chiefly as topical preparations for treating localized infections in the ear canal, eye, bowel, and urinary tract. Respiratory therapy may be achieved by means of nebulization. Intrathecal administration has been performed with aqueous preparations, but they are highly irritating. For topical use, polymyxins have been combined with neomycin and bacitracin or tetracycline to widen antibacterial activity.

Polymyxins have been given systemically (IM) to treat infections that are resistant to AGs and have shown some synergism with sulfonamide and trimethoprim. Colistin sulfomethate (sodium colistimethate) is the least toxic parenteral preparation. The major side effect of polymyxins is nephrotoxicity, although pain at the injection site, CNS signs, and neuromuscular blockade have also been noted. Toxicity has limited the usefulness of these drugs for systemic therapy.

34.7 CHLORAMPHENICOL, FLORFENICOL, AND THIAMPHENICOL

Chloramphenicol is a highly lipid-soluble, broad-spectrum antibiotic that is predominantly bacteriostatic and inhibits microbial protein synthesis. It is effective against a variety of pathogens, including *Mycoplasma*, *Rickettsia*, *Ehrlichia*, *Anaplasma*, *Neorickettsia*, *Chlamydia*, *Staphylococcus*, *Streptococcus*, *Pasteurella*, *Bordetella*, *Haemophilus*, and Enterobacteriaceae, including many *Escherichia*, *Proteus*, and *Salmonella*. This antibiotic has good activity against most obligate anaerobic bacterial pathogens. Thiamphenicol and florfenicol, closely related drugs, have been marketed for use in food-producing animals.

Infectious Diseases of the Dog and Cat, 3rd Edition

34.7.1 Administration

Chloramphenicol can be administered orally or parenterally, and absorption depends on formulation. The drug is usually given orally in capsular form but can be bitter tasting, causing salivation and anorexia if capsules are not swallowed intact. Oral film-coated tablets may overcome this problem. Chloramphenicol palmitate is an oral suspension that requires hydrolysis by digestive enzymes before absorption can occur. Plasma concentrations are lower initially with this dosage form in cats and poor in those that are not eating. Capsules or tablets therefore may be preferable in cats. Chloramphenicol sodium succinate, a water-soluble ester, is recommended for systemic use. Otic, ophthalmic, and topical preparations are also available.

34.7.2 Pharmacokinetics

Less than 50% of the drug is bound to plasma protein. In dogs and cats, most of the drug is metabolized by the liver to inactive metabolites excreted in urine, and a minor amount is excreted in bile, from where it undergoes enterohepatic circulation. Chloramphenicol diffuses rapidly and well into most tissues. Highest concentrations are found in liver, kidney, bile, spleen, lung, pancreas, and urine, and it penetrates all body fluids. Several hours are required for the brain concentration to approximate that of the plasma concentration; however, brain tissue concentration remains adequate for up to 12 hours, although plasma concentration diminishes before that time. The concentration of active chloramphenicol in urine is usually sufficient to be effective against susceptible bacteria. Thiamphenicol is also poorly protein bound, is not acted on to any great extent by the liver, and is mostly excreted unchanged in the urine.

34.7.3 Indications

Chloramphenicol is effective against most aerobic and anaerobic bacterial pathogens in dogs and cats. It is a preferred antibiotic for treating *Salmonella* and *Escherichia* infections in the GI tract. Chloramphenicol has been recommended for prophylaxis before intestinal surgery or dental procedures but is contraindicated with pentobarbital anesthesia. Chloramphenicol can be considered for treatment of UTIs in dogs with subnormal renal function because the drug is unlikely to accumulate in dogs unless renal failure is advanced.

285

Chloramphenicol penetrates the cornea well because it is lipid soluble and has low molecular weight. Systemic administration is required to treat intraocular and orbital infections and deep corneal lesions.

286

34.7.4 Toxicity

The most common side effects of chloramphenicol administration in dogs and cats are depression, anorexia, dysphagia, salivation, nausea, vomiting, and sporadic diarrhea. Reversible bone marrow suppression and severe irreversible bone marrow failure have been reported in people. The persistent pancytopenia is idiosyncratic and not dose related. However, only reversible bone marrow changes have been demonstrated in dogs and cats, with variable suppression of erythropoiesis and granulopoiesis. Chloramphenicol is more toxic to cats than it is to dogs, perhaps because of relatively poor hepatic glucuronidation capacity, which is important in elimination of chloramphenicol in other species. Bone marrow changes in cats can occur after only 1 week of therapy. Toxic changes do not develop if cats are given the drug on an intermittent basis or at low doses. Clinical improvement and resolution of hematologic changes usually occur within several days after cessation of therapy. A normal hemogram does not rule out toxicosis because bone marrow changes precede those in peripheral blood.

Infectious Diseases of the Dog and Cat, 3rd Edition

The small public health hazard associated with inadvertent contact with chloramphenicol has limited its use in food-producing species and may increase the veterinarian's liability to owners handling the drug intended for pets. Thiamphenicol, an analog of chloramphenicol, has been widely provided in Europe as a substitute. It has similar antibacterial properties, is associated with enhanced renal excretion of active drug, and is said not to cause irreversible marrow failure in people. Another drug related to thiamphenicol, florfenicol, is licensed for cattle and has not been reported to cause aplastic anemia in people. For further information on chloramphenicol, thiamphenicol, florfenicol, and dosage regimens, consult the Drug Formulary ([Appendix 8](#)).

Table 34-7 Properties of Tetracyclines^a

GENERIC NAME (TRADE NAME)	ROUTE OF ADMINISTRATION	COMMENTS AND SPECIFIC INDICATIONS
Short Acting, Water Soluble		
Tetracycline (Panmycin, Achromycin, Tetracylin)	PO, IV, IM	Therapeutic or prophylactic use for <i>Ehrlichia</i> ; IM injections painful; do not inject intraarticularly
Oxytetracycline (Terramycin)	PO, IV, IM	Reaches high concentration in lung liver, kidney, and mononuclear phagocyte system; better tolerated orally by cats
Chlortetracycline (Aureomycin)	PO	pH is very important for activity
Intermediate Acting^b		
Demeclocycline ^c (Declomycin)	PO	Photosensitivity may occur; dosage-dependent nephrogenic diabetes insipidus
Long Acting, Lipid Soluble		
Minocycline (Minocin, Vectrin)	PO, IV	More effective against <i>Ehrlichia</i> , <i>Babesia</i> , <i>Brucella</i> ; greater activity against <i>Nocardia</i> , <i>Staphylococcus</i> , anaerobes; wide distribution in tissues
Doxycycline (Vibramycin, Doxychel)	PO, IV	Same as for minocycline; tetracycline of choice for extrarenal infections with concurrent renal failure; more active against <i>Bacteroides</i> ; prophylaxis for bowel surgery; used to treat chronic prostatitis

PO, By mouth; IV, intravenous; IM, intramuscular.

a See [Appendix 8](#) for appropriate dosages.

b Also includes methacycline.

c Formerly demethylchlortetracycline.

34.8 TETRACYCLINES

Tetracycline antibiotics are bacteriostatic and interfere with protein synthesis of bacterial RNA in a concentration-dependent manner. They have a similar but weaker effect on eukaryotic cells. As a group, tetracyclines have broad-spectrum activity that includes certain aerobic and anaerobic gram-positive and gram-negative bacteria, mycobacteria, spirochetes, mycoplasmas, rickettsiae, chlamydiae, and some protozoa ([Table 34-7](#)). Being more lipid-soluble tetracyclines, doxycycline, and minocycline have increased activity against anaerobes and several facultative intracellular bacteria such as *Brucella canis*, presumably because of their ability to better penetrate bacterial cell walls. These two drugs are most commonly prescribed of the group because of a reduction in their dosing frequency and side effects and increased intracellular penetration. Newer glycylcycline derivatives are under clinical development and are administered parentally.³¹⁴ For additional information on susceptibility of pathogens to individual tetracyclines, consult the Drug Formulary ([Appendix 8](#)).

Infectious Diseases of the Dog and Cat, 3rd Edition

Bacterial resistance to tetracyclines is present among various genera of bacteria and can relate to the usage level of these drugs. Resistance is usually plasmid mediated, although it may occur following genetic mutation. Resistance has been a major problem with some tetracyclines but occurs less often with doxycycline and minocycline.

Resistance has been less of a problem among obligate intracellular pathogens such as *Chlamydomphila* and *Rickettsia*. However, tetracycline-resistant strains of *Chlamydia suis* have been isolated from swine that had been given low-dose tetracyclines in their feed.²¹⁹

286

287

34.8.1 Pharmacokinetics

All the tetracyclines can be given orally. They vary markedly in lipid solubility, a factor that determines their relative enteral absorption and tissue penetration. Highly lipid-soluble doxycycline and minocycline show better absorption and wider tissue distribution, although they are more protein bound. Absorption, a passive process that occurs primarily in the duodenum, is impeded by sodium bicarbonate and by divalent and trivalent cations in food, milk, aluminum hydroxide gels, calcium and magnesium salts, and iron preparations. Because absorption of doxycycline and minocycline is affected somewhat less by food or cations, these two agents are often given with meals to reduce GI irritation. However, tetracyclines undergo enterohepatic circulation, and intrainestinal multivalent cations can still chelate and reduce the bioavailability of parenterally administered drug.

The less lipid-soluble agents, tetracycline and oxytetracycline, are primarily excreted in urine: 60% is recovered as unchanged drug in urine, whereas 40% is excreted by the liver and found in feces. In contrast, lipid-soluble minocycline is eliminated primarily by hepatic metabolism, and only 10% enters the urine. The excretion of doxycycline is not controlled by hepatic or renal excretion; this drug is unique in that the major means of elimination appears to be diffusion across the intestinal wall. Doxycycline is highly protein bound in dogs so that plasma concentrations are higher than in interstitial fluid during constant IV infusion.²⁸ Minocycline and doxycycline may not reach high enough concentrations in the urine to be effective against some pathogens, although doxycycline has been given to eliminate the renal carrier state of *Leptospira*.

34.8.2 Indications

Tetracyclines enter most tissues, including the eye and CNS of dogs. They even penetrate well into the paranasal sinuses and secretions and are therefore useful for treating bacterial sinusitis. Tetracyclines are less active in alkaline media, especially in the case of chlortetracycline. Doxycycline and minocycline are better able to penetrate bacterial cell walls, as they do tissues, thereby being more effective against persistent intracellular pathogens such as species of *Brucella*, *Ehrlichia*, and *Mycobacterium*. Tetracyclines have been effective, especially topically, in reducing the progression of periodontal disease in dogs (see [Chapter 89](#)).⁴³⁷

Tetracyclines inhibit the activity of neutral matrix metalloproteinases, perhaps related to their chelation of multivalent cations. These enzymes are involved in the progression of cartilage degeneration in osteoarthritis. Dogs with experimentally induced anterior cruciate ligament injuries had less severe osteoarthritis when treated with doxycycline.⁴³⁵ This nonspecific protective effect should be considered in dogs that improve with tetracycline-responsive polyarthritis, which is often considered to have an infectious cause.

Tetracyclines also appear to have antiinflammatory activity in nonskeletal diseases, presumably also by inhibiting metalloproteinase enzyme inhibitors. In combination with niacinamide, tetracyclines have been useful in treating some immune-mediated skin diseases such as discoid lupus erythematosus, pemphigus

Infectious Diseases of the Dog and Cat, 3rd Edition

foliaceous, sterile pyogranulomatous dermatitis, and feline lymphoplasmacytic pododermatitis.^{25,267} Despite this immunosuppressive effect, treatment does not interfere with humoral immune response to vaccination.²⁶⁷

34.8.3 Toxicity

Numerous side effects have been associated with tetracyclines and are covered in detail with individual drugs in the Drug Formulary ([Appendix 8](#)). GI disturbances result from esophageal, gastric, and intestinal irritation and changes in enteric microflora. Esophagitis has been problematic, especially in cats given doxycycline. Because doxycycline and minocycline are well absorbed in the upper GI tract, they are less likely to alter lower intestinal flora. Orally administered tetracyclines frequently produce fever in cats with or without severe GI upsets from local irritation. As with chloramphenicol, tetracyclines inhibit hepatic microsomal enzymes and may delay elimination of hepatically metabolized drugs. Hepatotoxicity (including increased serum alanine aminotransferase activity) has been found in cats receiving tetracyclines.¹⁸⁹

Except for doxycycline, tetracyclines should be avoided in patients with renal failure because drug excretion is delayed and azotemia may worsen. The use of tetracyclines in dogs has been associated with direct nephrotoxicity from acute tubular necrosis. In people, the use of outdated tetracyclines or the drug's breakdown products has produced a Fanconi's syndrome–like disorder with reversible renal tubular dysfunction. Findings on urinalysis have included glucosuria, phosphaturia, and aminoaciduria with or without proteinuria. The nephrotoxicity occasionally produced by methoxyflurane anesthesia is accentuated by tetracyclines given before surgery. Demeclocycline has been shown to induce acute reversible nephrogenic diabetes insipidus in people.

Anaphylactic reactions to parenterally administered tetracyclines or their vehicles have occasionally been noted in dogs and cats. Phototoxic reactions, characterized by erythema and edema of the skin, have been associated with certain tetracyclines after exposure to ultraviolet (UV) light.

Tetracyclines become fixed in growing osseous structures. Staining of deciduous teeth of neonates and enamel hypoplasia may occur when tetracyclines are given to a bitch or queen during the last 2 or 3 weeks of pregnancy. The deciduous teeth of puppies or kittens may also be affected if these drugs are given during the first months of life. Doxycycline is less likely to cause this problem (see Drug Formulary, [Appendix 8](#)).

Thrombophlebitis frequently occurs after IV injections of tetracyclines and is seen more often with the less lipid-soluble agents. IM administration of soluble tetracyclines is discouraged because it causes pain and necrosis.

Tetracyclines may cause false-positive urine test results for glucose if copper sulfate reagents are employed (Clinitest, Ames Laboratories, Elkhart, Ind.), and false-negative test results may occur with glucose oxidase reagents. Leukocytosis, atypical lymphocytes, toxic granulation, and immune-mediated hemolytic anemia have been reported with tetracyclines in people. Interference of tetracycline with coagulation factors has also been noted.

34.9 MACROLIDES AND LINCOSAMIDES

Macrolides inhibit peptide formation by the 50s ribosomal subunit. Erythromycin is the parent drug of the macrolides. Oleandomycin and troleandomycin, two older members of the group, are less active and more toxic and are rarely administered now. Rosamicin is similar to erythromycin in antibacterial spectrum and usage. Josamycin is better absorbed and less toxic and is less likely to lead to bacterial resistance than erythromycin.

Infectious Diseases of the Dog and Cat, 3rd Edition

Rokitamycin achieves higher plasma concentrations after oral administration and causes fewer GI side effects than erythromycin. Dirithromycin is a potent derivative that has been shown to produce higher and longer lasting plasma concentrations than erythromycin base. This pro-drug is hydrolyzed during intestinal absorption to the active moiety erythromycylamine.

287

Macrolides are effective primarily against gram-positive bacteria, *Chlamydophila*, *Mycoplasma*, *Helicobacter*, *Campylobacter*, and some rickettsiae. The efficacy of macrolides against extracellular pathogens depends on the concentration of free drug and the organism's susceptibility. Macrolides are slowly bactericidal, with a poor relation between increasing concentration and rapidity of bacterial killing.

288

All macrolides accumulate intracellularly, primarily in neutrophils and macrophages. Several macrolides, namely erythromycin, azithromycin, clarithromycin, and tylosin, are discussed briefly here and more extensively in the Drug Formulary ([Appendix 8](#)). Because of its antiprotozoal efficacy, spiramycin is discussed in [Chapter 71](#).

The lincosamide antibiotics are structurally unrelated to macrolides but have similar antibacterial and pharmacokinetic attributes. Lincomycin and clindamycin are discussed later, and additional information is given in the Drug Formulary ([Appendix 8](#)).

34.9.1 Erythromycin

Erythromycin inhibits protein synthesis in bacterial cells and is bacteriostatic for susceptible organisms at usual dosages. Because its mechanism of action resembles that of chloramphenicol and lincosamides, erythromycin can compete with these drugs for binding sites.

Erythromycin is a weak base and is unstable in the presence of gastric acid, which reduces systemic availability after oral administration. Different formulations of erythromycin have been made to circumvent this effect, incorporating enteric coating, acid-stable salts (stearate), esters (ethylsuccinate), and salts of esters (estolate) ([Table 34-8](#)). GI absorption of erythromycin base and stearate is impaired by ingesta and gastric acid. The lactobionate and gluceptate esters can be administered parenterally but are relatively expensive. Topical preparations are also available for general use and as ophthalmic ointments to treat chlamydial and mycoplasmal conjunctivitis.

Erythromycin diffuses readily into most tissues and extracellular fluids, and therapeutic concentrations are reached within 2 to 3 hours. It is concentrated by the liver and excreted in bile in high concentration, undergoing enterohepatic circulation and final excretion in feces. High concentrations are found in most body fluids and secretions, with the exception of CSF and urine.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 34-8 Comparison of Erythromycin Formulations for Oral Use^a

GENERIC NAME (TRADE NAME)	ABSORBED AS FREE BASE	ABSORPTION AFFECTED BY GASTRIC ACID/INGESTA	FORMULATION	COMMENTS
Erythromycin base (Erythromycin, Ilotycin, Robimycin, E-Mycin, Eryc)	+	+/ \pm	Tablets	Enteric coating reduces irritation
Erythromycin stearate (Erythrocin, Ethril, Erypar, Wyamycin)	+	\pm /+	Tablets	Absorption increased by drinking large amounts of water
Erythromycin estolate (Ilosone)	—	—/—	Drops, tablets, suspension	Associated with increased risks of cholestasis and hepatotoxicity
Erythromycin ethylsuccinate (Pediamicin, Eryped, E.E.S.)	—	\pm / \pm	Drops, capsules, tablets, suspension	Milk enhances absorption

+, Yes; \pm , variable; —, no.

^a See text for properties and indications for each product. See Drug Formulary ([Appendix 8](#)) for appropriate dosages.

Erythromycin has a primarily gram-positive spectrum and is most effective against *Streptococcus*, *Staphylococcus*, *Erysipelothrix*, *Clostridium*, *Bacteroides*, *Borrelia*, and *Fusobacterium*. It is also effective against a few gram-negative organisms, such as *Pasteurella* and *Bordetella*, but not against aerobic enteric bacteria unless the environmental pH is alkaline (~8.0). Erythromycin has exceptional activity against *Campylobacter*, *Legionella*, *Mycoplasma*, chlamydiae, rickettsiae, spirochetes, some atypical mycobacteria, *Leptospira*, and amebae. Resistance in some bacteria has developed with increased usage. Erythromycin is rarely selected as a first-choice drug, except for treating *Campylobacter* or *Legionella* infections, and is used more often as an alternative to penicillin G or a lincosamide.

Erythromycin has relatively low toxicity; the most frequent side effect is GI irritation resulting in nausea, vomiting, and diarrhea. Water or dilute antacid solution, given with the drug, may decrease irritation and facilitate absorption. Erythromycin estolate and occasionally erythromycin ethylsuccinate have been associated with increased risk of cholestasis and hepatotoxicity, which may cause increased blood bilirubin concentration and hepatic enzyme activity. All parenteral preparations are irritating at injection sites.

34.9.2 Azithromycin and Clarithromycin

These azalides are derivatives of erythromycin with better enteral absorption and increased resistance to destruction by gastric acid. After oral administration, they are distributed widely to tissues in high concentrations except for the brain and eye.³⁹⁶ Azithromycin produces low extracellular concentrations but has high intracellular penetration, whereas clarithromycin produces high concentrations in both extracellular fluid and intracellular sites. They reach high concentrations in phagocytic cells throughout the body and are slowly released over several days after a single dose. These drugs are less active than erythromycin against gram-positive bacteria but more active against gram-negative aerobes and anaerobes. Azithromycin and clarithromycin have strong activity against *Mycoplasma*, *Borrelia*, and *Leptospira*. Clarithromycin has been suggested as an alternative treatment against *Toxoplasma* and atypical *Mycobacterium*. For further information on these drugs, see the Drug Formulary ([Appendix 8](#)).

288

289

Infectious Diseases of the Dog and Cat, 3rd Edition

34.9.3 Tylosin

Similar to other macrolides, tylosin is generally bacteriostatic against susceptible bacteria. Gram-positive bacteria, *Campylobacter*, and *Mycoplasma* are particularly susceptible to its effects, as are most organisms that are susceptible to erythromycin. Oral absorption of tylosin is variable, depending on the product formulation. The drug is metabolized by the liver and excreted in both urine and bile. Tylosin has been suggested also for the management of clostridial enteritis (see [Chapter 39](#)), inflammatory bowel disease, and chronic colitis in dogs and cats and in the supportive treatment of systemic coronaviral diseases in cats. Proof of efficacy in the latter disorder, however, is lacking. The drug is effective in the treatment of staphylococcal pyoderma in dogs.^{337,338} For additional information consult the Drug Formulary, [Appendix 8](#).

34.9.4 Lincomycin and Clindamycin

Lincosamides bind to 50s ribosomal subunits and inhibit protein synthesis in susceptible bacteria. The mode of action resembles that of chloramphenicol and the macrolides. Depending on the concentrations achieved, lincomycin is bacteriostatic to bactericidal. Clindamycin, a chlorosubstituted lincomycin, has increased bactericidal activity and rate of absorption and has shown less toxicity in animals than lincomycin.

Lincomycin and clindamycin are widely distributed in body tissues and fluids, including bile, peritoneal and pleural fluids, milk, placenta, prostatic fluid, and bone. For example, mean levels of clindamycin in canine mandibular bone were 8.18 µg/g following 5 days of treatment at 11 mg/kg.⁴³⁸ Neither drug enters the CSF or ocular structures unless inflammation is present. Both drugs accumulate in neutrophils, macrophages, and abscesses, making them useful in treating infections caused by anaerobic or persistent intracellular pathogens.

Both agents are primarily indicated to treat infections caused by gram-positive aerobes and obligate anaerobes. Lincomycin has been recommended for use in a variety of skin, respiratory, GI, soft-tissue, and bone infections, especially when gram-positive organisms are involved. Clindamycin is effective against a greater variety of organisms, including anaerobic bacteria and protozoa such as *Toxoplasma* and *Neospora* (see Therapy, [Chapter 41](#) and Therapy, [Chapter 80](#), respectively; and the Drug Formulary, [Appendix 8](#)). Clindamycin has been beneficial in treating oropharyngeal infections, including periodontal disease associated with anaerobic bacteria.²⁷⁴

Toxicity of these drugs has been relatively low in dogs that received supratherapeutic doses for relatively long periods. GI irritation, vomiting, and diarrhea may occur with oral administration.

Pseudomembranous colitis, a complication in some people treated with either drug, is exhibited by abdominal pain, fever, and mucus or blood in the stools. Overgrowth of resistant, toxin-producing strains of *C. difficile* is believed responsible. Diarrhea in treated dogs and cats does not seem to be caused by *C. difficile* toxin.¹⁴² If this side effect occurs, the practitioner should discontinue the drug and substitute vancomycin or metronidazole.

34.10 METRONIDAZOLE

For a discussion of this antimicrobial against anaerobic bacterial and protozoal infections, see Antiprotozoal Chemotherapy, [Chapter 71](#), and Drug Formulary, [Appendix 8](#).

Infectious Diseases of the Dog and Cat, 3rd Edition

34.11 NOVOBIOCIN

This antibiotic has a spectrum of activity similar to, but not as consistent as, that of penicillin G. Many gram-positive aerobic bacteria, including *Streptococcus* and *Staphylococcus*, are susceptible, whereas effectiveness against *Proteus* and *Pasteurella* is variable. Novobiocin inhibits bacterial DNA and subsequent RNA and protein synthesis, and antibacterial resistance to this drug does not transfer to other antibiotics.

Novobiocin is absorbed well after oral administration and is predominantly excreted in bile and feces. The antibiotic has been marketed mainly in fixed combination with tetracycline. In vitro studies have suggested possible inhibition reactions between these compounds. However, a subjective evaluation reported more clinical improvement in upper respiratory tract infections in dogs treated with novobiocin plus tetracycline than in dogs treated with either drug alone.²⁴⁴

34.12 NITROFURANS

These synthetic antibacterial compounds are chemical derivatives of 5-nitrofuraldehyde. The exact mechanism of action is uncertain, although they are known to interfere with many cellular enzymes. Nitrofurans are bacteriostatic or bactericidal, depending on the organisms and the amount of drug at the infection site. The nitrofurans have a relatively broad spectrum of activity but generally are more effective against gram-negative organisms. *Escherichia*, *Salmonella*, *Staphylococcus*, and *Streptococcus* are usually susceptible, whereas *Pseudomonas* and some *Proteus* and *Klebsiella* are resistant. *Pseudomonas* can actually grow in many preparations of nitrofurazone, which may lead to nosocomial wound infection. Resistance develops rarely during therapy with nitrofurans. Table 34-9 summarizes the uses of nitrofurans in veterinary practice.

Nitrofurantoin is absorbed rapidly after oral administration, but the low plasma concentrations are insufficient to treat systemic infections. Most of the drug is excreted rapidly in urine, which makes it helpful in UTIs. However, treatment with nitrofurantoin is probably not warranted if other drugs have failed. Nitrofurantoin in urine may cause positive test results for glucose when copper sulfate reduction method is used. Alkalinization of the urine, which increases the amount of nitrofurantoin excreted, should be avoided because the drug is more effective at acid pH. A macrocrystalline formulation is absorbed more slowly, reducing GI irritation and prolonging its effect. Nifuratel, an analog with a similar pattern of absorption, is unaffected by urine pH and has a wider spectrum of activity, including efficacy against *Candida*.

Furazolidone is not absorbed after oral administration and has been administered to treat local infections caused by enteric pathogens. Nitrofurazone is applied topically as powder, cream, or spray solution and is not absorbed. Evidence exists that the spray preparation may be carcinogenic. Nitrofurazone is frequently incorporated in an oil-base rather than a water-soluble cream, but this practice reduces its antibacterial efficacy and can delay healing by causing maceration of tissues.

Adverse reactions to nitrofurans are not uncommon. Nitrofurantoin frequently causes nausea and emesis in dogs and cats. The authors (CEG and AJDW) have observed acute polyneuropathy and myopathy in a dog given nitrofurantoin. For more information on nitrofurantoin and furazolidone, consult the Drug Formulary (Appendix 8).

289

290

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 34-9 Properties of Nitrofurans^a

GENERIC NAME (TRADE NAME)	ROUTE OF ADMINISTRATION (FORMULATION)	USES/COMMENTS
Nitrofurantoin (Furadantin, Macrochantin)	PO (tablet, suspension), IM (solution)	UTI; avoid in renal failure; macrocrystalline is absorbed slower and is less toxic
Nifuratel (Magmilor)	PO (tablet)	UTI; also effective against <i>Candida</i> at any urine pH
Furazolidone (Furoxone)	PO (tablet, suspension)	For enteric pathogens; not absorbed PO; used for <i>Salmonella</i> and coccidia
Nitrofurazone (Furacin)	Topical (ointment, powder, solution, cream, suppository)	For skin and mucosal infections; <i>Pseudomonas</i> can contaminate
Nifuroxime (numerous)	Topical (suppository, cream)	Antifungal properties; used together with other nitrofurans

PO, By mouth; IM, intramuscular; UTI, urinary tract infection.

^a See Drug Formulary ([Appendix 8](#)) for dosages of systemically administered drugs.

34.13 SULFONAMIDES

Sulfonamides were developed early in the era of antibacterial chemotherapy and have been superseded by many of the newer antimicrobial agents. However, resurgence has occurred in sulfonamide therapy since the introduction of diaminopyrimidine compounds that enhance their antimicrobial efficacy. Sulfonamides are derivatives of sulfanilamide and act by interfering with bacterial synthesis of folic acid from para-aminobenzoic acid (PABA). They are bacteriostatic and ineffective in the presence of pus, necrotic tissue, or blood containing PABA. Bacteria that are highly susceptible to sulfonamides include *Streptococcus*, *Bacillus*, *Corynebacterium*, *Nocardia*, *Campylobacter*, *Pasteurella*, and chlamydiae. However, *Bacteroides*, *Enterococcus*, *Pseudomonas*, *Serratia*, and *Klebsiella* are generally resistant. Caution must be exercised in interpreting disk susceptibility test results with these drugs because they frequently do not correlate with in vivo susceptibility. An increasing number of organisms are becoming resistant to sulfonamides. Resistance appears to develop more commonly with long-term therapy.

With few exceptions, sulfonamides are readily and rapidly absorbed and reach bacteriostatic plasma concentrations. Levels attained depend on the drug, route of administration, and dose. Sulfonamides are variably bound to plasma protein and distributed widely to all tissues and pleural, peritoneal, synovial, and ocular fluids. They cross the placenta and readily enter CSF. Sulfonamides generally undergo hepatic metabolism, with metabolites excreted mainly in urine, with smaller amounts in the bile. Sulfonamides have been used alone to treat a variety of human infections, but the combination of sulfonamides with a diaminopyrimidine (see later discussion) is now mostly used in dogs and cats. The orally absorbed sulfonamides can be divided into four groups ([Table 34-10](#)). The short-acting drugs, rapidly absorbed and excreted, require doses at 8-hour intervals. These drugs are given for systemic infections and UTIs. The intermediate-acting sulfonamides are excreted more slowly, administered every 12 to 24 hours, and are used mainly to treat UTIs; sulfisoxazole is often provided for this purpose. Long-acting sulfonamides, such as sulfadoxine, are excreted slowly and require administration every few days.

Some sulfonamides, poorly absorbed from the GI tract, will alter enteric microflora but will not disrupt the balance of microflora and rarely cause superinfection. Phthalylsulfathiazole has been administered to reduce coliform flora, stool bulk, and gas before colonic surgery.

Infectious Diseases of the Dog and Cat, 3rd Edition

Although marketed for topical application, sulfonamides are relatively ineffective in the presence of exudates. Mafenide, the only exception, is helpful for prophylaxis in burn patients because of its ability to inhibit *Pseudomonas*.

Certain sulfonamides have been administered for specific indications. Sulfapyridine, which is relatively toxic, is given only for treating dermatitis herpetiformis. Sulfasalazine (salicyl-azosulfapyridine) is used to treat colitis in dogs. Sulfasalazine is hydrolyzed by colonic microflora to sulfapyridine and 5-aminosalicylate.

Toxic reactions to sulfonamides are relatively common in dogs and cats. Acute hemolytic complications and precipitation of sulfonamide metabolites in renal tubules seen in people have not been seen in dogs. Failure of insoluble acetylated metabolites to cause renal problems in dogs may be explained by the fact that deacetylation of metabolites occurs more rapidly than their formation. Dogs given high doses of sulfonamides can develop cystic sulfonamide uroliths. Sulfonamide crystalluria and neurologic signs, including convulsions, occurred in a dog ingesting sulfonamide cream.¹¹⁸ However, cats may develop azotemia and renal failure during sulfonamide or trimethoprim-sulfonamide (T-S) therapy. Keratitis sicca can develop in dogs on acute or long-term treatment.⁹⁴ Schirmer's tear tests should be performed on dogs before administering these drugs, and sulfonamides should be avoided if tear production is low. The prognosis for return of lacrimation is poor, but topical cyclosporine appears to be effective in some cases.⁹⁴ For additional information, refer to the following discussion of T-S and the Drug Formulary ([Appendix 8](#)).

34.14 DIAMINOPYRIMIDINES-SULFONAMIDES

Sulfonamides inhibit bacterial synthesis of dihydrofolic acid. Trimethoprim and related pyrimidine-like compounds (ormetroprim, baquiloprim) interfere with dihydrofolate reductase, an enzyme that prevents the conversion of dihydrofolic acid (folic acid) to tetrahydrofolic acid (folinic acid), which is essential for synthesis of purines and pyrimidines and thus of DNA. Mammals, unlike microorganisms, acquire most folic acid preformed in the diet, which explains the selective action of sulfonamides against microbes. Increased production of dihydrofolate reductase by enteric bacteria makes them more resistant to the effects of this drug. Trimethoprim has less affinity for dihydrofolate reductase in mammals than it does in microorganisms, which accounts for the reduced toxicity of the drug for mammalian cells. Each drug alone is generally bacteriostatic, but synergistic interaction is expected when trimethoprim and sulfonamide are co-administered in a 1:5 ratio, with bactericidal activity whenever the optimum in vivo ratio of 1:2 is achieved.

290

291

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 34-10 Properties of Sulfonamides Commonly Used in Small Animal Practice^a

GENERIC NAME (TRADE NAME)	ROUTE OF ADMINISTRATION	INDICATIONS AND COMMENTS
Short Acting^b		
Sulfadiazine (Suladyne, Debenal)	PO, IM	Systemic and urinary infections and nocardiosis; frequently combined as triple sulfa to minimize renal tubular precipitation; may be combined with trimethoprim (see below)
Sulfamethazine (Sulmet)	PO, IM	As above
Sulfamethoxazole (Gantanol, Methoxal)	PO, IM	As above
Intermediate Acting^c		
Sulfisoxazole (Gantrisin, Soxisol, Sulfasox)	PO	UTI
Sulfadimethoxine (Sudine, Bactrovet, Albon, Madribon)	PO	UTI
Gastrointestinal Preparations^d		
Succinylsulfathiazole (Sulfasuxidine)	PO	Local antibacterial effects on gastrointestinal tract; administer with kaolin-pectin
Phthalylsulfathiazole (Sulfathalidine)	PO	<i>Shigella</i> enteritis, preoperative prophylaxis for gastrointestinal surgery; mineral oil, laxatives, and purgatives interfere with action
Special/Combination		
Sulfasalazine (Azulfidine)	PO	Colitis; salicylate component may help in therapy
Mafenide (Sulfamylon cream)	Topical	Burns; prophylaxis only
Trimethoprim and sulfamethoxazole (Septra, Bactrim)	PO	Systemic, respiratory, and urinary infections, <i>Pneumocystis pneumonia</i> , <i>Brucella</i> ; must be given to dogs at least twice daily for systemic infections; effective once daily for urinary infections and coccidiosis
Trimethoprim and sulfadiazine (Tribrissen, Di-Trim)	PO, IM	As for trimethoprim-sulfamethoxazole
Ormetoprim and sulfadimethoxine (Primor)	PO	Skin and UTI, wounds, coccidiosis
Baquiloprim and sulfadimethoxine (Zaquilan)	PO, IM	Skin, respiratory, urogenital, gastrointestinal, and soft-tissue infections

PO, By mouth; IM, intramuscular; UTI, urinary tract infection.

- a Most of these drugs are licensed for human use. See the Drug Formulary ([Appendix 8](#)) for specific information and dosages.
- b Rapidly absorbed and rapidly excreted.
- c Rapidly absorbed and slowly excreted.
- d Poorly absorbed.

Trimethoprim and its co-administered sulfonamides are rapidly and completely absorbed and widely distributed after oral administration. Therapeutic concentrations are achieved in CSF, brain, eye, prostate, bone, and joints. CSF concentrations can range up to 80% of plasma concentrations. Reducing the dosage is unnecessary in renal failure unless it is severe. Sulfadiazine has been chosen for administration with trimethoprim in dogs. Sulfamethoxazole is used in human preparations. Trimethoprim is available by itself in some countries but offers little advantage because it is less active and just as toxic as the combined product.

T-S has been recommended for treatment of respiratory infections and UTIs caused by *Escherichia*, *Streptococcus*, *Proteus*, *Salmonella*, and *Pasteurella*. Lesser and more variable activity is noted against *Staphylococcus*,

Infectious Diseases of the Dog and Cat, 3rd Edition

Klebsiella, *Corynebacterium*, *Clostridium*, and *Bordetella*. *Moraxella*, *Nocardia*, and *Brucella* are moderately susceptible. T-S has been administered simultaneously with AGs to enhance activity against gram-negative organisms. Bacterial resistance has developed with continued usage. Because of good CNS penetrability, the combination is an excellent choice for gram-negative pathogens producing meningitis.

All the side effects noted previously with sulfonamides can be seen with the drug combination (see 291 trimethoprim-sulfonamide, adverse reactions, in the Drug Formulary, [Appendix 8](#)). T-S causes greater adverse 292 reactions and has less margin of safety in cats, which are more likely to develop anorexia, vomiting, azotemia, anemia, and leukopenia.

Other toxicities have been reported in dogs and cats. Ataxia has sometimes been observed when higher therapeutic doses are given. Reversible cholestatic hepatitis has been observed in dogs with preexisting hepatic disease.¹⁴¹ Fatal hepatic necrosis and hepatic failure have been reported as an idiosyncratic reaction in dogs,^{370,387} unrelated to dose and duration of therapy. The hepatotoxic substance from sulfamethoxazole metabolism is thought to be a metabolite that concentrates in the periportal hepatobiliary areas and induces a cytotoxic response.¹²⁹ Aplastic anemia was associated with trimethoprim-sulfadiazine and fenbendazole administration in a dog.⁴¹⁴ Anemia resolved after withdrawal of the drugs and may have reflected drug idiosyncrasy or immune hypersensitivity rather than inhibited folate metabolism. Thyroid hormone synthesis is also impaired resulting in reduced levels in dogs treated with T-S for 10 weeks or longer.⁴²² See Drug Formulary, [Appendix 8](#), for further information.

Treatment with the trimethoprim-sulfadiazine combination has been associated with allergic immune complex reactions in dogs specifically as a result of the sulfonamide. Fever, polyarthritis, lymphadenomegaly, polymyositis, glomerulonephritis (proteinuria), urticaria, eosinophilic pneumonitis, pancreatitis, focal retinitis, suspected meningitis, hemolytic anemia, facial palsy, leukopenia (neutropenia), and thrombocytopenia have been noted.^{143,379} Doberman pinschers may be predisposed to these reactions. In a review of 40 dogs with potentiated sulfonamide hypersensitivity, Samoyeds (8%) and miniature Schnauzers (13%) were also overrepresented.³⁷⁹ Immune-mediated, cutaneous drug eruptions have occurred in dogs treated with trimethoprim-sulfamethoxazole (see Drug Formulary, [Appendix 8](#)). A presumed immune-mediated meningitis has been described in people given trimethoprim-sulfamethoxazole. An association exists between hypersensitivity after the receipt of sulfonamides and a subsequent reaction to sulfonamide nonantibiotics, but this appears to be a predisposition to allergic reactions because these individuals also have a higher reaction rate to penicillins.³⁵⁸ People have developed increased serum potassium and creatinine concentrations in some instances.²³⁸ See the Drug Formulary ([Appendix 8](#)) for a summary of the adverse reactions associated with T-S.

34.15 QUINOLONES

34.15.1 Pharmacokinetics

The quinolones (fluoroquinolones) are a diverse group of bactericidal naphthyridine derivatives that prevent bacterial DNA synthesis by partly inhibiting bacterial topoisomerase (TP)-II (DNA gyrase) and TP-IV. Quinolones affect primarily TP-II in gram-negative organisms and TP-IV in some gram-positive organisms. They have less activity against mammalian TPs. The lower susceptibility of TP-IV to quinolones may partly explain the higher MICs for many gram-positive organisms. Compared with some rarely used first- and second-generation compounds (nalidixic acid, flumequine, pipemidic acid), the third-generation quinolones, such as ciprofloxacin, marbofloxacin, difloxacin, orbifloxacin, ibafloxacin, and enrofloxacin ([Table 34-11](#)), have improved antibacterial spectrum, increased bioavailability, favorable pharmacokinetics, and less toxicity

Infectious Diseases of the Dog and Cat, 3rd Edition

and bacterial resistance. The last five drugs named are marketed for use in small animals; danofloxacin has been licensed for use in cattle and sarafloxacin for poultry. Third-generation quinolones have limited plasma protein binding and differ with respect to extent and rate of biotransformation, elimination rate, and route of excretion. Enrofloxacin is converted to ciprofloxacin, and then approximately 50% of the administered amount is excreted in urine as ciprofloxacin and its metabolites. Difloxacin is largely metabolized and excreted in bile, with minimal amounts in urine, while approximately 40% of orbifloxacin is excreted in urine. Approximately 50% of marbofloxacin is excreted unchanged in urine with equal amounts excreted unchanged in bile.

Fourth-generation quinolones licensed in human medicine have included levofloxacin, cilinafloxacin, sparfloxacin, gatifloxacin, gemifloxacin, grepafloxacin, trovafloxacin, and moxifloxacin and have enhanced pharmacokinetics and increased spectrum of activity against important pathogens. In people, these drugs are generally well absorbed orally and have longer half-lives, supporting once-daily dosing. Although levofloxacin is excreted primarily by the kidneys, the others are predominantly eliminated in the bile. The dose of levofloxacin must be reduced in renal failure, while that of the others must be reduced in patients with hepatic dysfunction. Additional studies are needed to show whether findings are similar for animals.

Variable GI absorption occurs with quinolones. Food and antacids inhibit their absorption. Absorption of all quinolones is impaired by concurrent administration of preparations containing multivalent cations (magnesium, bismuth, iron, zinc, aluminum) such as antacids and by sucralfate-containing preparations. To improve plasma concentrations in dogs and cats in these circumstances, giving the quinolone at least 2 hours before these preparations or using parenteral administration might be preferable.

Quinolones have high bioavailability, low ionization, and low protein binding and are lipophilic. Consequently, concentrations attained in tissues and body fluids often equal or exceed those in plasma. High levels are achieved in prostate, kidney, liver, and lung, with lower but therapeutic concentrations in respiratory secretions, saliva, and prostatic fluid. Urine concentrations are well above the MICs of most urinary pathogens, and CSF concentrations are adequate if inflammation is present. Fecal levels are adequate to inhibit most GI enteropathogens. Quinolones exhibit concentration-dependent killing of bacteria. High peak concentration reached in vivo and persistence of good concentrations, which together contribute to the AUC, are important in determining a dosage regimen to treat a particular infection.^{228,377} The total amount of drug given daily, rather than the dosing regimen, primarily determines the in vivo potency of these drugs.⁹ However, once-daily dosing achieves higher maximum fluid and tissue concentrations than divided dosing, and better owner compliance is anticipated. Marbofloxacin and difloxacin have half-lives that are twice that of enrofloxacin; hence the dose rate is somewhat lower for susceptible pathogens. When the maximum concentration of quinolone achieved exceeds twice the pathogen's MIC, a favorable response is expected. When the concentration of quinolone in a body fluid or tissue is eight or more times higher than the MIC, bacterial regrowth from selection of resistant subpopulations can be prevented. Higher plasma concentrations enhance penetration of quinolones into body fluids, secretions, and other harder-to-enter tissues, including CSF, prostate, and bone. Concentrations of quinolones in bile or urine may be hundreds of times greater than the MIC for susceptible bacteria. The drugs also enter skin and may accumulate there, especially with inflammation. High concentrations are achieved in phagocytic cells, exceeding plasma concentrations by a factor of 100. Co-administration with probenecid, furosemide, and nonsteroidal antiinflammatory drugs increases plasma concentrations of quinolones. For resistant organisms, the lowest recommended label dosages may not be suitable, and higher or twice daily dosing may be necessary. Current labeling for quinolones in the United States requires flexible dosing. Knowing the concentration likely to be achieved at the site of infection and the MIC data for the intended pathogen is helpful in making this determination. Achievable concentrations in tissues following intended dosages are listed in quinolone product inserts and the Drug Formulary ([Appendix 8](#)).

292

293

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 34-11 Quinolones Licensed for Human and Veterinary Use^a

GENERIC NAME (TRADE NAME [Mfgr])		ORAL BIOAVAILABILITY (%)	FORMULATIONS
First and Second Generation^b			
Nalidixic acid (NegGram [Sandofi])		95	Tablets: 500 mg
Cinoxacin (Cinobac [Oclassen])		95	Tablets: 250 mg, 500 mg
Third Generation^c			
Human	Norfloxacin (Noroxin [Merck])	30–50	Tablets: 400 mg
	Ciprofloxacin (Cipro [Bayer])	75–80	Tablets: 250 mg, 500 mg, 750 mg Injection: 200-mg and 400-mg vials
	Ofloxacin (Floxin [Ortho])	>95	Tablets: 200 mg, 300 mg, 400 mg Injection: 200-mg and 400-mg vials
	Lomafloxacin (Maxaguin [Searle])	>95	Tablets: 400 mg
	Enoxacin (Penetrex [Rhône-Poulenc])	90	Tablets: 200 mg, 400 mg
	Fleroxacin (Megalone [Roche], Quinodis [Roche])	>80	Tablets: 200 mg, 400 mg
	Amifloxacin (Investigational [Sterling Winthrop])	>90	200 mg
	Veterinary^a Enrofloxacin ^d (Baytril [Bayer])	>80	Tablets 5.7 mg, 22.7 mg, 68 mg Injection: 22.7 mg/ml
	Marbofloxacin (Marbocyl [Vetoquinol], Zeniquin [Pfizer])	>90	Tablets: 5 mg, 20 mg, 80 mg
	Orbifloxacin (Orbax [Schering-Plough])	97	Tablets: 5.7 mg, 22.7 mg, 68 mg
Fourth Generation^e	Difloxacin (Dicural [Fort Dodge])	>80	Tablets: 11.4 mg, 45.4 mg, 136 mg
	Ibafloxacin (Ibaflin [Intervet])	69–81	Tablets: 30 mg, 150 mg, 300 mg, 900 mg
	Levofloxacin (Levaquin [Ortho-McNeil])	~100	Tablets: 250 mg, 500 mg Injection: 250-mg and 500-mg vials
	Moxifloxacin (Avelox [Bayer])	>90	Tablets: 400 mg Injection: 400-mg bags
	Gatifloxacin (Tequin [Bristol-Myers])	>90	Tablets: 200 and 400 mg Injection: 200- and 400-mg vials
Gemifloxacin (Factive [GeneSoft])		~61	Tablets: 320 mg

- a Only third-generation drugs are licensed for veterinary purposes. The listed veterinary preparations are licensed for dogs and cats. In some countries, sarafloxacin, benofloxacin, enrofloxacin, and ofloxacin are licensed for poultry; enrofloxacin, danofloxacin, and orbifloxacin are licensed for cattle and swine. See Drug Formulary ([Appendix 8](#)) for more specific information and dosages.
- b Restricted to use in gram-negative urinary tract infections; not recommended because of high toxicity.
- c Primarily active against gram-negative aerobic bacteria, *Mycoplasma*, chlamydiae, some *Mycobacterium*, and rickettsiae.
- d Metabolized to ciprofloxacin. Bioavailability is extrapolated from absorption of ciprofloxacin.
- e Similar to third generation but more active against staphylococci, streptococci, and obligate anaerobes. Grepafloxacin, temafloxacin, trovafloxacin, and sparfloxacin have been withdrawn or have restricted use in people because of adverse effects such as cardiac arrhythmias, hepatic necrosis, or hemolytic-uremic syndrome.

Infectious Diseases of the Dog and Cat, 3rd Edition

Quinolones kill bacteria at concentrations close to MIC values and have marked PAE, which account for their ability to inhibit bacterial growth up to 4 to 8 hours after drug is eliminated from the body. The high drug concentrations in phagocytes means they reach higher concentrations at inflammatory sites.³⁰ They are partially metabolized by the liver and excreted in bile or urine as parent drug or metabolites, or both, most of which have antibacterial activity. Concentrations achieved in bile and urine are 10 to 20 times higher than that in plasma. Urine recovery varies from 30% to 70%, depending on the drug. The biliary excreted fraction of some quinolones undergoes enterohepatic circulation. At recommended dosages in dogs, levels of enrofloxacin were adequate to kill most pathogens; however, higher levels were needed to achieve levels for resistant organisms such as *P. aeruginosa*.³⁷

293

294

Use of quinolones in neonates and cats is restricted, because of their potential toxicity to growing cartilage and retinal tissue (see Toxicity later in this text). Pharmacokinetics of enrofloxacin in nursing kittens has been compared with that of young and adult cats.³⁴¹ The half-life and elimination of enrofloxacin administered IV or SC to 2-, 6-, and 8-week-old kittens was shorter than that in adults resulting in lower peak plasma concentrations. SC administration resulted in poor uptake by the 2- to 4-week-old kittens. Oral administration to all age kittens resulted in poor bioavailability and inadequate therapeutic concentrations. See Drug Formulary, [Appendix 8](#), for further information.

34.15.2 Indications

The third-generation quinolones are active primarily against gram-negative aerobic and facultative anaerobic bacteria and are more effective in alkaline pH (above 7.4). Although many gram-positive bacterial pathogens are susceptible, MIC ranges usually are higher than those for gram-negative organisms. Third-generation quinolones are not ideal for treating infections caused by obligate anaerobes or *Streptococcus*, and other drugs should be considered first. Activity against *Staphylococcus* is variable, but some staphylococci resistant to many other drugs may be susceptible to quinolones. Fourth-generation quinolones are broad-spectrum antimicrobials with excellent in vitro activity against gram-positive and gram-negative bacteria, including activity against intracellular pathogens. Although these quinolones have better activity against gram-positive organisms, they have less efficacy against gram-negative bacteria. For example, gatifloxacin, moxifloxacin, and gemifloxacin have enhanced activity against gram-positive bacteria, especially against streptococci; and although their efficacy against gram-negative bacteria is preserved, it is often less than the earlier generation quinolones.³²⁸ This lower activity is particularly true for *P. aeruginosa*. The activity of fourth-generation drugs against anaerobes is variable and not as strong as other first-choice drugs that offer better alternatives. Some rickettsiae are susceptible to quinolones. Some of the drugs have activity against chlamydiae, *Mycoplasma*, *Bartonella*, and some mycobacteria.³⁶⁰ Enrofloxacin was effective in treating *Mycoplasma haemofelis* infection in cats (see [Chapter 31](#)) but only at a higher dose that had a risk of retinal toxicity.¹⁰⁵ However, enrofloxacin was not effective in treating *Ehrlichia canis* infection in experimentally infected dogs.²⁷¹ Ciprofloxacin, enrofloxacin, and ofloxacin are active against *Mycobacterium tuberculosis* and some atypical mycobacteria but not against *Mycobacterium avium* complex. Quinolones have good activity against bacterial enteropathogens, such as *Salmonella*, *Shigella*, *Campylobacter*, *Yersinia enterocolitica*, and *Escherichia*. Third-generation drugs have some activity against some anaerobes such as *Bacteroides*, *Clostridium*, *Fusobacterium*, *Porphyromonas*, *Bilophila*, and *Prevotella*. However, activity against these anaerobic bacteria is weakest.

The primary indications for quinolones are recurrent UTIs caused by organisms that are difficult to eliminate, such as *Pseudomonas*, *Proteus*, and *Klebsiella*. They are very effective in the treatment of bacterial prostatitis. In treating *Brucella*, quinolones must be used in combination with another drug, such as doxycycline, to reduce

Infectious Diseases of the Dog and Cat, 3rd Edition

risk of relapse. Quinolones have also been used to treat enteric and respiratory infections caused by organisms resistant to other agents. Marbofloxacin, enrofloxacin, ciprofloxacin, and difloxacin have been shown to be effective, at varying levels, against *Bordetella bronchiseptica* in vitro.⁵⁹ Bone concentrations of quinolones are adequate to treat osteomyelitis if the pathogen is susceptible. Oral administration is advantageous for long-term therapy. When mixed flora are present in intraabdominal infections, quinolones have been effective against aerobic or facultative bacteria when given in combination with a drug effective against anaerobes, such as clindamycin or metronidazole. Gatifloxacin, gemifloxacin, and moxifloxacin have been licensed for use in respiratory tract infections in people. See [Tables 34-12](#) and [34-13](#) for summaries of information on quinolones used in dogs and cats.

34.15.3 Drug Resistance

Quinolones are now being used frequently in small animal practice. Unfortunately, this trend has led to increasing bacterial resistance of isolates from dogs and cats, as has been observed in human medicine.³³⁴ In essence, quinolones should only be prescribed when these drugs are expected to have optimal activity against the pathogen in a given organ system and other more empirically used drugs have expected or known resistance. A common misconception is that bacteria do not become resistant during treatment with quinolones. Resistance, which most often occurs during treatment of infections caused by *Pseudomonas*, *Klebsiella*, *Enterobacter*, *Acinetobacter*, *Serratia*, *Enterococcus*, and *Staphylococcus*, is chromosomal rather than plasmid mediated.^{226,227} Bacteria may become cross-resistant to several quinolones at one time but not necessarily to antimicrobials in other classes. The quinolones have been restricted from use in food-producing animals in hopes of preventing development of drug-resistant strains of zoonotic pathogens.¹¹ Multidrug- and quinolone-resistant *Escherichia* have been isolated with increasing frequency from companion animals under veterinary care.^{76,404} A significant increasing resistance was noted to canine urinary isolates such as *Proteus mirabilis*, *Staphylococcus intermedius*, and *E. coli* between the years of 1992 and 2001 for either ciprofloxacin or enrofloxacin.⁷³ A cause for concern is that these organisms, which can be isolated from many areas in the hospital environment, develop resistance from frequent exposure to a variety of broad-spectrum antimicrobials.³²⁷ To avoid increasing resistance, quinolones should be used prudently and carefully and not as drugs for first-time treatments or for infections that will likely respond to other drugs. One example would be in treatment of anaerobic infections or pyodermas in which other drugs should be tried first. Dosing for infections should always be adequate enough to prevent the induction of antimicrobial resistance as subinhibitory concentrations of enrofloxacin have caused a selection for drug-resistant mutants of *S. intermedius* in culture.¹²¹ In vitro studies with canine bacterial isolates from otitis externa and urinary infection showed that *Pseudomonas aeruginosa* and *Enterococcus* spp. develop resistance more rapidly and more consistently than *Klebsiella*, *Proteus*, and *Streptococcus* when exposed to enrofloxacin.⁴⁶

34.15.4 Toxicity

See [Table 34-14](#) for a summary of toxic effects of quinolones.

34.15.4.1 Gastrointestinal

The most common adverse events induced by quinolones are vomiting, diarrhea, abdominal discomfort, and taste disturbances. These effects are usually mild or moderate and can be alleviated by temporarily reducing or discontinuing therapy. Alimentary reactions associated with quinolones are product and dose related. The

Infectious Diseases of the Dog and Cat, 3rd Edition

mechanism is uncertain but presumably relates to direct irritation of the GI tract and to CNS stimulation because it can occur with both PO and parenteral administration. Dogs inadvertently or experimentally given high doses of quinolones have often vomited and therefore may not develop other acute toxic manifestations.

34.15.4.2 Cardiovascular

Quinolones are relatively safe at routine oral and parenteral dosages. Prokaryotic DNA gyrase is partially affected by these compounds; therefore extremely high concentrations of fluoroquinolones can cause systemic toxicity. Rapid IV administration of 10 to 30 mg/kg of certain quinolones to anesthetized dogs or cats produces systemic hypotension, presumably related to histamine release. Hypotension and tachycardia have also been seen after oral administration. In people, the newer quinolones, sparfloxacin and grepafloxacin have caused prolongation of the QT interval and rare arrhythmias and have been withdrawn from human use for this reason. All quinolones have the potential to cause this effect because of presumed gene inhibition involving the potassium channel. Moxifloxacin, gatifloxacin, and levofloxacin carry precautionary statements about this effect.

^a Lower concentration indicates greater susceptibility. This table should be used as a guide to efficacy. Isolates of the same bacterial species can differ in their antimicrobial resistance

Infectious Diseases of the Dog and Cat, 3rd Edition

depending on differences in time, geography, laboratory methodology, and prior exposure to antimicrobial drugs.

34.15.4.3 Central Nervous System

Abnormal electroencephalographic activity has been observed in dogs and cats after IV administration of 25 mg/kg or greater.⁶⁹ Quinolones directly inhibit gamma-aminobutyric acid and stimulate N-methyl D-aspartate receptors. Tremors and ataxia have been reported. Seizures developed in some animals, presumably those with low seizure threshold. Seizures have been precipitated by administration of quinolones parenterally with concurrent nonsteroidal antiinflammatory drugs, such as fenbufen and ibuprofen. The authors (CEG and ADJW) have also observed drug-induced seizures in a dog receiving quinolones and antiemetic phenothiazines concurrently. An accidental administration of a fourfold overdose of enrofloxacin caused a dog with CNS lymphoma to seizure.

34.15.4.4 Ocular

Quinolones have limited solubility at alkaline pH and may crystallize in various tissues. Dogs given high doses had subcapsular lenticular cataract formation and associated inflammation after treatment for 8 to 12 months. Cats given high or IV doses of enrofloxacin have developed acute blindness from retinotoxicity and photoreceptor damage.^{*} They develop acute blindness and mydriasis. Experimentally, administration of oral dosages greater than 30 mg/kg/day for 21 days resulted in retinal degeneration, abnormal electroretinograms, and microscopic changes in the retina.^{1,409} In case studies, cats receiving oral dosages ranging from 4.6 to 54 mg/kg/day developed retinal toxicity within 2 days to 12 weeks.¹²⁴ A majority of the cats received dosages much higher than 5 mg/kg/day given twice daily or were given IV infusions of the drug. Label recommendations indicate that cats should not receive a dose greater than 5 mg/kg/day, and IV injections of enrofloxacin should be avoided. Similar toxicity has been observed with orbifloxacin at higher than recommended dosages.^{190,420} Quinolone-associated retinal degeneration is a dose-related toxicity and not an idiosyncratic reaction. Use of co-administered drugs that increase quinolone plasma concentrations should be avoided. The blindness may be transient if it is recognized early and medication is discontinued.

Table 34-14 Fluoroquinolone Toxicity in Dogs and Cats

SYSTEM INVOLVED	ADVERSE REACTIONS OBSERVED
Central nervous system	Seizures, retinal blindness (cats)
Cardiovascular	Cardiac arrhythmias (people)
Musculoskeletal	Arthropathy in juveniles
Hepatic	Increased hepatic transaminases and alkaline phosphatase concentrations
Renal	Crystalluria-induced renal dysfunction
Gastrointestinal	Anorexia, vomiting, diarrhea
Dermatologic	Urticaria, photosensitization, pruritus

* References: 1, 84, 124, 420, 423.

Infectious Diseases of the Dog and Cat, 3rd Edition

34.15.4.5 Hepatic

Therapeutic doses may cause increased blood hepatic enzyme activities, especially in combination with other hepatotoxic drugs. Quinolones inhibit cytochrome P450-mediated drug metabolism.¹⁶⁸ As a result, they may increase the concentrations and potential toxicity of co-administered drugs that are metabolized by this system. Increased hepatotoxicity or delayed metabolism causing anorexia and increased blood hepatic transaminase concentrations have occurred when these drugs were co-administered with others, such as itraconazole, that are also metabolized by the liver and potentially hepatotoxic.¹⁴⁰ Trovafloxacin, a fourth-generation quinolone, was withdrawn from the market because of hepatotoxicity.

34.15.4.6 Renal

At high or supratherapeutic dosages in dogs, renal toxicity developed from crystalluria and crystal deposition in tubular lumens, especially at alkaline urine pH. Nephrotoxicity has also occurred uncommonly in people and dogs treated with usual therapeutic dosages. Temafloxacin, a fourth-generation quinolone, was withdrawn from the market because it caused hemolytic uremic syndrome and hypoglycemia.

34.15.4.7 Glucose Homeostasis

Some quinolones such as ciprofloxacin, levofloxacin, and moxifloxacin have caused minor alterations in blood glucose and insulin production in people. Gatifloxacin has been associated with more severe disruptions, especially in persons with diabetes and older adults.

34.15.4.8 Skeletal

Quinolones inhibit mitochondrial dehydrogenase activity and proteoglycan synthesis, resulting in cartilaginous damage.¹⁶³ Quinolones also chelate magnesium, altering chondrocyte-surface integrin receptors and cartilage-matrix integrity.⁵⁶ These findings are accentuated by magnesium deficiency. Cartilaginous defects in growing cartilage of young dogs^{54,55} were accentuated by exercise and prevented by exercise restriction. Dose levels may be important in the production of joint damage, given that juvenile dogs did not develop arthropathy if they were treated with ofloxacin at lower doses.^{431,434} Nevertheless, quinolones are contraindicated in dogs during the rapid-growth phase, between 2 to 8 months in small and medium breeds, up to 1 year in large breeds, and up to 18 months in giant breeds. Tendonitis and tendon ruptures have occurred in people.

34.15.4.9 Systemic

Allergic reactions are characterized by erythema and edema of the face and ears with shivering or shaking. Cats given high doses of ciprofloxacin developed pinnae erythema, vomiting, and clonic muscle spasms.

34.15.4.10 Reproductive

Because of effects on DNA synthesis and known fetal toxicity in other species, these drugs should not be given to young (under 6 months of age) or pregnant dogs or cats. High doses have been fetotoxic in animals.

Infectious Diseases of the Dog and Cat, 3rd Edition

Because these drugs are excreted in milk, they should be avoided in lactating animals. High doses (100 mg/kg) for longer than 3 months have been associated with impaired spermatogenesis and testicular atrophy in dogs.

34.15.4.11 Cutaneous

Allergic and photosensitive dermal reactions have developed in people being treated with quinolones. Suspected photosensitization, exhibited by inflammation of the planum nasale, was observed each time a dog was treated with enrofloxacin.¹⁴⁰ Quinolones have a high affinity for melanin pigments and are taken up by the iris, choroids, and dermal melanocytes. Thus the ocular and cutaneous toxicities may have a similar mechanism. The absorption of UV light results in the formation of cytotoxic photodegradation products that may lead to the cutaneous inflammation observed.

34.16 STREPTOGRAMINS AND OXAZOLIDINONES

Quinupristin-dalfopristin are two streptogramin antibacterials marketed in combination, as a 30:70 ratio mixture, for treating *resistant* gram-positive bacterial infections in people.¹¹⁰ They act synergistically on bacterial ribosomal protein synthesis for a bactericidal effect. This combination has been licensed to treat methicillin- and vancomycin-resistant staphylococci and *Enterococcus faecium* infections in people. Quinupristin-dalfopristin are inactive against *Enterococcus faecalis*. These drugs are effective also against *Mycoplasma* spp. and *Clostridium perfringens*. Worldwide, gram-positive bacteria from people have been highly susceptible; however, genes mediating dalfopristin inactivation have been found in resistant strains of *E. faecium* recovered from some animals such as chickens where antibacterials have been used as food additives.^{159,246} Linezolid is a synthetic oxazolidinone antimicrobial that also inhibits ribosomal protein synthesis. It is well absorbed when given orally. As with streptogramins, linezolid is effective against gram-positive bacteria, including both *E. faecium* and *E. faecalis*, and has been licensed for similar resistant strains of bacteria.¹¹⁰ Because of their important role in drug-resistant human bacterial infections and the risk of inducing resistant bacterial strains in food or companion animals, the use of these two groups of drugs should be restricted or avoided in veterinary patients.

34.17 PLEUROMUTILINS

Tiamulin and valnemulin are members of a novel antibiotic class that is marketed for use only in food-producing animals. These drugs act by interfering with ribosomal protein synthesis. This group of drugs is highly active against *Mycoplasma* and spirochetes. They have been used to treat drug-resistant spirochetal infections in swine such as swine dysentery, porcine proliferative enteropathy and porcine colonic spirochetosis, and porcine respiratory disease caused by mycoplasmas. Tiamulin and valnemulin are formulated as feed additives and have not been studied in dogs or cats. Valnemulin was used to treat drug-resistant *Mycoplasma* infections in two immunocompromised people.¹⁶⁰ Toxicity occurs when these drugs are given in combination with ionophore antimicrobials.

34.18 KETOLIDES

Telithromycin is the first drug licensed in this new class of antibiotics. It has a spectrum of activity against gram-positive organisms. Indications for people are treatment of upper and lower respiratory tract infections. Because of their important role in drug-resistant human bacterial infections and the risk of inducing resistant

Infectious Diseases of the Dog and Cat, 3rd Edition

bacterial strains in food or companion animals, the use of these drugs should be restricted or avoided in veterinary patients.

34.19 URINARY ANTISEPTICS

Methenamine (hexamethylenetetramine), a highly water-soluble organic compound, is rapidly absorbed after oral administration and excreted primarily in urine. It decomposes in acidic urine to form formaldehyde and is used only for long-term treatment and prophylaxis of UTIs. The tablets are enteric-coated to prevent degradation by gastric acid and often contain organic acids (mandelic, hippuric, sulfosalicylic salts) to lower urine pH and facilitate formaldehyde production. Antibacterial activity is largely confined to the bladder because transit through the upper urinary tract is rapid, allowing insufficient time to generate formaldehyde.

34.20 ANTITUBERCULOUS DRUGS

34.20.1 Isoniazid

This hydrazide derivative of isonicotinic acid is one of the most active compounds against *M. tuberculosis*. Isoniazid interferes with synthesis of mycolic acids in mycobacterial cell walls and acts only against replicating bacteria, leaving slow-growing or inactive organisms unaffected. Absorption of isoniazid from the intestine is rapid but inhibited by antacids, and much of the dose is excreted unchanged in the urine within 24 hours. Isoniazid penetrates most tissues well. CSF concentration is 20% of that of plasma but increases to 100% in the presence of CNS inflammation. Most strains of *M. tuberculosis* are sensitive to isoniazid, but resistance usually develops during therapy. Therefore drug susceptibility testing is recommended.

The principal side effects of isoniazid, hepatotoxicity and increased blood hepatic enzyme concentrations, are reversed if therapy is discontinued immediately. Peripheral neuropathy and CNS excitability may be caused by monoamine oxidase antagonism. Seizures, tremors, and hyperexcitability were seen in dogs that were overdosed.¹⁰⁰ Immune-mediated thrombocytopenia occurred in one dog treated with isoniazid.⁸⁸ GI irritation, allergic skin reaction, and vasculitis have also been reported in people.

34.20.2 Rifampin (Rifampicin)

This semisynthetic hydrazone derivative of rifampin B interferes with RNA synthesis. It is well absorbed from the GI tract. Rifampin is lipid-soluble and 75% to 90% of the drug is bound to serum protein. It penetrates all body tissues and reaches higher concentrations than those in blood in lung, liver, bile, cholecystic wall, and urine. Therapeutic concentrations of rifampin are attained in pleural exudate, ascites, milk, urinary bladder wall, soft tissue, and CSF. Much of the drug is metabolized by the liver and excreted in the bile. Only 6% to 30% appears in the urine.

Rifampin has antibacterial, antichlamydial, and some antiviral activity. It is primarily used to treat infections caused by *M. tuberculosis* and other mycobacteria. Rifampin is also one of the most active antibiotics against *Staphylococcus* and is effective against some gram-negative pathogens. This antibiotic is frequently helpful in combination with β -lactam drugs to treat resistant staphylococcal endocarditis or osteomyelitis. The drug has been combined with vancomycin or with cephalosporins to enhance efficacy against *Staphylococcus*. Rifampin was superior to tetracycline for treatment of experimental *Brucella* infection in laboratory animals but was inferior to minocycline in treating naturally occurring canine brucellosis. Rifampin also has effectiveness in

Infectious Diseases of the Dog and Cat, 3rd Edition

treatment of feline bartonellosis (see [Chapter 54](#)). Although ineffective against fungi when administered alone, rifampin has been shown to enhance the effect of amphotericin B and miconazole against *Candida*.

Resistance to rifampin may develop rapidly when it is used alone, but it can be hindered by combining it with other drugs. Side effects include orange-colored urine, tears, saliva, and sweat. Rash, GI signs, and increased liver enzyme concentrations may be associated with long-term daily administration. Many other side effects have been noted at higher doses; therefore it should always be reformulated to the calculated dose when given to dogs and cats. Rifampin accelerates hepatic metabolism of other drugs and reduces the activity of concurrently administered glucocorticoids, digoxin, quinidine, barbiturates, isoniazid, dapsone, and theophylline.

34.20.3 Rifabutin

This drug is structurally similar to rifampin but is more lipid-soluble. Rifabutin has better tissue distribution but lower oral bioavailability. Rifabutin is extensively metabolized to active intermediates, and it can be used as a substitute for rifampin and has less effect on hepatic metabolism of other drugs.

34.20.4 Ethambutol

This tuberculostatic drug interferes with RNA synthesis and is active only against dividing organisms. It is well absorbed from the GI tract and is widely distributed in body tissues, including CSF. Most of the drug is excreted unmetabolized in urine, and the dose should be reduced in patients with renal failure. The main toxic effect is optic and peripheral neuritis.

34.20.5 Miscellaneous Drugs

Para-aminosalicylic acid is an analog of PABA that is mycobacteriostatic, interfering with folic acid synthesis. It potentiates the effect of isoniazid by delaying its metabolism. Pyrazinamide, a tuberculostatic drug with an unknown mode of action, is relatively hepatotoxic. Cycloserine inhibits bacterial cell wall synthesis and is excreted primarily by the kidneys. Ethionamide inhibits protein synthesis and has widespread tissue distribution. PABA is combined in therapy when resistance is found to other drugs. Viomycin, capreomycin, kanamycin, and amikacin have all been shown to be effective against mycobacteria when combined with other drugs. See [Chapter 50](#) for a discussion of tuberculosis in dogs and cats.

34.21 DRUGS AGAINST RAPIDLY GROWING OPPORTUNISTIC MYCOBACTERIA

Some antituberculous drugs, such as isoniazid, rifampin, and AGs, are effective in treating other mycobacteria. Other antimicrobials have also been successful in some cases, including erythromycin, clarithromycin, doxycycline, minocycline, enrofloxacin, clofazimine, T-S, and drugs used to treat human leprosy (see Therapy sections, [Chapter 50](#)).

Dapsone is a sulfone derivative that is bacteriostatic to bactericidal against *Mycobacterium leprae*. It is absorbed completely from the bowel, metabolized in the liver, and eliminated mainly by renal excretion. Toxic effects in dogs have consisted of hemolytic anemia, leukopenia, thrombocytopenia, and increased liver enzyme activities. Acedapsone is a derivative with longer duration of action. Clofazimine, a dye with antiprotozoal and antifungal activity, is active against *M. leprae*, *M. avium*-complex organisms, and opportunistic mycobacteria. This drug should always be given in combination with other drugs. For additional information on dapsone and clofazimine, see [Chapter 50](#) and the Drug Formulary ([Appendix 8](#)).

Infectious Diseases of the Dog and Cat, 3rd Edition

34.22. TOPICAL ANTIBACTERIAL DRUGS

34.22.1 Bacitracin

This mixture of cyclic peptides has bactericidal activity against many gram-positive aerobic pathogens, including *Staphylococcus*, *Streptococcus*, *Corynebacterium*, *Clostridium*, and *Actinomyces*. Bacitracin is not absorbed to any extent after topical or oral administration and is nephrotoxic when given parenterally. Accordingly, its use is limited to surface application for treating infections of skin, ear, and eye. Bacitracin is often given in conjunction with an AG (usually neomycin) and polymyxin. The principal toxic effect of bacitracin is hypersensitivity associated with topical application.

34.22.2 Mupirocin

This novel antibiotic, unrelated in structure and action to other known antimicrobials, inhibits bacterial protein synthesis. It is bactericidal against *Staphylococcus*, *Streptococcus*, and some gram-negative aerobic pathogens. The drug is available commercially as a topical ointment. The only side effect observed has been local dermal hypersensitivity reaction at the site of application in some animals.

34.22.3 Fusidic Acid

The principal interest in fusidic acid lies in its excellent activity against *Staphylococcus* spp., including β -lactamase-producing and methicillin-resistant strains. Fusidic acid is available in some countries in enteral, parenteral, and topical preparations.

34.22.4 Topical Buffered EDTA Solution

Many gram-negative bacteria are susceptible to chelating agents such as ethylenediaminetetraacetic acid (EDTA). The bactericidal effect appears to occur by removal of cations from the bacterial cell wall, resulting in leakage of cell solutes. Alkaline pH appears to facilitate bactericidal activity. Research has proved EDTA to be safe when applied topically to animal tissues. Appropriate pH is maintained by combining it with stable amino buffers, such as tromethamine (TRIS) hydrochloride at pH 8. Administration of this combination is restricted to topical application or irrigation because toxicity can result from removal of blood cations such as calcium and production of nephrocalcinosis. The buffered EDTA solution can be made with easily obtainable ingredients or it is available commercially (Table 34-15). Incorporation of sodium dodecyl sulfate, an ionic detergent, improves efficacy. Buffered EDTA solutions have been administered alone and in combination with several antimicrobial agents to treat various resistant bacterial infections in dogs and cats. A primary use has been against *Pseudomonas* organisms, which are resistant to many antibacterial drugs. Use with lysozyme, gentamicin, or oxytetracycline has been attempted to increase the potency of these drugs and to decrease the incidence of antimicrobial resistance.^{112,113,349} The increased permeability of gram-negative bacterial cell walls may facilitate drug penetration and antimicrobial activity. Overgrowth of fungi may occur during such treatment unless an antifungal drug is used simultaneously. Such overgrowth may be more likely when treating infections in body regions lacking a normal competitive microflora, such as the urinary bladder. Repeated catheterization and flushing with these solutions may also favor introduction and persistence of resistant bacterial strains.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 34-15 Improved Formula for Buffered EDTA Solution^a EDTA, Ethylenediaminetetraacetic acid; NaOH, sodium hydroxide.

1. Dissolve 1.2 g of EDTA in 1 L of 0.05 M (6.05 g) tromethamine (hydroxymethyl) aminomethane (TRIS) and 1.9 g/L sodium dodecyl sulfate^b
2. Adjust pH to 8.0 (usually requires concentrated NaOH)
3. Sterilize in autoclave (121° C for 20 min) or filter with 0.22-µm filter.
4. Store in sterile bottles at room temperature. Stable for 1 year.
5. Can add gentamicin (3 mg/ml) or amikacin (9 mg/ml).

^a Also available commercially: Tricide and Tricide (Neo), Molecular Therapeutics LLC, Athens, GA.

^b Sodium dodecyl sulfate improves efficacy.

Table 34-16 Safety of Antimicrobial Drugs in Various Clinical Situations

	RENAL DYSFUNCTION	HEPATIC DYSFUNCTION	PREGNANCY	NEONATE
Probably safe	Chloramphenicol, doxycycline, griseofulvin, macrolides, penicillins (including clavulanate)	Aminoglycosides, cephalosporins, penicillins (including clavulanate)	Cephalosporins, erythromycin, lincomycin, penicillins (including clavulanate)	Cephalosporins, macrolides, penicillins (including clavulanate)
Consider dosage adjustment	Fluoroquinolones, lincomycin, trimethoprim-sulfonamide (dog)	Clindamycin, metronidazole	Nitrofurantoin, sulfonamides, trimethoprim-sulfonamide, tylosin	Lincomycin
Use caution, can accumulate ^a	Chloramphenicol (cat), flucytosine, nitrofurantoin, tetracyclines (not doxycycline)	Chloramphenicol, lincomycin, macrolides, metronidazole, sulfonamides, tetracyclines	Aminoglycosides, amphotericin B, chloramphenicol, fluconazole, flucytosine, ketoconazole, metronidazole	Aminoglycosides, polymyxins
Potentially toxic; avoid use	Aminoglycosides, ^b amphotericin B, polymyxins, trimethoprim-sulfonamide (cat)	Chlortetracycline, erythromycin estolate, griseofulvin, ketoconazole, trimethoprim-sulfonamide (dog)	Fluoroquinolones, griseofulvin, nalidixic acid, tetracyclines	Fluoroquinolones, nitrofurans, chloramphenicol, sulfonamides, tetracyclines, trimethoprim-sulfonamide

^a Or, potentially damaging in pregnancy.

^b If an aminoglycoside must be used in renal failure, maintain the dose but lengthen the interval by multiplying the usual interval in hours by patient's creatinine divided by the higher reference value for creatinine.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 34-17 Some General Guidelines for Antibacterial Drug Selection^a

ORGANISMS	CLINICAL CONDITIONS	FIRST CHOICES	ALTERNATIVES	GENERALLY INEFFECTIVE
<i>Staphylococcus</i>	Canine pyoderma, osteomyelitis	First-generation cephalosporins, isoxazoyl penicillins, macrolides, clindamycin	Chloramphenicol, trimethoprim-sulfonamide, amoxicillin-clavulanate, quinolones	Penicillin G, aminopenicillins
<i>Pseudomonas</i>	Soft-tissue infections	Gentamicin, ticarcillin, ceftazidime	Cefoperazone, carbenicillin, quinolones	Aminopenicillins, first- and second-generation cephalosporins
	Urinary tract infections	Tetracyclines, quinolones	Carbenicillin	
<i>Helicobacter</i>	Gastric inflammation and ulceration	Combination of bismuth, doxycycline, metronidazole	Azithromycin, clarithromycin	
<i>Leptospira, Borrelia</i>	Leptospirosis, Lyme borreliosis	Aminopenicillins, tetracyclines, aminoglycosides	Macrolides	Third-generation cephalosporins, azithromycin
Intracellular persistent organisms ^b	Pyogranulomatous inflammation, granulomas	Combinations of tetracyclines and aminoglycosides	Clarithromycin, azithromycin, quinolones, clofazamine, rifampin	β-Lactams
Other gram-positive aerobes and facultatives, plus <i>Pasteurella</i>	Oral infections, bite wounds, upper respiratory infections	Penicillin G, isoxazoyl penicillins, macrolides, lincosamides	Aminopenicillins, trimethoprim-sulfonamide, chloramphenicol	Third-generation quinolones
Other gram-negative aerobes and facultatives	Urinary tract infections, small and large intestinal infections	Amoxicillin-clavulanate, first-generation cephalosporins, trimethoprim-sulfonamide	Aminoglycosides, second- and third-generation cephalosporins, quinolones, tetracyclines	Penicillin G, isoxazoyl penicillins, aminopenicillins
Obligate anaerobes ^c	Stomatitis, gingivitis, bite wounds, abscesses, pleuritis, colitis, peritonitis	Clindamycin, metronidazole, penicillin G	Amoxicillin-clavulanate, chloramphenicol, cefoxitin, cefotetan	Fourth-generation quinolones

a For specific guidelines, see chapters listed under clinical conditions. For *Mycoplasma* and *Chlamydiae*, see therapy tables in [Chapters 30, 31 and 32](#).

b *Brucella*, *Mycobacteria*, and *Bartonella*.

c *Clostridium*, *Prevotella*, *Bacteroides*, *Fusobacterium*, etc.

34.23 SAFETY OF ANTIBACTERIAL DRUGS AND GUIDELINES FOR SELECTION

A listing of the safety factors of various antimicrobial drugs in various medical conditions is provided in [Table 34-16](#).

[Table 34-17](#) lists general guidelines for antibacterial drug selection.

35 CHAPTER 35 Streptococcal and Other Gram-Positive Bacterial Infections

35.1 STREPTOCOCCAL INFECTIONS

Craig E. Greene

John F. Prescott

Streptococci are gram-positive, nonmotile, facultatively anaerobic cocci that cause localized to widespread pyogenic infections in animals and people. Although numerous are pathogenic, many species are commensal microflora of the oral cavity, nasopharynx, skin, and genital and gastrointestinal (GI) tracts. Species differences among streptococci are responsible for the varying host ranges and virulence. Several classification systems exist for streptococci based on cultural characteristics, antigenic composition, and biochemical features. Because it tends to correlate with pathogenicity, Lancefield classification⁸² based on antigenic differences in cell wall carbohydrates is used to distinguish the groups. The action on erythrocytes in culture medium has also been used to distinguish different groups of streptococci. β -Hemolysis is characterized by complete lysis of erythrocytes and clearing around the bacterial colonies. α -Hemolysis is characterized by a greenish-colored zone and intact erythrocytes in the discolored region. Some are nonhemolytic. β -Hemolytic strains tend to be most pathogenic. Lancefield groups A, B, C, E, G, L, and M are usually β -hemolytic. Group D is usually α -hemolytic but can be nonhemolytic and contains numerous species that have been reclassified as *Enterococcus* (see Enterococcal Infections section in this chapter). Organisms in the α -hemolytic and nonhemolytic categories are found on mucous membranes and skin of clinically healthy animals. If present in an infectious process, they are usually regarded as contaminants or unimportant invaders. When they do cause illness, it may take the form of valvular endocarditis or embolic abscess. The precise species classification of streptococci in numerous disease processes described next is in doubt, especially in the older literature. Increasingly, Lancefield grouping combined with detailed phenotypic characterization by commercial identification systems classifies streptococci correctly and defines more clearly the strains responsible for significant infections in dogs and cats.

35.1.1 Group A Streptococcal Infections of Dogs and Cats

People are the principal natural reservoir hosts of group A streptococci, and most human infections are caused by this group, which includes *Streptococcus pyogenes* and *Streptococcus pneumoniae*. Dermatitis, pharyngitis, and scarlet and rheumatic fevers are the main syndromes caused by *S. pyogenes* (Table 35-1). Rarely, these organisms produce perianal cellulitis, vaginitis, and localized abscesses. Certain strains produce pyrogenic exotoxins, which may cause toxic shocklike syndrome. *S. pneumoniae* produces lower respiratory infection with occasional dissemination. Of all the streptococcal groups, group A organisms have the greatest virulence for human adults, whereas organisms of the other groups, such as B, C, D, F, and G, cause the most severe manifestations in neonates.

35.1.1.1 *S. pyogenes*

S. pyogenes is the predominant cause of group A infections of people and is the type species for this group. The sites of greatest carriage of group A streptococci in people are the caudal aspects of the pharynx and tonsillar region. Group A streptococci can survive extremes in environmental temperature and humidity; however, most infections are associated with direct or close contact among susceptible individuals (Fig. 35-1). As is true with many streptococcal infections, some individuals can harbor the infection for extended

Infectious Diseases of the Dog and Cat, 3rd Edition

periods in the absence of clinical illness. Prevalence rates for group A streptococci are higher in young children, especially those in day-care or classroom situations. The prevalence of positive throat culture findings in such circumstances may approach 50%, even in the absence of an obvious epidemic.⁵⁹ Symptomatic rather than carrier children are most likely to bring infection into the home. Under such circumstances the isolation rate in other people in the household approaches 25% to 50%. If the child is asymptomatic, the rate is only 9%.⁷² Dogs and cats have been suggested as possible sources of reinfection of treated household members, but no convincing evidence shows that dogs and cats are significant reservoirs of infection for people. However, veterinarians may need to be consulted on this topic.

Whenever streptococcal typing has been performed on the oropharyngeal region of dogs and cats, groups G, C, L, and M have been present (in order of decreasing frequency). However, screening for group A streptococcal colonization of the tonsils of dogs and cats from random households in urban environments has shown the apparent prevalence to range between 1% and 10%. In one study in which recurrent group A streptococcal pharyngitis occurred in people, the prevalence for households was said to be 42% for dogs and 36% for cats. However, because only bacitracin susceptibility was used to distinguish group A from non-group A strains in many of these studies, the findings of high prevalence must be regarded as unproven at best and fictitious at worst. When Lancefield typing has been done, the prevalence of true group A streptococcal carriage has varied from 0% to 3% of dogs and has not correlated with the presence of infection in the owner.^{28,169} Biochemical testing of isolates from dogs and cats cannot accurately distinguish between those from groups A and G.¹¹⁵

Domestic pets that come into close contact with infected individuals can sometimes apparently develop pharyngeal colonization with group A streptococci. Infected pets show no clinical illness or tonsillar enlargement. Because clinical symptomatology is absent in these animals, the main consideration is their potential public health risk. If pets are overlooked during treatment of their infected owners, they might serve as possible reservoirs for reinfection of family members. However, pets usually lose their infection within 2 to 3 weeks after they are removed from the household. Infected people are carriers of group A streptococci for much longer periods.¹¹⁷ It is not acceptable to consider culturing and treating a dog and or cat in a household in which reinfection occurs without doing so for the human contacts.

Table 35-1 Summary of Streptococcal and Enterococcal Infections of People, Dogs, and Cats

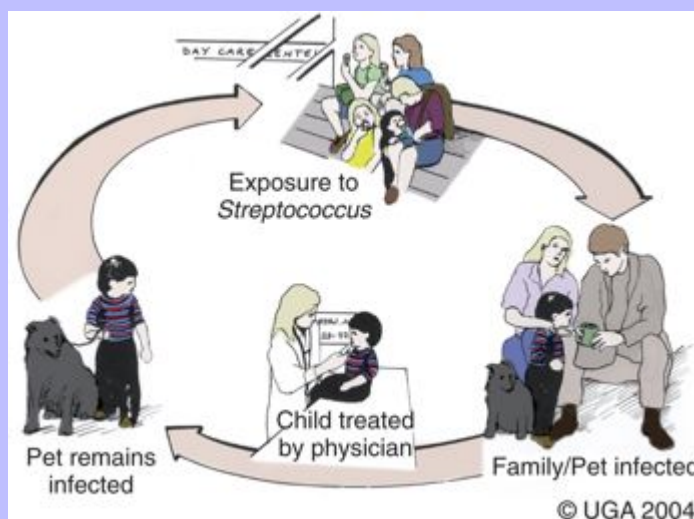

SPECIES (SEROGROUP)	HOST SPECIES ^a	MICROFLORAL DISTRIBUTION ^b	DISEASE SYNDROMES ^b
<i>Streptococcus</i>			
<i>S. pyogenes</i> (A)	P	Tonsils	Tonsillitis, pharyngitis, otitis, impetigo, bacteremia, toxemia, ^{12,13} toxic shock, necrotizing fasciitis
<i>S. pneumoniae</i> (A)	B	None (human reservoir)	Asymptomatic
	P	Tonsils	Pneumonia, otitis, bacteremia, polyarthrits, meningitis
<i>S. agalactiae</i> (A)	C	None (human reservoir)	Polyarthrits, bacteremia ¹⁴
	P	Anorectum, vagina	<i>Neonatal</i> : sepsis ^{16,18} <i>Immunosuppressed</i> : bacteremia, meningitis, endocarditis ^{23,27,28} <i>Postparturient</i> : metritis; septic arthritis; pharyngitis; respiratory, skin, and wound infection
	D	Urogenital region	Fatal septicemia in pups, necrotizing pneumonia, bacteremia, endocarditis, pyelonephritis ¹⁰⁰
	C	Urogenital region	Peritonitis, septicemia, placentitis ³⁶
<i>S. equi</i> ssp. <i>zooepidemicus</i> (C) D	D	Skin, genitourinary tract	Endocarditis, septicemia, ¹¹⁴ acute fibrinopurulent bronchopneumonia death, ^{37,47} UTIs
<i>S. dysgalactiae</i> ssp. <i>quisimilis</i> (C)	P	None (animal reservoir)	Pharyngitis, glomerulonephritis, ^{55,58} pericarditis
<i>S. suis</i> (D or none)	C	Oropharynx	Dermatitis, fibrinonecrotic pleuropneumonia ³⁷
<i>S. milleri</i>	P, D	Skin, mucosae	Opportunistic infections, abscesses in many tissues ⁴⁵
<i>S. intermedius</i> (F)			
<i>S. dysgalactiae</i> (G)	P	Tonsils, vagina	Pharyngitis, tonsillitis, wound infections, neonatal and puerperal sepsis, endocarditis
<i>S. canis</i> (G)	C	Nasopharynx, genitalia, skin	Abscesses, neonatal sepsis, umbilical infections, ^{67,71,74,80} pyelonephritis ⁹¹
	D	Tonsils, anorectum, ⁹² genitalia	Otitis media, neonatal sepsis (fading puppy?), umbilical infections, polyarthrits, abscesses, dermatitis, meningoencephalitis, ²¹ mastitis, ^{33,96,98,99,100} genital infections: infertility, anestrus, abortion, failure to conceive, ¹¹¹ UTI; pericarditis, ¹³⁰ streptococcal toxic shock syndrome/necrotizing fasciitis
<i>Streptococcus</i> sp. (L)	D	Genitalia	Abortion, fading puppy syndrome, sterility in bitch, endometritis ^{12,101,102}
<i>Streptococcus</i> sp. (M)	D	Tonsils ¹⁰¹	Asymptomatic colonization
<i>Streptococcus</i> sp. (E)	D	Skin, upper respiratory tract ⁹⁶	Asymptomatic colonization found as mixed flora in mucosal inflammation ¹¹¹
<i>Enterococcus</i>^c			
<i>E. faecalis</i> , <i>E. avium</i> , <i>E. faecium</i> (all D)	D, P, C	Intestine, feces, ⁹⁶ tonsils	Asymptomatic colonization, urinary tract infection, nosocomial surgical infections

Infectious Diseases of the Dog and Cat, 3rd Edition

<i>E. hirae</i> (D)	D	Intestine, feces	Diarrhea, symptomatic upper intestinal colonization ^{37,83}
a <i>P</i> , Human; <i>B</i> , dog and cat; <i>C</i> , cat; <i>D</i> , dog; <i>UTI</i> , urinary tract infection.			
b Numbers footnote symbols in this <i>column</i> refer to the reference list on the CD-ROM.			
c Also includes <i>E. cecorum</i> , <i>E. durans</i> , and <i>E. zymogenes</i> .			

The recovery of group A streptococci is affected by the method used when swabbing the throat, because overgrowth by indigenous microflora can result in the death of group A streptococci. Sedation may be needed, because sterile swabs should be rubbed over the surface of the exposed tonsils in their crypts. Swabs that are unrefrigerated during transport should be kept dry, otherwise overgrowth by contaminating microflora occurs. Latex agglutination and enzyme-linked immunosorbent assay (ELISA) tests are available for rapid detection of group A streptococci in children. Their value in detection of asymptomatic group A infections in dogs and cats is likely to be low.

Fig 35-1 Zoonotic aspects of group A streptococcal infection in pets. Children usually acquire the infection at school. When they are treated, reinfection may result if a household pet has acquired infection and is not simultaneously treated. Treatment of additional family contacts is equally important in breaking the cycle. (Courtesy University of Georgia, Athens, Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 35-2 Drug Therapy for Streptococcal Infections in Dogs and Cats^a

DRUG ^b	SPECIES	DOSE ^c (mg/kg)	ROUTE	INTERVAL (HOURS)	DURATION (DAYS)
Penicillin G	Dog and cat	10,000–20,000 U/kg	IM, SC	12–24	5–7
Penicillin V	Dog and cat	8–30	PO	8	5–7
Erythromycin	Dog	3–20	PO	12–24	5–7
Chloramphenicol	Dog	15–25	PO, IV, SC	8	5–7
	Cat	10–15	PO, IV, SC	12	5–7
Cephalexin	Dog and cat	10–40	PO	12	5–7

IM, Intramuscular; SC, subcutaneous; PO, by mouth; IV, intravascular.

a For specific dosages for perinatal group G infections in cats, see [Table 35-4](#).

b For additional information, see [Appendix 8](#).

c Dose per administration at specified interval, expressed as mg/kg unless otherwise stated.

The spectrum of effective antimicrobials for treatment of group A streptococcal infection in pets is the same as that for human strains. It is judicious to treat pets when they may be a source of recurrent infection of household members. Isolates of group A streptococci from dogs have shown the greatest susceptibility to penicillin, erythromycin, and chloramphenicol. Recommended total daily dosages are listed in [Table 35-2](#). Resistant strains can be treated with cephalosporins.

35.1.1.2 *S. pneumoniae*

S. pneumoniae (formerly *Diplococcus pneumoniae*) can produce pneumonia, bacteremia, otitis media, endocarditis, and meningitis in people but is of no significance in dogs and cats. A single report of bacteremia and septic arthritis in a cat attributed the infection to transmission of *S. pneumoniae* from a human infant in the same household.¹³² A French bulldog developed hyperesthesia and central vestibular disease from meningoencephalitis caused by *S. pneumoniae*.⁷⁰

35.1.2 Group B Streptococcal Infections of Dogs and Cats

Group B streptococci (*Streptococcus agalactiae*) have been associated mainly with neonatal septicemia and postpartum metritis in people and mastitis in cows. Skin, pharyngeal, and wound infections can occur. Immunosuppressed individuals can develop disease in many tissues (see [Table 35-1](#)). Group B streptococci are more frequently isolated than group G from people with these syndromes. Factors at the time of delivery, such as low birth weight or difficult delivery, precipitate the development of clinical illness.

Group B streptococcal infections are rare in dogs and cats. They have been reported to cause septicemia in a dog, endometritis, and “fading puppy syndrome,” symptoms of which include bacteremia, pyelonephritis, and necrotizing pneumonia. Group G streptococci have been far more commonly isolated than group B as causes of neonatal sepsis. Similarly, peritonitis with septicemia and parturient endometritis and placentitis have been described in cats. Whether canine and feline strains are indigenous or of human or other animal origin is uncertain. In one dog the organism was isolated from the skin and may have been a transient resident from a human source.⁵⁰ Treatment is similar to that for group A streptococcal infections (see [Table 35-2](#)).

Infectious Diseases of the Dog and Cat, 3rd Edition

35.1.3 Group C Streptococcal Infections of Dogs and Cats

Disease associated with group C streptococci has been described only in dogs (although dogs and cats may carry these organisms as commensal flora) in lower frequency than group G. Identification of group C streptococci in the lower respiratory tract washings of clinically healthy dogs and dogs with chronic infectious respiratory infections in kennels was associated with more severe respiratory disease in infected populations.²⁰ Histologic analysis revealed that dogs with group C streptococci were more likely to have intraalveolar neutrophils than those without this infection. 304 305

Acute hemorrhagic and purulent pneumonia has been described as a cause of acute respiratory infection with group C organisms, primarily in racing greyhounds or research dogs.^{137,171} Weakness, coughing, dyspnea, fever, hematemesis, and red urine have been the predominant clinical signs. Many of the dogs developed septicemia, and some died suddenly without signs of clinical illness. Gross lesions at necropsy of diseased animals consisted of widespread petechial and ecchymotic hemorrhages and pulmonary congestion with mediastinal and free pleural hemorrhage. Microscopically, streptococci were found in clusters intracellularly throughout the lung parenchyma and in the spleen. The circumstances leading to group C streptococcal septicemia or pneumonia in adult dogs kept in kennels or groups are unclear, and these infections appear to be rare. The isolates have been identified as *Streptococcus equi* subsp. *zooepidemicus*, although more details of the bacterial characterization are needed to determine whether this finding is correct (see streptococcal toxic shock syndrome discussion in this chapter). Other group C streptococci isolated from less severe infections (urinary tract infections [UTIs] or abscesses) in dogs have been identified as *Streptococcus dysgalactiae* subsp. *equisimilis*, although this subspecies also has caused serious losses through septicemia and pneumonia in captive coyotes.⁵⁵ Drugs and dosages recommended for treatment are similar to those for group A infections (see Table 35-2).

35.1.4 Group G Streptococcal Infections

35.1.4.1 Cats

β -Hemolytic streptococci are commensal microflora of the skin, pharynx, and upper respiratory and genital tracts of cats. The majority of β -hemolytic streptococcal infections in cats are caused by Lancefield group G streptococci and are apparently *Streptococcus canis*. Whether more virulent disease-producing strains of this organism exist is uncertain, but these organisms can cause severe infections in kittens. Neonatal kittens are infected with the streptococci from the vagina of the queen. Streptococci can gain entrance via the umbilical vein and can spread by direct extension into the peritoneal cavity or through the ductus venosus and portal circulation of the liver, resulting in bacteremia. In juvenile kittens (3 to 7 months old), cervical lymphadenitis may follow a subclinical episode of pharyngitis and tonsillitis. Group G infections of older cats are often opportunistic and result from wounds, trauma, surgical procedures, viral infections, and immunosuppressive conditions. These suppurative infections can result in septicemia and embolic lesions, most often in the lung and heart.

Although infections in juveniles and older cats are generally sporadic, several kittens in a litter can be affected at one time, most frequently in the first litter of queens younger than 2 years. Young queens that become infected carry higher numbers of organisms in the vagina, and the carrier state persists throughout pregnancy, whereas older, multiparous queens can eliminate the carrier state by midgestation.

Infectious Diseases of the Dog and Cat, 3rd Edition

The prevalence of infection is low in kittens born to older or multiparous queens. A higher prevalence of infection occurs in cats housed in groups. Occasional outbreaks of neonatal infections with high mortality can occur in breeding catteries, especially after the introduction of group G streptococci into a naïve population. Approximately 50% of female household cats younger than 2 years and 70% to 100% of similarly aged queens in breeding catteries may carry group G streptococci in the vagina. Queens in endemically affected catteries can develop protective levels of antibodies by 8 months of age. Kittens receive levels of antibodies equivalent to those of the dam via the colostrum.

Group G streptococci also can be found in the tonsils and pharynx or in the prepuce of the tom. Age, exposure, and immune responses are all important in determining whether this commensal organism causes illness.

The clinical signs vary with the site of infection and host immunocompetence. Sites of streptococcal infections in cats are listed in [Table 35-3](#). Although cats of any age may be affected, most cases involve neonatal kittens (younger than 2 weeks of age). Most infected kittens gain less weight than littermates, and occasionally an affected kitten has a swollen, infected umbilicus. Death usually occurs by 7 to 11 days of age, but kittens born to queens with minimal prior exposure may die suddenly at younger than 3 days of age with overwhelming sepsis. In kittens with septicemia the febrile response is transient, occurs within 24 hours before death, and frequently remains undetected. Older kittens are febrile and anorexic with swelling and purulent exudate at the site of infection. Cervical lymphadenitis is a unilateral or bilateral swelling in the ventral cervical lymph nodes ([Fig. 35-2](#)). Abscess, pharyngitis, pneumonia, diskospondylitis, osteomyelitis, and arthritis are other localizations of the infectious process in this age group.⁶⁶ Animals with respiratory localization with pneumonia have fever, anorexia, coughing, and dyspnea. Those with diskospondylitis have fever, paraspinal hyperesthesia, and progressive paresis. Fever, joint swelling, and lameness are characteristic of arthritis and may involve one or more joints or extremities.

The leukogram shows a typical neutrophilic inflammatory response with a left shift. Neonatal kittens (younger than 2 weeks of age) usually have a degenerative left shift in the leukogram because of the limited bone marrow storage pool. With overwhelming sepsis, cocci may be found in the cytoplasm of circulating neutrophils.

Gram staining of exudates from affected tissues reveals single and chains of gram-positive cocci. Confirmation is based on bacteriologic culture of the affected tissues. Aerobic culture of exudates or needle aspirates of enlarged lymph nodes yield β -hemolytic, gram-positive cocci on sheep and bovine blood agar plates. In fatally affected neonates the organism is found most consistently in the liver, lung, umbilicus, and peritoneal cavity ([Fig. 35-3](#)).

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 35-3 Anatomic Distribution of β -Hemolytic Streptococcal Isolates^a from Lesions in Cats

SOURCE	NUMBER OF ISOLATES	NUMBER OF PURE ISOLATES ^b
Integumentary system	57	23
Respiratory system	38	11
Genital (female) tract	28	12
Urinary tract	17	4
Serous cavities	22	9
Neonatal sepsis	12	6
Other ^c	34	13
TOTAL	208	78

Data compiled from cases during a 17-year period at the Veterinary Medical Teaching Hospital, University of California, Davis, Davis, Calif.

- a Of 38 isolates tested, 34 were Lancefield group G positive.
- b Number of times isolated in pure culture (only organism isolated).
- c Other sites include oral cavity, lymph node, central nervous system, eye, ear, joint, or mammary gland.

Table 35-4 Therapy for Group G Streptococcal Infections in Cattery Cats Based on Age

DRUG ^a	AGE	DOSE ^b	ROUTE	INTERVAL (HOURS)	DURATION (DAYS)
Prevention at Parturition					
Ampicillin (amoxicillin)	N	25 mg/kg	PO, SC	8	5–7
Procaine and benzathine penicillin	N	6,250 IU ^c	SC	48–72	3–5 ^d
	Q	150,000 IU ^c	SC	48–72	3–5 ^d
Infection (Lymphadenitis or Arthritis)					
Procaine and benzathine penicillin	J,A	75,000–150,000 IU ^c	SC	48–72	3–5 ^d
Procaine penicillin	J,A	50,000 IU ^c	SC	24	5
Penicillin V	J,A	20 mg/kg	PO	8	5

N, Neonates; Q, queens; J, juveniles; A, adults; IU, international units;

- a For additional information, see [Appendix 8](#).
- b Dose per administration at specified interval.
- c Total dose needed for each drug in a fixed combination, based on 2- to 3-kg cat. This drug has been associated with injection-site sarcomas.
- d Only one or two doses are usually given during this treatment regimen.

Fig 35-2 Unilateral *S. canis* cervical lymphadenitis in a 4-month-old kitten.
(From Timoney JF, et al [eds]. 1998. *Hagan and Bruner's microbiology and infectious diseases of domestic animals*, ed 8. Cornell University Press, Ithaca, N.Y.)

Necropsy findings in affected neonatal kittens with septicemia include omphalophlebitis, peritonitis, and less frequently, embolic hepatitis, pneumonia, diskospondylitis, and myocarditis. Untreated cases of cervical lymphadenitis in juvenile cats can progress to embolic myocarditis and embolic pneumonia with secondary pulmonary infarction and pleuritis and pyothorax.¹⁷⁰ Valvular endocarditis has also been described.⁹⁴ Older cats are less susceptible to systemic spread of streptococci.

Fig 35-3 Peritonitis and umbilical vein abscess with extension into the liver in a 7-day-old kitten.

Group G streptococci are very sensitive to penicillin and its derivatives. Juvenile and older cats with lymphadenitis should be treated immediately with oral or parenteral therapy (Table 35-4). Draining and flushing the abscesses hasten recovery. These cats should be examined for predisposing conditions such as feline leukemia, feline infectious peritonitis, feline immunodeficiency virus or viral respiratory infections, feline urologic syndrome, and wounds.

For prevention of infection in newborn kittens, dipping the navel and umbilical cord in 2% tincture of iodine and treating of all kittens at birth with ampicillin, amoxicillin, or procaine combined with benzathine penicillin have been successful. A much higher dose of combined procaine and benzathine penicillin should be given immediately to the queen of an infected litter or as a single preventive dose at parturition. Although the population of group G streptococci can be temporarily suppressed by antimicrobial therapy, the carrier state cannot be eliminated.

Treatment of infected juvenile or adult cats with lymphadenitis or arthritis can be accomplished with parenteral or oral therapy (see Table 35-4). Doses are higher than normally recommended because the organism can be harbored in the tonsillar crypts, and a considerable amount of pus forms in the abscess. Cats with diskospondylitis have required up to 6 months of therapy. Parenteral therapy can be instituted in the veterinarian's office, and medication can be dispensed for subsequent oral administration.

Group G streptococci have received increasing attention as a cause of pharyngitis, tonsillitis, wound infection, cellulitis, neonatal and puerperal septicemia, and endocarditis in people. Group G streptococci in

Infectious Diseases of the Dog and Cat, 3rd Edition

cats appear to be *S. canis* and to be distinct from human group G streptococci.¹¹⁵ In a review of all reported human group G infections in Great Britain, a majority of the patients had underlying immunosuppressive illness.⁶⁶

35.1.4.2

Dogs

Group G streptococci are the major streptococcal type isolated as commensal flora from the skin and mucosa of dogs.^{13,14} The majority of group G isolates from dogs are *S. canis*. Nevertheless, some group G isolates have the biochemical characteristics of human group G streptococci. More work is needed to define the biotypic variation within *S. canis* and the identity of unusual group G streptococci isolated from dogs. Historically, the veterinary literature has contained numerous reports of diseases in dogs caused by these organisms, including abortion, infertility, sterility, and neonatal death. In addition, cellulitis, mastitis, pharyngitis, pericarditis, tonsillitis, polysynovitis, and genital infection have been described (see [Table 35-1](#)). Metaphyseal osteomyelitis may occur in growing pups.⁵² Some of the historical descriptions of disease, especially pharyngitis, tonsillitis, infertility, and sterility, caused by group G streptococci should be carefully considered because of the frequency with which these organisms are isolated from clinically healthy animals and the lack of clear description of the microbiology of the infections. However, it is also likely that streptococcal infections have declined in importance in the last 50 years with the widespread use of penicillin and its derivatives in dogs.

S. canis is generally an opportunistic pathogen of dogs and is isolated from an array of nonspecific infections, including genitourinary tract, wound, mammary gland, and skin (especially otitis externa). In addition, it may cause bacteremia or septicemia and polyarthritis in neonatal puppies, forming part of the fading puppy syndrome, in which the pup is predisposed because of lack of warmth, improper navel disinfection, and lack of nursing. Infection in these pups may come from microflora or the environment; no correlation was found between the organisms found in the milk of bitches with those isolated from dead septicemic pups.¹²² Group G streptococci have also been associated with a rapidly progressive systemic infection in older dogs (see streptococcal toxic shock syndrome discussion in this chapter). *S. canis* is a common commensal of the genital tract. It may be an opportunistic organism associated with vaginitis, but its historical role in infertility in bitches is not supported by current findings. Historical but no current accounts exist of the association of this organism with acute tonsillitis and suppurative cervical lymphadenitis in dogs in kennels and other settings. Group G streptococci have also been isolated from the cerebrospinal fluid (CSF) of dogs with meningoencephalomyelitis as a result of hematogenous spread or penetrating injuries.²¹ Space-occupying abscess formation may occur within the confines of the central nervous system (CNS) in some cases. Results of CSF analysis are marked pleocytosis (usually greater than 100 cells/ μ l) with a predominance of neutrophils and in some cases, intracellular bacterial cocci. Antimicrobial choices for group G infections are similar to that for group A streptococcal infections (see [Table 35-2](#)). For CNS infections, therapeutic options include high-dose intravenous (IV) penicillins, trimethoprim-sulfonamide, or IV third-generation cephalosporins.

35.1.4.3

Streptococcal Toxic Shock Syndrome and Necrotizing Fasciitis

The last decade has had a resurgence of severe group A human streptococcal infections characterized by septic shock associated with multiple organ failure and with or without necrotizing fasciitis (NF) ([Table 35-5](#)). It usually originates from bacterial seeding of internal or soft tissues. One report has been made of this syndrome in a person; the source was group G streptococci.¹⁵⁶ Group G dog (*S. canis*) isolates that resisted

Infectious Diseases of the Dog and Cat, 3rd Edition

phagocytosis were examined for virulence genes comparable to those found in group A (*S. pyogenes*) human isolates. Only M-protein genes associated with surface fibrillar material and streptolysin O genes were identified in most of the canine isolates.³⁹ Increased invasiveness of streptococci correlates with a change in the M-protein, which inhibits phagocytosis by neutrophils and macrophages. Once the streptococci develop this new protein, they can enter the body and avoid host defenses.

Multiple organ involvement in streptococcal toxic shock syndrome (STSS) suggests a toxin produced by the pathogenic bacteria might also be involved in the pathogenesis.¹¹³ Bacterial superantigens, a family of highly mitogenic proteins secreted by the organisms, are suspected. Superantigens simultaneously bind to major histocompatibility complex class II molecules and T-cell receptors simultaneously, resulting in sudden high cytokine levels. In vitro, the fluoroquinolone enrofloxacin caused bacteriophage-induced lysis of an *S. canis* strain that had been isolated from a dog with STSS.⁶⁹ Bacteriophage induction was associated with an enhancement of expression of a superantigen gene relative to the same organism in noninduced cultures. The presence of this gene on enrofloxacin-induced bacteriophages may explain the association between this drug treatment and the occurrence of STSS in dogs. Most of the dogs reported with this type of infection had received enrofloxacin in the early stages of disease; however, the drug was not effective in halting the progression of the disease, despite in vitro susceptibility in some cases. In fact, enrofloxacin may have been responsible for triggering the pathologic events caused by these virulent streptococci.

The dramatic and severe multisystemic (STSS) and locally invasive (NF) group A streptococcal infections in people have been dubbed *toxic shock infections* and *flesh-eating bacterial infections*, respectively, in the popular media. A similar clinical picture caused by various isolates of *S. canis* or other group G streptococci has been identified in dogs^{96,101,102,111,112} and cats.^{146a,163} In most cases, affected animals were previously healthy adult dogs or cats younger than 1 year. The dogs had a history of mild trauma, bite wound, or respiratory or urinary tract disease. Affected kittens had suppurative lymphadenomegaly typical of group G infection. In addition, they had multifocal purulent ulcerative skin lesions. They were generally depressed but afebrile.¹⁶³ All the dogs were febrile (40°C to 41°C [104°F to 105.8°F]) at admission. Dogs with NF had severe, rapidly developing cellulitis, usually of a limb but in one case of the ventral thorax. The most consistent clinical sign in the history and on physical examination was intense, excruciating pain localized around the affected area but sometimes involving the whole body. Localized heat and swelling were identified at presentation or within 2 days of hospitalization. Once evident, the cellulitis developed rapidly (Fig. 35-4). Colonies of streptococci in chains can be readily demonstrated in fluid aspirated from the cellulitis or in underlying tissues by histopathologic examination (Fig. 35-5). Dogs with NF were extremely depressed when examined and eventually went into shock. They had extensive exudate accumulation along fascial planes. The fascia required surgical debridement. In two dogs, acute onset of posterior paresis with lower motor neuron deficits developed because of the presence of septic emboli in blood vessels of the gray matter of the spinal cord and because of extension of infection into the surrounding connective tissue and peripheral nerves.

307

308

Table 35-5 Clinical Features of Systemic Streptococcal Infections

Case Definition of Streptococcal Toxic Shock

- I. Isolation of streptococci from normally sterile site
- II. Hypotension
- III. Previous two factors in addition to two or more of the following:
 - A. Renal impairment (elevated creatinine)
 - B. Coagulopathy (thrombocytopenia or disseminated intravascular coagulation)
 - C. Liver abnormalities (elevated aminotransferase activities or bilirubin levels)
 - D. Acute respiratory distress (pulmonary capillary leakage, edema)
 - E. Extensive soft-tissue necrosis (fasciitis, myositis, gangrene)
 - F. Erythematous rash

Case Definition of Necrotizing Fasciitis

- I. Necrosis of soft tissue with fascial involvement
- II. Previous factor in addition to one or more of the following
 - A. Death
 - B. Shock (hypotension 90 mmHg)
 - C. Disseminated intravascular coagulation
 - D. Organ system failure
 - 1. Respiratory
 - 2. Hepatic
 - 3. Renal
 - E. Isolation of hemolytic streptococci from normally sterile site

Clinical Findings

- I. Hyperesthesia, vomiting, diarrhea, dyspnea, tachycardia, fever
- II. Hypotension, localized erythema, localized swelling and edema

Laboratory Findings

- I. Hypoalbuminemia, hypocalcemia, elevated liver transaminases and creatinine activities
- II. Prolonged coagulation times, high creatine kinase with fasciitis

Fig 35-5 Histopathologic appearance of necrotizing fasciitis with large number of colonies of streptococci in chains in the fascial layers overlying the muscle (H and E stain, $\times 400$). (Courtesy University of Georgia, Athens, Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Other dogs with severe invasive *S. canis* infection developed STSS without clinically apparent NF. The dogs with STSS had severe depression, fever, and rapidly developing hypotension and shock. In most the lungs were considered the primary site of infection, and acute infection appeared to be superimposed on chronic preexisting pulmonary infection. In one dog a urinary infection was the presumed source.¹⁰¹

Some kittens with NF responded favorably to treatment with amoxicillin-clavulanate, supportive care, and wound management with topical antibiotic application, while in other cases, the kittens were moribund or dead.^{196a,163} The dogs with STSS died or were euthanized within 48 hours of hospitalization, but those with NF survived. All dogs had full-thickness skin sloughs and required debridement of necrotic tissue, appropriate antibiotic treatment, and intensive supportive medical care (crystalloids, colloids, plasma, low-dose heparin) aimed at treating shock with disseminated intravascular coagulation. IV plasma has been used in people to control hypotension and neutralize bacterial toxins.⁷⁸ IV IgG therapy has also shown some benefit in clinical improvement and reduction of mortality in treated versus control human patients.^{29,135} Less commonly, glucocorticoid treatment was used. More appropriate antibiotics for treatment of this condition are penicillin G, aminopenicillins (ampicillin, amoxicillin), erythromycin, and clindamycin. In human STSS or NF, clindamycin is regarded as the drug of choice. In addition to its antibacterial activity, clindamycin is a potent suppressor of bacterial toxin synthesis, inhibits M-protein synthesis (which facilitates phagocytosis), and suppresses lipopolysaccharide-induced monocyte synthesis of tumor necrosis factor (TNF).¹³⁴ The authors (CEG and JFP) have found this drug to be valuable in the treatment of affected pets.

308

309

35.1.4.4

Public Health Considerations

In general, public health risks from *S. canis* colonization of infection in dogs or cats are low. Only rarely have people been infected with this organism.¹⁶² Nevertheless, when veterinarians drain and debride NF lesions, they should recognize the extreme risk of inadvertent infection of cuts on their hands. This risk can probably be contained by wearing latex gloves and protective clothing when handling dogs with STSS or NF. Group G streptococci are normal inhabitants of the skin, oropharynx, GI tract, and female genital tract of people. Human strains generally belong to the species *S. dysgalactiae* rather than *S. canis*. Asymptomatic pharyngeal carriage of group G streptococci is found in up to 23% of people. The organisms commonly colonize human skin, and approximately 5% of asymptomatic puerperal women harbor them on the genital mucosa. Group G streptococcal infections in people are not common and involve primarily dermatitis and pharyngitis; however, bacteremia and septicemia, endocarditis, peritonitis, peripheral sepsis, soft-tissue infection, and septic arthritis are unusual.

Little evidence shows that dogs are a significant source of human infection.¹⁶ In one report,¹⁶ dogs were mentioned as a possible source of group G streptococcal arthritis in people, but the association was speculative. The source of infection was more likely autogenous. In one report of meningitis,⁷¹ the isolate was not completely characterized. In another report, *S. canis* was isolated from the blood of a person with septicemia.⁹ The organism was specifically typed on the basis of biochemical and genetic analysis. It was presumably transmitted from the family dog and colonized the varicose ulcers of the person's legs. The occurrence of such infections probably involves close contact between the animal and open skin wounds. Routine hand washing after animal contact and not allowing dogs to lick people, especially their wounds, are always advisable.

Infectious Diseases of the Dog and Cat, 3rd Edition

35.1.4.5 Other Streptococcal Infections of Cats and Dogs

Group L streptococci have been similarly associated with syndromes that parallel some of those reported historically for group G streptococci (abortion, infertility, and septicemia in puppies), although their isolation frequency from normal and diseased dogs has been low (see [Table 35-1](#)). Groups M and E have been found as normal microflora of dogs, although they are isolated with very low frequency from the oral, urogenital, and respiratory mucosae. Group D streptococci are considered normal GI flora of dogs, and many of these species have been classified as enterococci. These enteric cocci are often found in urinary tract or nosocomial tissue infections of dogs. *Streptococcus suis* has been isolated rarely from pleuropneumonic conditions in cats but appears to be of little significance.

35.2 ENTEROCOCCAL INFECTIONS

Craig E. Greene

John F. Prescott

Enterococci are gram-positive cocci that grow into short chains and are impossible to distinguish morphologically from streptococci. They were initially classified as group D streptococci but now have their own genus, which contains species such as *Enterococcus faecalis*, *Enterococcus faecium*, and *Enterococcus hirae*. These organisms can survive under more adverse environmental conditions than the less robust streptococci. In addition to being saprophytes, their major habitat in the host is the GI tract, where they are normal microflora ([Table 35-6](#)).³⁴ In fact, they have been used in probiotic preparations and fed to dogs in an attempt to suppress more enteropathogenic bacteria.¹⁵³ Under certain circumstances, enterococci may proliferate and colonize the entire surfaces via fimbriae that adhere to the brush border of enterocytes. Although inflammation is minimal and toxin production is absent, they may cause a decrease in activity of brush border digestive enzymes. Enterococci are not as virulent as other streptococci, but their resistance to many antimicrobials allows them to persist in host tissues after antimicrobial therapy. In people and pets, they have predominantly caused infections in hospitalized patients as nosocomial complications. Systemic infections such as bacteremia and endocarditis and localized infections of the abdominal cavity, genitourinary tract, soft tissue, or respiratory tract have been most frequent.¹²² The multiple antibiotic resistance of some isolates, including notable resistance to vancomycin in rare cases, has led to the increasing prominence of these poorly virulent bacteria.

Vancomycin-resistant enterococci (VRE) are becoming a major threat to human health. People often become infected in hospital settings or their home environments. In Europe, community-acquired infections are 309
presumably more common because a vancomycin-related glycopeptide, avoparcin, has been used extensively as a 310
growth promoter for food-producing animals.⁹⁷ VRE have been recovered from dogs with urinary tract infections¹²⁶ and dog food sold in the United States.⁴³ VRE with the same genotype as those found in people have been recovered from the feces of pet dogs and cats.^{38,118,154}

Infectious Diseases of the Dog and Cat, 3rd Edition

<i>S. dysgalactiae</i> (G)	0	8	0	0

Enterococci are generally resistant to several antimicrobials used to treat gram-positive organisms^{95,121}. Nevertheless, penicillin, ampicillin, and rarely vancomycin combined with aminoglycosides are the treatments of choice. Trimethoprim-sulfonamide is not effective, despite in vitro susceptibility, because these organisms can circumvent the folate synthesis block in vivo.

35.2.1 Dogs

Although resistant nosocomial enterococcal infections have primarily been observed in the veterinary hospital, published reports have implicated *E. hirae* as a cause of diarrhea in dogs. *E. hirae* was isolated from the small intestine of an 11-day-old pup.^{23,36} The pup was one of three that died in a litter affected with acute diarrhea. Microscopically, bacterial colonization of the apical surfaces of the enterocytes in the jejunum was diffuse with mild inflammatory infiltrates. A mixed growth of *Escherichia coli* and *E. hirae* was cultured. Although bacterial attachment has been seen in the ileum and colon of healthy pups, it is not usually found in the upper small intestine. Although enterococci have been associated with malabsorption and diarrhea in other animals, their exact role in the diarrhea or death of these three puppies is uncertain. Concurrent infection with an undetected organism may have been possible. Bacterial adhesion has also been reported in two other mature dogs with diarrhea.⁷⁴ *E. faecium* was one of many floral organisms isolated from feces of one of these affected dogs. Replication and adherence of bacteria in the upper small intestine must be distinguished from bacterial overgrowth because it can develop as a result of other small intestinal disorders.

35.2.2 Cats

E. hirae was identified as a cause of anorexia and diarrhea with fatal outcome in a 2-month-old Persian kitten.⁸³ The kitten was from a commercial breeding colony in which kittens had a history of anorexia and diarrhea at weaning and queens had a history of weight loss by the end of gestation. The kitten had intermittent anorexia

Infectious Diseases of the Dog and Cat, 3rd Edition

for 4 weeks postweaning followed by diarrhea for 4 days and eventual shock. Fluid and antimicrobial therapy was only temporarily beneficial. Continuous mats of enterococci were adherent to the brush border epithelium of the small intestine of this kitten at necropsy. Similar bacteria were located in the hepatobiliary and pancreatic duct systems associated with suppurative inflammation in the periductal regions of the liver and pancreas. A

10.5-year-old Himalayan queen had intermittent vomiting and diarrhea for 7 days.⁶⁴ Continuous mats of bacterial cocci were adherent to the brush border epithelium; the bacterium was identified as *E. faecium*.

35.3 *RHODOCOCCUS EQUI* INFECTION

Craig E. Greene

Rhodococcus equi (previously *Corynebacterium equi*) is a soilborne, pleomorphic, gram-positive bacillus that has been primarily associated with suppurative infections in domestic livestock, especially foals. It is acquired by inhalation from soil, inoculation into a wound or mucous membrane, or ingestion. Reports of infections in cats are rare but increasing and probably associated with immunosuppressive illness such as that caused by retrovirus infection. Cats with *R. equi* infection should be examined for predisposing immunocompromising viral infections. Although isolates of the organism have been made from dogs, they have generally been clinically healthy, and the prevalence of infection is rare. Disseminated infection and death was reported in one dog.¹⁹

R. equi commonly produces purulent pneumonia in foals, suppurative lymphadenitis in pigs, and granulomatous lymphadenitis in cows. *R. equi* has also been isolated from lesions in dogs, but isolation from abscesses in cats have been most commonly reported. It is increasing in prominence in human beings because immunocompromised people, particularly those infected with the human immunodeficiency virus (HIV), have been affected. Pulmonary lobar infiltration with cavitation, similar to that observed with tuberculosis, has been the most frequently observed syndrome in patients with the acquired immunodeficiency syndrome (AIDS).^{146,155} *R. equi*, a saprophyte, is commonly recovered from soil that has herbivore manure and from feces of herbivores. The organism may enter the body through a penetrating wound contaminated by the environment and subsequently spread via lymphatics to regional lymph nodes and via the blood to the liver, spleen, and visceral lymph nodes. It is also commonly inhaled in dust. *R. equi* is a facultative intracellular parasite that invades lymphatic tissues and macrophages, resulting in granulomatous inflammation. Underlying immunosuppression is usually thought to be responsible for this hematogenous dissemination. The organism has virulent properties, which interfere with phagolysosomal fusion. In horses, *R. equi* virulence has been related to a plasmid that encodes a virulence protein, VapA, which allows its persistence in macrophages. This protein has not been consistently identified in human or other animal infections.^{19,144,145} In nonequine species, immunodeficiency in the host likely allows less virulent strains to persist intracellularly.

Pyogranulomatous lesions are the characteristic finding, and most cats have had primary involvement of an extremity.⁴⁶ Localized swelling with ulcerations or fistulas and purulent drainage have been found. Unlike typical bite wound abscesses, the lesions are generally not painful, and systemic signs of fever and anorexia are usually absent. Pyothorax from mediastinal lymphadenitis is manifest by anorexia, weight loss, and dyspnea. Abdominal distention with a palpable fluid wave, hepatomegaly, and mesenteric lymphadenomegaly may be found with dissemination.

In the one infected dog, generalized hyperesthesia was present.¹⁹ Dissemination to many organs caused necrotizing pyogranulomatous hepatitis, osteomyelitis, and polymyositis. Osteolytic and osteoproliferative changes were seen in the bones via radiography. Gross findings included intramuscular swelling.

Infectious Diseases of the Dog and Cat, 3rd Edition

Hematologic abnormalities may consist of leukocytosis with a left shift. Gram staining of the purulent discharge shows large, pleomorphic, gram-positive bacilli, which may be found inside macrophages. Thoracic or abdominal effusions are typically exudates with high protein (>3.5 g/dl) and nucleated cell counts (>10,000 cells/ μ l); the majority of cells are lymphocytes or nondegenerate neutrophils. Organisms may not be apparent.

Peripheral abscesses often have many sinus tracts with purulent drainage. Lymph nodes may be enlarged and necrotic with a similar discharge on sectioning. Histologic examination reveals that the lesions have been pyogranulomatous or granulomatous with necrotic foci. Macrophages contain phagocytized gram-positive bacteria. Pyogranulomatous lesions containing bacteria may be observed in parenchymal organs such as the liver and lung in animals with disseminated disease. In the laboratory the organism grows readily in an aerobic environment and has distinctive colonial characteristics, but laboratories not familiar with horse isolates may fail to identify it correctly. Clinicians should communicate their suspicion to the laboratory to ensure that proper microbiologic techniques are used to enhance colony growth. Culture of tissue specimens following maceration appears to be superior to taking swabs of exudates or infected tissues for isolation of this intracellular bacterium.¹⁰⁹ Growth of the organism in culture is optimal at 30°C.

310

311

Table 35-7 Drug Therapy for *Rhodococcus equi* Infection in Cats

DRUG ^a	DOSE ^b (mg/kg)	ROUTE	INTERVAL (HOURS)	DURATION (DAYS)
Gentamicin	2	SC	12	5 ^c
Lincomycin	20	PO	12	7–10 ^c
Erythromycin	10	PO	8	14
Erythromycin	15	PO	12	14
Rifampin ^d	5	PO	12	14
Amoxicillin-clavulanate	12.5	PO	12	14–16

PO, By mouth; SC, subcutaneous.

a For additional information, see [Appendix 8](#).

b Dose per administration at specified interval.

c A second course of therapy may be used with a 1-week interval between courses.

d Rifampin should be used only in combination with another drug such as erythromycin.

Surgical removal of extremity lesions is only temporarily effective, and new lesions commonly develop even after limb amputation. Surgical drainage of abscesses is an essential adjunctive procedure. Antimicrobial susceptibility testing should always be performed because resistant strains have been identified. In general, in vitro susceptibility is greatest to erythromycin, rifampin, aminoglycosides, glycopeptides, and imipenem.¹⁶⁰ Premaflaxacin, an extended spectrum quinolone, has the greatest in vitro activity against *R. equi* compared with numerous other antimicrobials, including other quinolones.¹⁵ In cats, treatment with lincomycin and gentamicin has been most effective, and results with erythromycin have varied ([Table 35-7](#)). Cats treated with penicillin and streptomycin have responded poorly because the organism is not very susceptible to these drugs. Cats with disseminated lesions also respond poorly. Amoxicillin-clavulanate therapy has been effective in reducing the size of the lesions when it was used for a minimum of 14 to 16 days.⁴⁶ In people with pneumonia, only long-term treatment with erythromycin, combined with either rifampin or vancomycin, has been the effective chemotherapy.¹⁵⁵ As with treatment of other persistently intracellular organisms, combination treatment is superior. The standard, highly effective treatment in foals is prolonged oral administration of erythromycin and rifampin. This combination can be recommended for cats, although greater toxicity may occur. Infected cats have not been considered a source of

Infectious Diseases of the Dog and Cat, 3rd Edition

infection for people, who usually acquire the infection from environmental exposure. Nevertheless, infected cats with discharge could pose a theoretical risk to immunocompromised owners.

35.4 **CORYNEBACTERIUM INFECTIONS**

Craig E. Greene

Numerous seemingly nonpathogenic corynebacteria have been isolated as microflora of dogs and cats. Some have been reported as causing otic infections or UTIs.²⁴ *Corynebacterium ulcerans* has been isolated from nasal swabs from two cats with nasal discharge.¹⁴⁷ These isolates were found to contain the diphtheria toxin and may have been responsible for the clinical illness in these cats. Human infection with this organism is rare; however, it may result in similar respiratory signs. Consumption of raw milk or its unpasteurized products or close association with horses or cows is often a source of infection for people.

35.5 **LISTERIOSIS**

Craig E. Greene

Listeria monocytogenes is a pathogenic, β -hemolytic, gram-positive, rod-shape facultative anaerobe that is morphologically indistinguishable from diphtheroids and may be mistaken for a contaminant in tissues. It is capable of growing in a wide range of temperatures, including refrigerator temperatures (4°C to 10°C). Although at least 16 serotypes of the organism exist, most infections are caused by only a few serotypes. As a ubiquitous saprophyte, *L. monocytogenes* can be isolated from soil, water, sewage, dust, and decaying vegetation. Commonly, it can be found in farm animal feed and silage and in food products made from these animals. A study of fecal specimens from animals in Japan found a prevalence of 0.9% in dogs, but no bacteria were isolated from cats.⁶⁷

L. monocytogenes differs from nonpathogenic species in that it possesses a hemolytic toxin, a factor that has been implicated in its virulence. This species is also able to persist as a facultative intracellular organism indefinitely in macrophages and to escape humoral immune responses. A cell surface protein, internalin, interacts with epithelial cells inducing phagocytosis. Once in the cell, listeriolysin O, along with phospholipases, enables the bacterium to escape host cell killing via phagosomes. In the cytoplasm the organism pushes pseudopod-like projections outward, which are ingested by adjacent macrophages, enterocytes, or hepatocytes. Thus the organism can move among cells in a new way without being exposed to antibodies. Host immunity is extremely important in the development of illness. Exposure via ingestion is common, but the disease is rare. Cell-mediated immunity (CMI) appears to be an important factor in preventing the intracellular persistence of the organism and in the development of clinical listeriosis. Coinfection with canine distemper virus has been reported as an immunosuppressive factor in disseminated listeriosis in a raccoon dog (*Nyctereutes procyonoides*).⁴

Natural infection usually results from ingestion of contaminated food; damage to the intestinal mucosal integrity is not necessary. More than one billion organisms are needed to infect healthy mammals. Alkalinization of the stomach by antacids may promote infection. Foodborne epidemics are associated with ingestion of contaminated feed or silage by domestic herbivores or of contaminated meat and dairy products by people. *Listeria* infection in dogs and cats is uncommon; when it occurs, it is usually associated with ingestion of contaminated meat or meat by-products. Exposure in itself does not always produce disease. The incubation period in people ranges from 11 to 70 days. Reports of septicemic listeriosis in dogs and cats after oral ingestion of contaminated food have been rare. Pathogenic strains of *L. monocytogenes* can be recovered from the GI tracts of asymptomatic animals. After penetration of the intestinal mucosa, *L. monocytogenes* produces a bloodborne bacteremia, localization in

Infectious Diseases of the Dog and Cat, 3rd Edition

mononuclear phagocyte tissues, and septic embolization of many organs, including the CNS. The organism has a predilection for localizing in the CNS and placenta.

Clinical signs are caused by the degree of intestinal inflammation and the sites of embolic microabscess formation. Fever, diarrhea, and vomiting have been most frequent. Neurologic signs have been apparent in some cases.

Abortion was suspected in one bitch.¹³⁶ Localized infections have also been infrequently reported.^{80a} Peritonitis was reported in one cat as a result of a plant awn migrating through the bowel into the peritoneal cavity.¹⁵² Another cat developed an abscess of the front paw 2 weeks after an insect bite at the same location.⁷⁷

Cytologic evaluation of bone marrow from one dog with septicemia had coccobacilli within macrophages and neutrophils.¹²³ In the case of CNS infection the organism may be recognized premortem with gram-stained sediment of CSF. Organisms appear as short, intracellular and extracellular gram-positive bacilli to coccobacilli. Diagnosis of infection is usually made at necropsy, because infected animals often succumb to the septicemia. Microabscess formations and focal necrotic lesions may be grossly or microscopically visible in many organs, especially the liver and spleen. Immunohistochemical staining of formalin-fixed, paraffin-embedded brain sections has been used to confirm infection.¹⁵⁹ In the absence of contaminating organisms, *L. monocytogenes* can grow and be identified within 36 hours on routine media at suitable incubation temperature. Laboratory cultivation of the organism from a nonsterile site is difficult unless special precautions are taken. Selective media and cold cultivation (4°C) have been used to isolate the organism, but weeks of cold enrichment are needed because of the slow growth at this temperature. Because the organism can be commonly isolated from the GI tract of asymptomatic animals, rectal cultures may not be meaningful. (See [Appendix 5](#) for a list of laboratories that perform the test for *Listeria* organisms.)

Antimicrobial agents effective against *Listeria* bacteria in vitro are penicillin and ampicillin, erythromycin, chloramphenicol, rifampin, tetracycline, trimethoprim-sulfonamide, and aminoglycosides. Trimethoprim-sulfonamide and aminoglycosides are bactericidal and recommended as the first choices for clinical use. Gentamicin and tobramycin have more activity than the other aminoglycosides. The combination of gentamicin and ampicillin is considered the most desirable therapy, although high doses or alternative, widely distributed drugs such as trimethoprim-sulfonamide and rifampin may be needed to reach the CNS or treat resistant infection. Chloramphenicol therapy has been associated with failure and relapse in treated people. Quinolones are ineffective.

Listeria infection in animals has not always been considered a public health risk because animals and people are exposed to the same source of environmental contamination. Nevertheless, an association has been made between human outbreaks and contact with food-producing animals or their products. Direct transmission from animals has occurred in veterinarians and farm workers through contact of unprotected skin or mucous membranes with infected animal tissues.⁹⁹ Most outbreaks occur in urban areas, where foodborne contamination is suspected. Infants, older adults, and pregnant women are most commonly affected. In a case of reverse zoonosis, listerial gastroenteritis was suspected in a litter of puppies and a newborn infant that received *Listeria*-infected milk discarded from the human mother's mammary gland.¹³⁸

35.6 ANTHRAX

George E. Moore

Craig E. Greene

Infectious Diseases of the Dog and Cat, 3rd Edition

35.6.1 Etiology

Anthrax, a disease found in mammals worldwide, is caused by *Bacillus anthracis*, a large (1 to 1.2 μm \times 3 to 6 μm), gram-positive, aerobic, spore-forming bacillus. The disease and species name is derived from the black, charcoal-appearing cutaneous lesion it causes in people. Microscopically the organisms may appear as long chains of gram-positive, square-ended bacteria, similar to a string of boxcars; shorter chains of two to three cells may be seen. Vegetative *B. anthracis* cells produce a polypeptide capsule visible when the organism is stained with methylene blue or Giemsa stains. Encapsulated anthrax organisms are refractory to phagocytosis, enhancing their ability to produce disease. Toxin production and capsule synthesis by the bacteria are mediated by plasmids designated pX01 and pX02, respectively.

B. anthracis begins to sporulate at the end of the growth phase in its life cycle, an adaptation crucial to the perpetuation of the organism in nature. Spores are not seen on direct staining of specimens; however, they appear in culture when nutrients are depleted. Atmospheric oxygen is considered necessary for sporulation because sporulation does not occur in the unopened carcass of an animal succumbing to anthrax. Anthrax spores are very resistant to heat, radiation, disinfectants, and desiccation, resulting in their persistence for more than 40 years in certain soils and environments.

35.6.2 Epidemiology

As mentioned, anthrax has a worldwide distribution. It has been sporadically reported in the United States, most commonly in the central and the Mississippi Delta regions. Warm temperatures ($>18^{\circ}\text{C}$, or 60°F), moisture, and alkaline soils with high nitrogen content allow vegetative growth and proliferation of spores that have been released into the soil from carcasses of animals that died of anthrax.⁵⁷ Epizootics tend to occur in summer or fall after heavy rainfall or flooding preceded by drought conditions. Livestock usually become infected by ingesting spores while grazing or by eating contaminated feed. Isolated infections in dogs have been recorded during major anthrax outbreaks in farm animals. Infections in captive canids and felids have also been recorded after feeding raw meat from contaminated carcasses; however, they are relatively resistant to inhalation anthrax.

Recent events in the United States have involved documented terrorist dissemination of anthrax spores to induce inhalation anthrax in humans.⁷⁵ Companion animals in urban environments, although at reduced risk from infection through contact with infected livestock, are presumed to be at greater risk for infection from terrorist acts.

35.6.3 Pathogenesis

Infection occurs after inert *B. anthracis* spores enter the host body by ingestion, by inhalation, or through a break in the skin. The incubation period is usually 3 to 7 days. Based on evidence from natural and experimental infections, dogs and cats are considered relatively resistant,²⁷ people have intermediate resistance, and ruminants and horses are most susceptible to infection. In experimentally infected dogs, lesions have been restricted to local foci in the lungs because the organisms are generally contained by fibrin and cellular infiltrations.⁵⁶

After spores contact the pulmonary alveoli, they are phagocytized by macrophages that migrate through the alveolar membrane and enter pulmonary lymphatics, eventually reaching hilar lymph nodes. At the point of entry in the GI mucosa, a primary focal hemorrhagic lesion is produced. Bacteria migrate to regional lymph

Infectious Diseases of the Dog and Cat, 3rd Edition

nodes and the spleen. Within host cells the spores quickly germinate into fully encapsulated vegetative cells that release toxins. Vegetative cells respond to the host factors of high body temperature and carbon dioxide levels, resulting in transcriptional activation of capsule and toxin genes. The capsule is thought to be an antiphagocytic factor, and the toxin induces large-scale generation of cytokines such as interleukin (IL)-1 that result in septic shock.⁹³ Multiplication of the bacteria results in intoxication and death of the phagocytes, resulting in a continuous bacterial release into the blood. Additional replication of bacilli in high numbers in the bloodstream intensifies the systemic manifestations.

Although most *Bacillus* species are nonpathogenic to animals and people, *B. anthracis*, through its pXO1 plasmid, produces three toxin proteins: protective antigen (PA), edema factor (EF), and lethal factor (LF). The three components are serologically distinct and cause no lesions when injected separately, but in binary combinations they produce edema toxin (PA and EF) and lethal toxin (PA and LF). Protective antigen mediates the entry of either EF or LF into the cytosol of host cells. EF is an adenylyl cyclase that inhibits TNF- α synthesis and impairs host defenses. LF, a metalloprotease, inhibits mitogen-activated protein kinases and induces macrophage lysis.

If not superseded by septicemia and death, the host response involves specific IgG antibodies against PA, with antibodies functioning to inhibit spore germination and stimulate phagocytosis by macrophages. Antibiotic therapy started after initial infection does not interfere with the immune response to *B. anthracis*.

35.6.4 Clinical Findings

Anthrax infections can be characterized by either the rate of disease progression (peracute, acute, or subacute/chronic) or the primary route of inoculation (inhalational, GI, or cutaneous). The two characterizations are somewhat parallel, but clinical signs are influenced by species susceptibility to anthrax. Various reports of anthrax in dogs and cats suggest that some animals may be exposed to but not develop infection or are asymptomatic during infection. Thus morbidity and mortality caused by anthrax in companion animal species are reduced but not necessarily eliminated.

Cutaneous anthrax, the most common manifestation in people worldwide, is rarely the primary clinical form in canids or felids. After entering a cut or abrasion in the skin, the organisms multiply and produce toxin. The cutaneous lesion appears first as a papule, progresses to a vesicle, ruptures, and develops into a black eschar secondary to focal necrosis. Although cutaneous infection usually resolves without medical treatment, antibiotics are recommended because cases may progress to systemic involvement and fatal septicemia.

Naturally occurring anthrax in free-roaming, captive, or domestic canids or felids is most commonly GI in origin and caused by ingestion of meat or hides from infected carcasses. After oral exposure, the infection in dogs and cats is usually manifest as fever (39.4°C to 40.5°C, or 103°F to 105°F); anorexia; and local inflammation, necrosis, and edema of tissues of the upper GI tract—the first tissues to contact the swallowed organism. Swelling of the head and neck tissues is usually apparent. Subsequent spread to the local and mesenteric lymph nodes, spleen, and liver typically occurs, causing enlargement. Acute gastroenteritis, which is often hemorrhagic, can occur, as may sudden death, particularly in younger animals. Signs in younger or immunocompromised dogs and cats may resemble systemic anthrax in more susceptible species, described as fulminating septicemia in which the principal lesions are edema, hemorrhage, and necrosis.

Experimental exposure of dogs to aerosolized anthrax spores did not reliably produce clinical disease other than short-term fever and anorexia in some dogs.⁵⁶ In more susceptible species with suspected natural inhalational exposures, clinical signs include fever, lethargy, cough, dyspnea, and septicemia.

Infectious Diseases of the Dog and Cat, 3rd Edition

35.6.5 Diagnosis

Pus or tissue specimens from animals suspected of infection should be stained with Gram's stain to show gram-positive bacilli (which have the "boxcar" appearance) and methylene blue to show the polypeptide capsule (which has the "string of pearls" appearance).

Serologic testing, using an ELISA to detect IgG to *B. anthracis* PA and capsular antigen in people, is highly sensitive; however, positive results are not completely specific for this type of anthrax.⁶³ A fourfold changing titer is needed to confirm active infection or recent exposure. Some people with prior exposure to herbivorous animals or their by-products have seropositive test results. Few other premortem tests are recommended. A skin test for diagnosis of anthrax in people was used in the former Soviet Union. This anthrax skin test, which detects heightened CMI against the organism, was usually positive after 3 days of illness in 97% of those affected.¹²⁵

Necropsy of affected carcasses is not advisable because sporulation occurs, releasing the resistant spores into the environment. Examination of the stained smears of blood from a peripheral vein or of fine-needle aspirates is the most effective and safest means of making a diagnosis.

Bacterial culture is used for confirmation of anthrax in specimens. The organisms can be isolated from samples on routine culture media if the materials are fresh. Colonies are gray-white to white and nonhemolytic. The isolates are nonmotile and have a capsule; they show catalase positivity, lysis by γ -bacteriophage, penicillin susceptibility, and endospore production. Prior treatment with antibiotics may reduce the ability to isolate the organism. Vegetative cells may be isolated from blood, sputum, CSF, eschar, and feces (if the animal had GI anthrax). In cases of suspected inhalation exposure, *B. anthracis* spores may be collected for culture using sterile-water moistened swabs taken from the nares and haired muzzle or face within 24 to 48 hours of exposure to aerosolized spores.⁶¹

Immunocytochemical direct fluorescent antibody examination of nasal swab smears, pleural fluid smears, or pulmonary biopsy specimens using antibodies to *B. anthracis* cell wall and capsule has been used to diagnose inhalation anthrax in people.³¹ If available, polymerase chain reaction (PCR) of sterile body fluids (blood or pleural effusion) can be helpful in rapidly confirming a diagnosis. Another means of specific identification is laboratory animal inoculation. Commercially available test strips (API Products, Plainview, N.Y.) can be used to aid identification.

Diagnostic pathology laboratories and shippers should always be alerted before receiving shipments of materials suspected of containing *B. anthracis*. Specimens or intact carcasses should be shipped using a biosecure procedure; they should be wrapped in plastic and kept refrigerated during transit. Public health authorities should also be notified when a diagnosis is suspected or confirmed in an animal.

313

314

35.6.6 Pathologic Findings

Carcasses of animals that have died of anthrax generally show little or no rigor mortis, and dark, nonclotting blood is usually seen oozing from the oral and nasal cavities and anus. The carcass often is bloated and decomposes rapidly. It is not advisable to necropsy or cut into such carcasses because exposure to air causes the vegetative organisms to form resistant spores that contaminate the environment. Blood or tissue samples for cytologic examination or culture can be obtained by taking blood from a large vein or through percutaneous aspiration. Should necropsy be inadvertently performed on an infected animal, characteristic lesions will be

Infectious Diseases of the Dog and Cat, 3rd Edition

observed. GI anthrax has significant pathologic symptoms associated with the alimentary tract region where the ingested organisms penetrated the mucosal surface. Extensive gelatinous edema with focal areas of hemorrhage and necrosis are commonly seen and may be present around lymph nodes and in any area of the tract, from oral cavity to rectum. Diphtheritic membranes and ulcers may be present on the tonsillar surfaces. Gram-positive bacterial colonies may be present in the fibrinous exudates in the surface ulcerations of the GI mucosae. Extensive areas of necrosis in submucosal tissues are accompanied by neutrophilic infiltrates. Splenomegaly and a friable liver are often observed. Petechial hemorrhage secondary to septicemia may be noted on serosal surfaces. GI anthrax is typically also associated with extensive edema around and hemorrhage within pharyngeal and mesenteric lymph nodes.

Studies of inhalation anthrax symptoms in dogs describe discrete, dark, firm pulmonary lesions, consisting of a hemorrhagic core surrounded by dense masses of fibrin and a highly cellular periphery formed from dense accumulation of neutrophils, plasma cells, monocytes, and large macrophages.⁵⁶ This intense fibrinous and cellular local response has been interpreted as a restrictive reaction by the resistant canine host to contain the *B. anthracis* invasion (Fig. 35-6). Intrathoracic lymph nodes were commonly enlarged because of reactive hyperplasia, but bacilli were not observed during histologic examination. In people, lymph node enlargement causes mediastinal widening, a pathognomonic radiographic sign in the diagnosis of inhalation anthrax. Mild pulmonary infiltrates and pleural effusion may also be detected radiographically.

Diagnosis of anthrax can be confirmed in pathologic specimens by specific immunohistochemical staining with an antibody conjugate that specifically identifies the galactose-N-acetyl-D-glucosamine polysaccharide unique

Infectious Diseases of the Dog and Cat, 3rd Edition

to *B. anthracis*.⁹⁸ Electron microscopy with specific immunogold labeling of the vegetative organisms can also be used. Cultivation of the organism (as described previously) can be performed on tissue specimens

35.6.7 Therapy

Information regarding the recommended treatment of dogs or cats with suspected or confirmed clinical anthrax is extrapolated from literature reports of other species. *B. anthracis* is susceptible to a wide range of antimicrobials, including penicillin (which is historically the treatment of choice), ciprofloxacin/enrofloxacin, and tetracyclines (Table 35-8; see also Appendix 8, Drug Formulary). Other antimicrobials showing in vitro efficacy but that have not been clinically evaluated are chloramphenicol, erythromycin, aminoglycosides, and sulfonamides. Because of bacterial production of a cephalosporinase, *B. anthracis* isolates are typically resistant to cephalosporin antibiotics; potentiated sulfonamides are also ineffective. Initial doses of antimicrobials should be administered IV because of the potential rapid development of bacteremia and septicemia in infections. IV penicillin G is the drug of choice for people with bacteremia and should be used in dogs and cats. Although tissue cultures become negative within 24 hours after treatment is started, antibiotics are usually administered for 7 to 14 days. Postexposure prophylaxis protocols for people recommend at least 60 days of antibiotic administration because of concerns about environmental and pulmonary spore persistence.¹⁷ Amoxicillin or ampicillin may be substituted when the treatment course is prolonged or pregnancy or lactation are contraindications for the preferred drugs.

Additional supportive care as needed is also indicated. Animals with respiratory compromise from cervical edema may need treatment with glucocorticoids or tracheostomy. Pleural effusion may require drainage. Skin or superficial lesions should never be surgically removed. Dressings with drainage from lesions should be incinerated, autoclaved, or disposed of as biohazardous waste. A dog or cat with suspected coat or skin exposure to anthrax aerosol should be immediately decontaminated by a soap and water rinse. A 0.5% sodium hypochlorite solution inactivates or kills the anthrax spores but is too caustic for prolonged use on skin. This solution should be reserved for gross decontamination only and rinsed after a few minutes.

35.6.8 Prevention

In endemic areas or during an outbreak, all meat fed to dogs and cats should be thoroughly cooked to eliminate the risk of exposure. Livestock at risk should receive annual vaccinations. Livestock or human anthrax vaccines currently marketed have not been tested in companion animals nor are they licensed or recommended for use. Animal vaccines approved for large animals commonly use an avirulent nonencapsulated (pXO2-deficient) spore strain, which was discovered by Sterne in 1939.¹⁶⁴ Two subcutaneously (SC) administered doses 2 to 3 weeks apart are recommended, as are annual boosters for animals in anthrax-endemic areas. Localized vaccine reactions, presumably caused by the adjuvant, are occasionally reported. In contrast, a U.S.-licensed anthrax vaccine for people is a cell-free filtrate containing protective antigen and alum. Six SC injections (at 0, 2, and 4 weeks and 6, 12, and 18 months) are required for immunity, and annual booster injections are recommended for maintenance. Local and systemic reactions have been reported with this vaccine.¹⁴⁹ Inflammatory reactions to the vaccine have been more common in women. An attenuated live vaccine for people, which was developed in the former Soviet Union, has been effective; however, it is not available in other countries.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 35-8 Antibiotic Treatment for Anthrax Exposure or Clinical Anthrax in Dogs and Cats

DRUG ^a	SPECIES	DOSE ^b	ROUTE	INTERVAL (HOURS)	DURATION ^c (DAYS)
Penicillin	B	20–40 × 10 ³ U/kg	IV	8	prn
Doxycycline	D	5 mg/kg	PO	12	60
	C	50 or 100 mg per cat	PO	12	60
Amoxicillin	B	11–22 mg/kg	PO	8	60
Ciprofloxacin	D	10–15 mg/kg	PO	12	60
Enrofloxacin	D	2.5–10 mg/kg	IV, PO	24	60
	C	2.5–5 mg/kg	PO	24	60

B, Both dog and cat; D, dog; C, cat; IV, intravenous, PO, by mouth; prn, as needed.

a For additional information on each drug, see [Appendix 8](#).

b Dose per administration at specified interval.

c Because of the persistence of the organism in the environment, a long treatment interval is recommended to prevent exposure or reinfection during an outbreak. IV treatment is used only initially in the course of treating acutely ill animals to control manifestations of bacteremia.

35.6.9 Public Health Considerations

Anthrax is a natural disease of herbivores, and people, dogs, and cats are incidentally infected. Anthrax is a notifiable disease and should be reported to state and federal agencies. Care must be taken when handling infected tissues or carcasses, because the organism can penetrate cuts in the skin, resulting in localized infection with subsequent dissemination. In developed countries, most of the naturally occurring cases in people are cutaneous in origin. Lesions are painless, pruritic papules, sometimes surrounded by vesicles, with an ulcerated, circular, black necrotic scab. Although less common, inhalation or ingestion can result in either a highly fatal septicemia caused by hemorrhagic pneumonitis or an oropharyngitis and gastroenteritis, respectively. Anthrax has been developed as a biologic warfare agent by Japan, the United Kingdom, the United States, Iraq, and the former Soviet Union. One millionth of a gram of inhaled anthrax spores is a lethal dose to a person. Apart from terrorist events, infection in people is almost always transmitted from infected animals or their by-products. To minimize environmental contamination by anthrax spores, carcasses of animals dying from anthrax should be destroyed by incineration or buried deep with a covering of quicklime (anhydrous calcium oxide). Personnel who are cleaning up after an outbreak or terrorist attack that kills livestock and contaminates or injures more resistant dogs and cats should wear protective clothing and respirators. Decontamination involves a sporocidal solution of lye because ordinary disinfectants are ineffective (5% NaOH for 1.5 hours at 27.8° C or 3.6 hours at 21.1° C kills 99% of spores).¹⁶⁵ In the laboratory, surfaces can be decontaminated with either 5% hypochlorite or 5% phenol (carbolic acid). Instruments used should be autoclaved or boiled at 100°C for 10 minutes.¹⁶⁵ All areas, equipment, and buildings that may have contacted infected animals should be cleaned and disinfected. Control of flying insects and scavenging insects and animals should be implemented. (For additional information on decontaminating the environment for *B. anthracis*, see [Chapter 94](#).)

35.7 ERYSIPELOTHRIX INFECTIONS

Craig E. Greene

Infectious Diseases of the Dog and Cat, 3rd Edition

Erysipelothrix rhusiopathiae (*insidiosa*) and *Erysipelothrix tonsillarum* are small gram-positive nonmotile, nonsporulating pleomorphic facultatively anaerobic rods. These organisms, which are found worldwide, are associated with swine production. *E. rhusiopathiae* is the causative agent of swine erysipelas and other diseases in animals such as joint-ill in sheep and cattle and septicemia in turkeys, ducks, and laboratory mice. The anaerobes can be cultured from the tonsils of clinically healthy swine, the skin of freshwater and saltwater fish, and the decomposing plant and animal matter in their environments. Occupational exposure to these sources of bacteria may cause localized cutaneous or systemic infections in people.

Initially, the genus *Erysipelothrix* was thought to have a single species—*rhusiopathiae*—but biochemical and genetic analyses have identified *E. tonsillarum*, a nonpathogenic commensal of the tonsils of swine.¹⁴¹ In dogs, endocarditis and septicemia were initially thought to be caused by *E. rhusiopathiae* after natural⁶⁵ and experimental⁵⁸ inoculation. However, all available isolates from endocarditis reported in dogs have been now reclassified as serovar 7 of *E. tonsillarum* and have been nonpathogenic for swine.^{80,141} DNA hybridization studies have confirmed this relationship.¹⁴² Clinical signs of fever, shifting-leg lameness, and recent onset heart murmur are characteristic of infected dogs.

The isolated strains have been susceptible to penicillin and ampicillin in vitro but resistant to aminoglycosides and sulfonamides.¹⁴¹ Most cases of *Erysipelothrix* bacteremia are associated with endocarditis, therefore high doses of antimicrobials are recommended for at least 6 to 8 weeks. Relapses and reinfection are common in infected animals and people. Most human infections are acquired through occupational exposure; infections are found in slaughterhouse workers, food handlers, and animal trappers.⁹⁹ Infected dogs do not seem to pose a public health hazard.

Infectious Diseases of the Dog and Cat, 3rd Edition

³⁶CHAPTER 36 Staphylococcal Infections

Hollis Utah Cox

36.1 ETIOLOGY

Staphylococci are facultatively anaerobic, gram-positive cocci. Their principal habitats are the skin and mucous membranes of mammals and birds.⁷⁰ Staphylococci are classified into over 36 species (nine of which contain subspecies) based on genotypic differences and consideration of habitat or pathogenic processes.^{55,70} Co-evolution of animal hosts and their species of *Staphylococcus* has occurred.^{1,12,70,120} Although geographic differences between the distribution of *Staphylococcus* species in apparently similar human populations have been demonstrated, studies comparing dog and cat populations have not been reported.⁷⁰ All species of staphylococci isolated from normal animals are potentially pathogenic. However, individual species display a wide spectrum of virulence, host preference, and site specificity; and relatively few species are commonly isolated from infections of dogs and cats.* Host-adapted species may transiently colonize another host species when contact between hosts is frequent or infections are present. Staphylococci are readily acquired from environments (e.g., fomites, soil, air, water) associated with animals and from a variety of animal products. Of the nonsporulating bacteria, staphylococci survive well in the environment because they are among the more resistant bacteria to drying and disinfection.

Staphylococci are not inherently invasive and can colonize the intact epithelium of healthy animals without causing disease. In this sense, normal animals are subclinical carriers of both transient and resident colonizing staphylococci. Rather, as opportunistic pathogens, staphylococci invade epithelium damaged by traumatic insult (e.g., incisions, wounds), other infections (e.g., demodicosis, dermatophytosis), or clinical conditions (e.g., seborrhea, thyroid dysfunction, immunosuppression).⁸ Disease therefore results from a disturbance in the natural host-parasite balance. The typical feature of staphylococcal disease is abscess formation because leukocytes are the primary host defense mechanism against these bacteria.

Knowledge of the pathogenesis of staphylococcal infections remains limited. In general, the obvious associations between disease and the genetic profile of individual strains have not been shown.⁸ Although many underlying causes are known to predispose animals to canine pyoderma, the specific host defect that allows staphylococci to proliferate and the bacterial factors that contribute to lesion development and tissue damage are not known.

Virulence is often equated with the presence of specific cell envelope components and extracellular toxins and enzymes that potentially produce a wide variety of biologic effects on the host after tissue invasion. None of these virulence factors alone has been consistently implicated in clinical infections, although intradermal injections of staphylococcal extracts and protein A produce epidermal lesions and histologic changes similar to those observed in clinical cases of canine superficial pyoderma and pustular dermatitis.⁶⁴ However, little genetic diversity is found between isolates of *S. intermedius* from diseased and healthy dogs.⁸ Attempts to determine whether subpopulations of virulent and nonvirulent staphylococci reside on dogs are inconclusive. Staphylococci can produce various exotoxins that modulate the host immune systems.^{45,59a} In people, exotoxins produced by certain strains of *S. aureus* and group A streptococci act as superantigens by bypassing phagocytes with direct activation of V5B receptors on large numbers of T cells, causing massive cytokine release, which can result in necrotic lesions and systemic toxicity (toxic shock). Because superantigens work directly on cytokine release, this reaction can occur even in severely immunosuppressed animals.²⁹ The exotoxin production, which exists for *S. intermedius*

317

Infectious Diseases of the Dog and Cat, 3rd Edition

isolated from dogs, does not contribute to pruritus or recurrence of pyoderma^{19,25,45} but may contribute to cellulitis and toxic shock syndrome. Based on analysis of digests of DNA after restriction endonuclease treatment, *S. intermedius* isolates from canine pyoderma differ from *S. intermedius* isolates from normal dogs but do not differ in recognized virulence factors or exoproteins.³ If dogs are colonized by more than one strain of *S. intermedius*, apparently the recognized toxins are not important virulence markers, and an as yet unrecognized factor may be involved.³ Genetic constructs encoding staphylococcal enterotoxins have been used as immunogene therapy for neoplasia in dogs.¹¹⁶ Staphylococcal extracts have also been used for a variety of immunotherapeutic purposes in dogs and cats (see Immunomodulators, [Chapter 2](#)).

Coagulase, an enzyme present in most clinically significant staphylococci, polymerizes fibrinogen and clots plasma. Although coagulase is not toxic itself, its presence in a strain correlates with the presence of the other recognized virulence factors or extracellular products. *S. aureus*, *S. intermedius*, and three other species often produce coagulase and are generally more pathogenic relative to species that do not. Coagulase-negative staphylococci are also constituents of the normal microflora and capable of producing infections in hosts that are immunosuppressed or following invasive procedures. Protein A, an extracellular or a cell-bound protein produced by some canine and feline strains of *S. intermedius*, may enhance virulence by activating complement and by nonspecifically binding to immunoglobulins. These and other biologic effects may provoke various inflammatory and allergic responses, particularly delayed hypersensitivity, which intensify the pyogenic process and heighten the damage produced by staphylococcal infections. Some of these responses may be related to the high concentrations of circulating immune complexes that are found in dogs with recurrent pyoderma and pyoderma secondary to generalized demodicosis.^{27,67} Complex polysaccharide capsules and slime layers (glycocalyx) produced by many strains of staphylococci may also enhance virulence by promoting bacterial adherence, inhibiting host phagocytosis, and resisting antibacterial drugs. Increased bacterial adherence may explain why certain breeds (German shepherd, English bulldog, and bull terrier) are predisposed to developing severe, often deep and recurrent, pyoderma.^{33,66} Staphylococci are able to adhere to biomaterials used as surgical implants resulting in common infections.⁷ Survival of *S. epidermidis* inside macrophages has been an important factor involved in infections associated with surgical implants. Administration of interferon (IFN)- γ to mice protected them against biomaterial-associated infection.¹⁵ In endocarditis, causative staphylococci have been shown to produce bacterial factors such as adhesins and toxins that allow their cellular invasion and attachment to the endocardial surfaces.⁴⁶ Acetylsalicylic acid has been used in vitro and in experimental models to reduce vegetative growth and attenuate the progression of *S. aureus*-induced valvular lesions.^{58,69} *S. intermedius* isolates from dogs, cats, people, and other animals, in contrast to coagulase-negative staphylococci from these same hosts, contain some enterotoxin genes and produce enterotoxins in vitro.⁹

Transmissible plasmids are common in human strains of *S. aureus*. They may carry genes for virulence factors and for antimicrobial resistance to penicillin, ampicillin, amoxicillin, lincomycin, erythromycin, tetracycline, chloramphenicol, cephalosporin, kanamycin, and gentamicin. Other staphylococcal species infrequently carry similar plasmids, and most antibiotic resistance resides in chromosomal genes.^{41,71,101} However, the potential exists for transfer of virulence and antimicrobial resistance genes from human strains of *S. aureus* to animal strains of staphylococci. The antimicrobial susceptibility patterns of clinically important isolates of staphylococci from dogs and cats have not changed considerably.^{*} Although not common, multiresistant staphylococci are sometimes isolated from dogs with deep pyoderma or a history of antibiotic therapy.⁵³ Nosocomial transfer is known to modify the staphylococcal flora because nasal carrier rates for coagulase-positive staphylococci increase considerably with prolonged hospitalization of humans and dogs.

Infectious Diseases of the Dog and Cat, 3rd Edition

The predominant staphylococcal species of the resident bacterial microflora of dogs is *S. intermedius*. Specific biotypes have been persistently isolated in temporal studies from the hair coat and mucous membranes of individual dogs. However, the subpopulations at these two sites cannot be differentiated on the basis of antibiotic or phage susceptibility profiles, ribotyping, or other techniques. Random amplified polymeric DNA–polymerase chain reaction (PCR) analysis has been the best method used to identify different genotypes in dogs and other host species.^{96,120} Although agreement as to the natural anatomic habitat for *S. intermedius* is still debated, cultural studies have clarified the situation. Puppies acquire *S. intermedius* from the dam within 8 hours after birth.^{4,95} The oral and nasal mucosae are the most frequently colonized sites, followed by abdominal skin. The level of colonization of the dam influences the level of colonization of pups.⁹⁵ Although many different genotypes are transferred to the pups, only one or two predominate and persist.⁹⁶ In adult dogs, large populations of several species of staphylococci reside at moist sites such as the nasal, anal, and oral mucosae and in rather occluded areas of the interdigital spaces and the ear canal.^{4,21,43} The staphylococcus of the genital mucosae of breeding bitches following parturition is almost exclusively *S. intermedius*.^{4,13} Lesser populations found at the skin surface and the distal hair coat probably indicate contamination or transient colonization rather than true resident status.^{4,92} Because staphylococci can survive in inhospitable areas that are drier, more salty, and less humid, they are able to displace less tolerant species.²¹ Other studies have suggested the possibility of a resident population within the pilosebaceous units from which secondary surface colonization can occur. The staphylococci on the distal hair shaft are contaminants whose origin is the resident population on the mucosae.⁴³ A temporal study compared the carriage of *S. intermedius* on normal dogs with that of atopic dogs in clinical remission and concluded that atopic lesions had become secondarily colonized from mucous membrane sites (nares, oral cavity, and anus).⁹² When secondary staphylococcal infections were resolved, significant differences in isolation of *S. intermedius* at any single site of the two groups of dogs was not evident. Dogs with pyoderma had significantly denser populations of *S. intermedius* at mucosal sites than did healthy household pets, a further indication that mucosal sites are the source for skin contamination. Results from one study indicated that nasal carriage was dependent on skin colonization.⁴⁴ However, when mucosal populations of *S. intermedius* were decreased by application of fusidic acid to mucosal surfaces, *S. intermedius* at nontreated skin sites was significantly reduced, further illustrating that mucosal carriage serves as the significant reservoir of infection in the dog.⁹¹

317

318

The coagulase-negative species *S. scirui* is widespread in nature and has been isolated from mucous membranes (anterior nares and mouth) and from the haired skin of dogs.¹¹⁰ *S. epidermidis*, a coagulase-negative commensal of the skin and mucous membranes, was isolated from a dog with diskospondylitis.² This disease is most commonly caused by *S. intermedius* (see [Chapter 86](#)). Coagulase-negative *S. schleiferi* subsp. *schleiferi* and coagulase-positive *S. schleiferi* subsp. *coagulans* have been isolated from the skin of dogs with recurrent pyoderma.³⁴

The predominant resident staphylococcal species of cats are *S. felis* and *S. xylosus*.⁵⁴ *S. intermedius* and *S. aureus* are isolated primarily from the hair coat of household cats and rarely from mucous membranes or from cats confined in a cattery. Apparently, they are transient residents acquired from contact with people or other animals. Coagulase-negative species are generally considered nonpathogenic commensals, and only a few isolations from pathologic lesions have been made. *S. felis* was isolated from cutaneous lesions of cats with otitis externa, paronychia, and excoriated skin lesions.⁷⁹ *S. auricularis* was isolated in combination with anaerobic bacteria in an inner ear infection in a cat.²³ In general, a less heterogeneous population of staphylococci is associated with cattery cats when compared with household cats or dogs.

* References: 3, 40, 43, 44, 48, 49, 74.

36.2 CLINICAL FINDINGS

Coagulase-positive staphylococci are most frequently isolated from pyogenic infections of dogs and, less commonly, cats. As significant pathogens, they can affect every organ system independently or concurrently but are most common in abscesses and infections of the skin, eyes, ears, respiratory and genitourinary tracts, skeleton, and joints. In dogs, *S. intermedius* is the most common staphylococcal species isolated from pyoderma, otitis externa, diskospondylitis, bacteremia, conjunctivitis, and urolithiasis. Staphylococci are also found in valvular endocarditis and pericarditis.^{86,109}

Other syndromes have been associated with staphylococcal infections in dogs. Botryomycosis, a poorly understood lesion caused by staphylococci and resembling mycetoma or actinomycosis, was found as an intraabdominal mass in a dog.¹⁰⁴ As with toxigenic streptococci (see [Chapter 35](#)), staphylococci have also been associated with skin scald, toxic shock, and necrotizing fascitis.³⁷ Staphylococci were associated with an unusual cutaneous reaction, similar to psoriasiform-lichenoid dermatitis in people, that developed after topical treatment with cyclosporine A.¹²² Staphylococci, unlike other potentially pathogenic microflora, are not usually associated with septicemia in neonatal pups.⁹⁷

The infection sites are similar for cats; however, *S. felis* is the most frequent (45%) species, whereas *S. aureus* (13%) and *S. intermedius* (10%) are less common.⁵⁴ Abscesses or inflammatory granulation tissue with eosinophilic infiltration has been attributed to infection of cats with methicillin-resistant staphylococci.⁷⁵ The most frequently associated location of the lesions were subcutaneous or lymph nodes of the neck, or in the abdominal cavity, with or without mesenteric lymph node involvement.

36.3 DIAGNOSIS

Staphylococcal infections can be diagnosed presumptively by direct microscopy. Staining of a clinical specimen with Gram's stain or rapid cytologic stain will reveal neutrophils and cocci arranged singly or in pairs, short chains, or, rarely, irregular clusters. For culture, collection methods other than swabbing should be used whenever possible and should be designed to avoid superficial contamination. Surfaces of intact pustules, furuncles, or abscesses should be gently cleansed with alcohol, and the exudate directly aspirated or expressed onto a sterile swab without touching the skin (see Specimen Collection, [Chapter 33](#)). Punch biopsy procedures are suitable for both superficial and deep skin infections. Otic specimens are best obtained with a swab protected by a sterile otoscope cone inserted to the level of the horizontal ear canal. Before obtaining blood by venipuncture or urine by cystocentesis for culture, hair around the area should be shaved and the skin scrubbed as if for surgery. Respiratory tract specimens should be taken by transtracheal aspiration technique, bronchoscopic wash, or percutaneous transthoracic aspiration to bypass the oral flora. Specimens from deep-seated infections are often taken by direct biopsy or during surgery, such as aspirates or bone fragments curetted in cases of diskospondylitis.

Staphylococci in clinical specimens survive for up to 48 hours when kept cool (4°C [39.2°F]), particularly on commercial swabs containing a holding medium. Clinically significant staphylococci and normal flora contaminants grow best aerobically and may overgrow other pathogens when specimens are cultured on general-purpose, nonselective media.

Infectious Diseases of the Dog and Cat, 3rd Edition

Serologic assays, especially for antibodies reactive with teichoic acid or nucleases, are used as clinical aids in the diagnosis and management of bacteremia, endocarditis, and other deep-seated staphylococcal infections in people. However, the use and interpretation of results of these assays are controversial. Dogs with deep recurrent staphylococcal skin infections have high serum antistaphylococcal IgG levels compared with clinically unaffected dogs.^{67,105} Dogs with superficial pyoderma secondary to atopy had high IgE levels. Despite these findings, serotesting will not likely be adapted for clinical use in animal infections.⁵² High titers are more a reflection of bacterial hypersensitivity that perpetuates the inflammatory response.

36.4 THERAPY

Dosages for antimicrobials used to treat staphylococcal infections are listed in Table 36-1 and the Drug Formulary (see Appendix 8) and also under skin infections, Table 85-3. Staphylococci are rarely resistant (less than 5% of isolates) to first-generation cephalosporins (cephalexin, cefadroxil), β -lactamase-resistant synthetic penicillins (oxacillin, dicloxacillin, amoxicillin-clavulanate), gentamicin, tobramycin, enrofloxacin, mupirocin, bacitracin, and polymyxin B.⁷⁸ These drugs should be the drugs of first choice when culture and susceptibility results are unavailable and staphylococcal infection is suspected. Resistance to trimethoprim-sulfonamide combinations, chloramphenicol, and tylosin is relatively infrequent (6% to 19% of isolates).¹⁰² Resistance to lincomycin, clindamycin, and erythromycin is relatively frequent (20% to 37% of isolates). Clinical isolates of staphylococci from dogs and cats are most frequently resistant (40% to 83%) to penicillin, ampicillin, amoxicillin, neomycin, and tetracycline.^{57,60,72} Antimicrobials for which resistance is common should not be given for staphylococcal infections unless an isolate is shown to be susceptible by antimicrobial testing or by lack of β -lactamase production. Deep pyoderma or a history of antimicrobial therapy for staphylococcal infection indicates a need to culture regardless of the antimicrobial agent being considered for therapy.⁷¹ Increased resistance of *S. intermedius* to chloramphenicol, clindamycin, and erythromycin has been associated with previous unspecified antimicrobial therapy of canine pyoderma. *S. intermedius* has been observed to acquire its macrolide-aminoglycoside resistance genes by horizontal transfer.¹⁶ However, during a 1-year study in which dogs with recurrent folliculitis were treated with repeated courses of cephalexin, antimicrobial susceptibility patterns of *S. intermedius* from lesions and noninfected body sites were unchanged.²⁴ Canine isolates of *S. aureus* are more resistant to antibiotics than are *S. intermedius* isolates.⁵¹ Clindamycin has been shown to be efficacious in the treatment of canine pyoderma^{14,260} and experimentally induced *S. aureus* osteomyelitis in dogs.¹⁸ Increasing resistance has been observed with the quinolone antibiotics.⁵⁹

Table 36-1 Drug Therapy for Staphylococcal Infections in Dogs and Cats

DRUG ^a	SPECIES	DOSE ^b (mg/kg)	ROUTE	INTERVAL (HOURS)	DURATION (DAYS)
Amoxicillin-clavulanate	B	12.5–20	PO	8–12	prn
Oxacillin	B	22	PO	8	prn
Cephalexin or cefadroxil	B	22	PO	12	prn
Clindamycin	B	11	PO	24	14–42
Quinolones ^c	B	5	PO	24	prn
Erythromycin	D	10–15	PO	8	prn
Chloramphenicol	D	15–25	PO, IV, SC	8	prn
	C	10–15	PO, IV, SC	12	prn
Trimethoprim-sulfonamide	D	22	PO	12	prn

B, Dog and cat; D, dog; C, cat; PO, by mouth; prn, as needed; IV, intravenous; SC, subcutaneous.

- a For additional information on these drugs, see [Appendix 8](#).
- b Dose per administration at specified interval.
- c Includes marbofloxacin, danofloxacin, orbifloxacin, and enrofloxacin.

36.5 PUBLIC HEALTH CONSIDERATIONS

36.5.1 *S. aureus* Infections in Animals

People are the natural hosts for *S. aureus*, which colonizes the nasal passages of up to 40% of healthy adults and rarely other body sites in the absence of dermatoses. Although variants adapted to other hosts (ruminants, horses, and pigs) occur, *S. aureus* comprises less than 10% of clinical isolates from normal dogs and cats and apparently is not indigenous or site-specific in these hosts. Methicillin-resistant *S. aureus* (MRSA) is problematic as a cause of nosocomial infections and increasingly as a community-acquired, human pathogen. Staphylococcal resistance to methicillin has been attributed to multiple genetically controlled mechanisms. Most notable is their possession of a low-affinity penicillin-binding protein, PBP2a, which is encoded by an extra 30- to 50-kilobase chromosomal gene *mecA*. Nosocomial MRSA are considered resistant to all commonly used antibiotics, regardless of in vitro test results. This finding is justified based on the poor clinical response of MRSA to these antimicrobials. MRSA have been isolated from wound infections of a dog and cat in Japan,³¹ from three dogs and a horse in Ontario,⁷³ from dogs in Korea,⁷⁶ a postsurgical wound of a dog in the Netherlands,¹¹⁹ and from 11 canine infections associated with surgical treatment, especially orthopedic surgery, and recurrent pyoderma in Wisconsin, North Carolina, and London.¹¹⁷ In another report, identical strains of MRSA were isolated from two dog owners, one concurrently colonized and one infected the previous year following surgery.⁷³ Two other owners had been hospitalized or had frequent outpatient visits. The MRSA isolated from these four animals were indistinguishable from the major human clones found in Ontario. Human mupirocin- and MRSA-strains have been identified in the nasal passage of clinically healthy pet dogs and their human contacts in a household.^{29a,63,104a,108,119a} Clinical infection in the people was eliminated only after successful treatment of the organism in the dog.

These cases suggest an antroponotic source for MRSA isolated from animals. However, unlike nosocomial MRSA, canine infections caused by community-acquired MRSA respond favorably to oral antibiotics to which the isolates are susceptible in vitro and are usually resistant only to β -lactam antibiotics.¹¹⁷ In people, infections with MRSA have become a critical health complication. The emergence of community-acquired MRSA and the possible colonization of pets may become an increasing problem to monitor in the future. In multiresistant strain infections, newer peptides such as vancomycin and teicoplanin, and oxazolidones such as linezolid, are the only effective antimicrobials. For this reason, use of these drugs, which might induce resistant strains, should be restricted or avoided in pets (see also [Chapters 85](#) and [99](#)).

36.5.2 *S. intermedius* Infections in People

Staphylococci of dogs and cats are true zoonotic opportunistic pathogens. However, for many years, other than bite wound infections, zoonotic transmission of staphylococci of dogs and cats was thought to be uncommon. In early studies, only 1 of 144 veterinary hospital personnel had nasal colonization with *S. intermedius*.¹¹² In later reports, nosocomial transmission of *S. intermedius* in veterinary hospitals was considered to be rare.¹⁷ For additional on transmission of staphylococci between people and dogs and cats, see [Chapters 85](#) and [99](#).

Infectious Diseases of the Dog and Cat, 3rd Edition

Among the general pet-owning public, the transfer of *S. intermedius* from pets to people has become of concern. In past surveys, *S. intermedius* was rarely found in people, even among individuals with frequent animal exposure.¹¹¹ A study of hospitalized people identified only two *S. intermedius*-positive isolates among 3397 consecutive isolates of coagulase-positive staphylococci.⁶² A human case of pneumonia in a surgical patient was described as the first case of invasive methicillin-resistant *S. intermedius* (MRSI).³⁶ In another human case involving otitis externa, identical strains of *S. intermedius* were isolated from the patient and her dog.¹¹³ Mastoid cavity infection caused by *S. intermedius* developed in a person who had a dog that licked the owner's ears following mastoidectomy.⁵⁶ Bacterial strains from the dog's saliva and the otic discharge in the patient were genetically identical.

In a study of 13 individuals with dogs affected by deep pyoderma and 13 without daily contact with dogs, seven of the dog owners and only one of the nonowners carried multiple antimicrobial-resistant *S. intermedius*.⁴² In six of the dog owners, genetic analysis found identical strains in the dogs and their owner. Strains detected were resistant to up to five different antimicrobial groups, including penicillins, fusidic acid, macrolides and lincosamides, tetracyclines, and chloramphenicol. MRSI are infrequently isolated from animal infections; however, they have resistance patterns similar to community-acquired MRSA.* These data are alarming with regard to spread of animal staphylococci, or potential spread of transferable antimicrobial resistance genes to human pathogenic staphylococci. In multiresistant strain infections, newer peptides such as vancomycin and teicoplanin, and oxazolidones such as linezolid are the only antimicrobials that are effective. For this reason, use of these drugs, which might induce resistant strains, should be restricted or avoided in pets.

37 CHAPTER 37 Gram-Negative Bacterial Infections

Stephen A. Kruth

37.1 ETIOLOGY

Each gram-negative bacterial species has evolved a relatively complex outer membrane in addition to its cytoplasmic membrane and peptidoglycan layer. This outer membrane distinguishes the group from gram-positive bacteria and spirochetes. The outer surface of this membrane consists predominantly of a lipopolysaccharide (LPS, or endotoxin), which has a lipid portion embedded in the membrane (lipid A—the active component of endotoxin) and a polysaccharide portion extending from the bacterial surface (the O antigen; [Fig. 37-1](#)). In addition to conferring a gram-negative staining characteristic, these structures are important virulence factors and partially determine antibiotic susceptibility.

Gram-negative bacteria fall into numerous heterogeneous phylogenetic groups, and many can be pathogenic in dogs and cats. Some of these bacteria are discussed in other chapters: *Pasteurella* spp. (see [Chapters 52 and 53](#)), *Bordetella bronchiseptica* (see [Chapters 6 and 16](#)), and *Salmonella* spp. (see [Chapter 39](#)). This chapter focuses on the general characteristics of *Escherichia coli*, *Proteus* spp., *Klebsiella* spp., and *Pseudomonas* spp. infections. Information and references to other chapters are also provided for *Citrobacter* spp., *Acinetobacter baumannii*, *Providencia alcalifaciens*, *Serratia* spp., and *Enterobacter cloacae* infections.

37.1.1 Classification

E. coli, *Proteus* spp., and *Klebsiella* spp. are members of the family Enterobacteriaceae. They are non-spore-forming, non-acid-fast, facultative, anaerobic gram-negative rods that are natural inhabitants of the intestinal tract of mammals. The Enterobacteriaceae family has 28 genera, with more than 100 well-defined species. Important species include *E. coli*, *Proteus mirabilis*, *Proteus vulgaris*, and *Klebsiella pneumoniae*.

Pseudomonas spp. are ubiquitous, non-Enterobacteriaceae, gram-negative bacteria that are found in soil, water, decaying vegetation, and animals. The most important and ubiquitous pathogenic pseudomonad is

Pseudomonas aeruginosa. In Asia, Eastern Europe, and Africa, *Pseudomonas mallei* is the cause of equine glanders; dogs and cats can become infected from the horse reservoir (see [Chapter 46](#)). *Burkholderia* (formerly *Pseudomonas*) *pseudomallei* is a soil organism found in Asia, central Africa, and Australia. In dogs and cats, it can cause syndromes ranging from a benign pulmonary infection to a lethal systemic disease (see [Chapter 46](#)).

Infectious Diseases of the Dog and Cat, 3rd Edition

37.1.2 Antigenic Structure

An internationally recognized serologic classification scheme has been developed for the Enterobacteriaceae based on antigenic differences in highly variable bacterial surface molecules. The *serogroup* is determined by the *O* antigens—sugars on the most external part of LPS (Fig. 37-2). The *serotype* is determined by flagellar *H* antigens. Additionally, *K* antigens can be identified in strains with a capsule. The antigenic formula of the strain indicates the presence of specific antigens (e.g., 055:K5:H21). However, for most strains, only O and H antigens are determined. At least 170 different serogroups have been identified for *E. coli*, and some correlation has been found between serogroup and virulence (e.g., O157:H7 and hemolytic uremia syndrome in humans).

37.2 EPIDEMIOLOGY AND PATHOGENESIS

The bacteria are commonly isolated from normal epithelia and spontaneously arising clinical infections of several different organ systems of dogs and cats (Table 37-1). They can cause sepsis, nosocomial infections, and opportunistic infections in immunocompromised animals. Isolates can be endogenous or exogenous to the individual. These types of infections may be increasing in frequency because of the overuse of new antibiotics, invasive procedures, and immunosuppressive therapies.

321

	Bronchitis, pneumonia, pyothorax			
	Sepsis, including neonatal septicemia			
	Meningitis			
	Infection from IV catheters			

^a Tissue from which *E. coli*, *Klebsiella*, *Proteus*, or *Pseudomonas* or all of these bacteria can be cultured.

Infectious Diseases of the Dog and Cat, 3rd Edition

37.2.1 Virulence Factors

Some strains of *E. coli* are true pathogens; however, most *E. coli*, *Klebsiella*, *Proteus*, and *Pseudomonas* organisms are opportunistic pathogens. The pathogenicity of gram-negative bacteria depends on the presence of various virulence factors (e.g., adhesins, toxins, iron-acquisition systems, capsules) expressed by the organism. It is the set of virulence genes carried and expressed by the organism that confers pathogenicity rather than the genus or species designation. Examples of virulence factors follow.

The establishment of infection first depends on bacteria adhering to an epithelium. Adhesins are located on bacterial pili (or fimbriae), the slender external structures that facilitate attachment to host cells. Colonization factor antigen I (CFA-I) and colonization factor antigen II (CFA-II) are specific pilus adhesins-hemagglutinins that promote colonization by some enteropathogens. Another fimbrial antigen is the vir antigen, which is associated with sepsis in some species. Bacterial capsules are polysaccharides, which protect the outer membrane from the membrane attack complex of complement and also inhibit the attachment of phagocytic cells. Colonization with *Pseudomonas* spp. occurs when the fibronectin coat covering host cells is disrupted by infection or mechanical trauma. The pili and exozyme S of *Pseudomonas* spp. promote attachment to epithelial cells, and the extracellular slime is antiphagocytic. Siderophores, such as aerobactin, aid the bacterium in competing with the host for iron in low-iron environments.

The production of various toxins is important in the pathogenesis of gram-negative infections. Secreted α -hemolysin damages host cell membranes. Endotoxin (LPS) stimulates various cytokine cascades, as well as the complement cascade. Excessive activation of these systems leads to sepsis and septic shock (see [Chapter 38](#)). *Pseudomonas* spp. variably produce collagenase, lecithinase, lipase, proteases, hemolysins, fibrinolysin, leukocidin (also called *cytotoxin*), and enterotoxin. Many strains also secrete exotoxin A, a cytotoxin that causes tissue necrosis, allowing the organism to colonize deep tissues in burn and trauma cases. As with the Enterobacteriaceae, *Pseudomonas* LPS can act as an endotoxin.

37.2.2 Virulence Factors Associated with *E. coli* Intestinal Infections

The documentation of pathogenic *E. coli* infections is confusing because many of these organisms exist as normal enteric constituents and can be found in the microflora of clinically healthy animals. Analysis for specific toxin genes or molecular typing can be done to differentiate among the different isolates. Toxin analysis is important in addition to genetic studies because many of the genes identified may not be expressed by the organisms isolated. Pathogenic *E. coli* have been classified on the basis of their virulence properties into virotypes ([Table 37-2](#)). Virotypes usually contain more than one serotype. Virotypes are not clear-cut distinctions; some enteropathogens isolated from dogs have predominantly “uropathogenic” traits, but they cause diarrhea. Groups that have been described in dogs and cats based on phenotypic and genotypic factors are discussed in the following sections.

37.2.2.1 Systemic Infections

E. coli with particular pathogenic features are a frequent cause of extraintestinal and extraurinary tract infections. Such isolations include a report of *E. coli* endocarditis in a cat.²⁰ An outbreak of fatal hemorrhagic pneumonia and bacteremia in kennel dogs was attributed to a pathogenic *E. coli* that was positive for virulence factors α -hemolysin and cytotoxic necrotizing factor 1 and for the adhesin factor

Infectious Diseases of the Dog and Cat, 3rd Edition

class-III papG allele.⁴⁵ These organisms have the phenotypic and genotypic characteristics of extraintestinal virulent bacteria that are a risk for people and other animals.

37.2.2.2

Enteropathogenic *E. coli*

Enteropathogenic *E. coli* (EPEC) adhere to mucosal cells of the small intestine and colon, causing loss of microvilli (effacement, or attaching and effacing lesions) and the formation of filamentous actin pedestals or cuplike structures under the organisms. These changes in microvillous morphology are associated with an inflammatory response. EPEC also occasionally invade mucosal cells. Clinically, EPEC cause watery diarrhea as a result of host cell invasion and alteration of signal transduction systems rather than as a result of production of toxin.^{9,111}

Table 37-2 Characteristics of Pathogenic *Escherichia coli* Strains

CLASSIFICATION	GENES	PATHOGENIC FACTORS	CLINICAL FEATURES
Enteropathogenic <i>E. coli</i> (EPEC)			
Class I	Locus for enterocyte effacement (LEE) coding for adhesion, intimin, and Tir proteins	Attaching and effacing; adhere to Hep-2 cells	Loss of microvilli; watery and chronic diarrhea
Class II	Unknown	No adherence to Hep-2 cells	Unknown
Enterotoxigenic <i>E. coli</i> (ETEC)	Heat labile (LT) and heat stable (ST) toxin genes and Type 1 fimbria	Attachment factors; LTs and STs	No histologic mucosal changes with diarrhea; no fever; hypersecretion of water and electrolytes
Enterohemorrhagic <i>E. coli</i> (EHEC) and <i>E. coli</i> O157:H7	Two types of Shiga toxin or vero toxin (VT) genes; LEE; plasmid with hemolysin gene	LTs and STs; Shiga-like (VT) toxins; vascular damage to endothelium	Hemorrhagic colitis, diarrhea; hemolytic uremic syndrome
Necrotoxicogenic <i>E. coli</i> (NTEC)	Cytotoxic necrotizing factor (CNF) genes: CNF-1 chromosomal and CNF-2 plasmid	CNFs	Diarrhea, bacteremia, and urinary tract infections in people
Uropathogenic <i>E. coli</i> (UPEC) or extraintestinal <i>E. coli</i> (ExPEC)	papG gene, CNF1 gene, adhesin hemolysin and aerobactin genes	Adhere to uroepithelium via pili	Dysuria, hematuria, urinary tract inflammation; pneumonia, sepsis, meningitis
Enteragggregative <i>E. coli</i> (EAEC or EaggEC)	Adhesins (plasmid encoded fimbria); hemagglutinins	Adhere to intestinal epithelium via pili	Nonbloody, watery diarrhea with some inflammation
Enteroinvasive <i>E. coli</i> (EIEC)	Outer membrane proteins (plasmid encoded)	Invade epithelium	Hemorrhagic diarrhea with mucus and leukocytes (dysentery)

Infectious Diseases of the Dog and Cat, 3rd Edition

37.2.2.3 Enterotoxigenic *E. coli*

Enterotoxigenic *E. coli* (ETEC) adhere to small intestinal mucosal cells and produce diarrhea by elaborating toxins. Little inflammation and usually no histologic changes develop in mucosal tissues to which the bacteria are attached. Heat-labile toxins (LTs) and heat-stable toxins (STs) are well characterized. LTs (LT-I, LT-II) alter adenyl cyclase activity in epithelial cells of the small intestine. This results in inhibition of sodium and chloride absorption in villous epithelial cells and in active secretion of chloride by crypt cells, causing extensive loss of water and chloride. Data conflict about whether LT-producing *E. coli* have been isolated from dogs.^{9,25,43,78,111}

STs (STa, STb) are a family of small toxins, some forms of which deregulate guanylyl cyclase, with resultant fluid secretion similar to that induced by LTs. Other forms stimulate cyclic nucleotide-independent secretion. ST-secreting *E. coli* have been isolated from dogs and cats with enteritis, supporting a causal association.^{9,43}

323

37.2.2.4 Enterohemorrhagic *E. coli* and *E. coli* O157:H7

Enterohemorrhagic *E. coli* (EHEC) and *E. coli* O157:H7 bind tightly to epithelial cells and produce the same type of attachment-effacement lesions as EPEC. EHEC are minimally invasive but do incite an inflammatory response. They preferentially localize in the colon. EHEC produce verotoxins (VTs), which have two major antigenic forms (VT-I and VT-II). These toxins are sometimes called *Shiga toxins* (Stx 1 and Stx 2) or *Shiga-like toxins* (SLT). VTs inhibit protein synthesis by interfering with 28S rRNA, leading to damage of the vascular endothelium in target organs such as the kidney, gastrointestinal (GI) tract, and central nervous system (CNS). Within these bacteria, gammalike phages harbor the Stx genes. Chemical agents or drugs that damage DNA may activate dormant viral particles, allowing it to infect susceptible *E. coli* within the host and create new toxin-possessing bacteria.⁹⁴ Therefore although their use is widespread, antimicrobials such as quinolones might induce more virulent bacteria when they are used to treat virulent *E. coli* infections.

In people, EHEC infections have been associated with diarrhea, hemorrhagic colitis, and hemolytic-uremic syndrome (HUS). In almost all humans the toxin-producing organism has originated from the GI tract; however, one report includes a urinary source of infection.¹⁰⁴ EHEC have been isolated from stools of normal dogs and cats and those with diarrhea. A case-control study suggested that VT-II-positive isolates may be causally associated with diarrhea in dogs, whereas VT-I-positive isolates are carried but do not appear to cause diarrhea.⁹

In kenneled greyhounds, enterotoxin genes were identified in *E. coli* from dogs with and without diarrhea; however, only the presence of Shiga toxin Stx1 correlated with diarrhea (Staats et al, 2003). The presence of toxigenic *E. coli* in clinically healthy and diseased dogs indicated a potential zoonotic risk.

E. coli O157:H7 is an EHEC serotype responsible for foodborne and waterborne infection in people. It is harbored by cattle but does not cause them to develop any clinical illness. Undercooked beef and water contaminated by feces from infected animals or people are the most common source for spread. Large numbers of cattle tested at slaughterhouses harbor this bacterium; however, not all strains carry the virulence factors incriminated in severe disease. Dogs living on farms and feed lots have been documented as harboring *E. coli* O157:H7.^{44,58,94,109} The dogs were not clinically ill, and the organism was isolated from their feces. Infected cattle were considered the source of infection. Infection was also documented in a pet

324

Infectious Diseases of the Dog and Cat, 3rd Edition

dog that was fed food scraps⁸⁷ and in dogs frequenting beaches.²⁹ In all these reports the dogs were asymptomatic for infection, and the public health risk was of most concern.

Cats in Ontario, Canada were examined to determine the prevalence of verotoxigenic *E. coli* (VTEC) in feces related to the presence or absence of clinical disease.⁹⁸ Organisms were screened for VT genes by the polymerase chain reaction (PCR); the overall prevalence of enteric VTEC in 179 cats was 12.3%. However, no statistical association was found between the presence of the bacteria and clinical illness. Cats were positive for generic VT but not for VT-I or VT-II genes, suggesting that the VT may have been a new, nonpathogenic variety. Some of the isolated serotypes were similar to those found in people and cattle, suggesting that cats might be capable reservoirs for human infection.

37.2.2.5 Correlation of Pathogenic *E. coli* and Diarrhea

Samples of feces from clinically healthy dogs in kennels or households and in dogs with acute or chronic diarrhea were analyzed for various pathogenic *E. coli* including EPEC, ETEC, VTEC, EHEC, enteroinvasive (EIEC), and enteroaggregative (EAaggEC) strains.⁹³ More of the dogs with diarrhea were excreting EPEC and VTEC than the kennel or household control dogs. The EPEC attaching and effacing A (*eaeA*) gene and the verocytotoxin 1 (*VT1*) gene encoding for VTEC were often found together. Isolates from dogs with diarrhea had more aggregate and cytotoxic effects on cultured cells in vitro.

37.2.2.6 Hemolytic-Uremic Syndrome and Cutaneous and Renal Glomerular Vasculopathy of Greyhounds (“Alabama Rot” or “Greenetrack Disease”)

HUS in people is characterized by acute renal failure, microangiopathic hemolytic anemia, fever, and thrombocytopenia and is often associated with diarrhea or upper respiratory infection. One cause of HUS is infection with the VT-producing 0157:H7 serotype of *E. coli*, usually acquired through contaminated water or meat. VTs bind to vascular endothelial cells and induce necrosis, microthrombosis, and consumptive thrombocytopenia. A syndrome similar to HUS, characterized by hemorrhagic gastroenteritis, acute renal failure, and microangiopathic hemolytic anemia has been described in a small number of dogs; however, evidence of *E. coli* infection was not shown in these cases.⁵¹

Cutaneous and renal glomerular vasculopathy (CRGV) of greyhounds is an acute, potentially lethal syndrome of unproven etiology that was recognized in 1985.⁴⁷ CRGV typically occurs in young racing greyhounds but has also been described in a Great Dane.⁹² It is characterized by distinctive, slowly healing, sharply demarcated cutaneous ulcers involving the limbs but sparing the head and dorsum. Some affected dogs have no other signs and appear otherwise healthy. However, in addition to cutaneous lesions, some dogs develop fever, distal limb edema, and acute renal failure (with some dogs developing renal failure without fever or other systemic signs), whereas other dogs develop renal failure before the cutaneous lesions. Normocytic, normochromic anemia with evidence of microangiopathic hemolysis, thrombocytopenia, elevated alanine transferase and creatine kinase activities, hypoalbuminemia, azotemia, hematuria, proteinuria, and isosthenuria are variably present. Partial thromboplastin and one-stage thrombin times are usually normal, activated partial thromboplastin time can be prolonged, and fibrinogen degradation products are usually low. Treatment is supportive, and the mortality of dogs developing renal failure is high.

Histologically, the glomerular lesions are similar to those seen in the childhood form of HUS. It was common practice for racing and training greyhounds to be fed beef of 4D quality (i.e., diseased, debilitated, dying, or dead) from rendering plants. 0157:H7 has been isolated from this type of meat and recovered from

Infectious Diseases of the Dog and Cat, 3rd Edition

the stools of dogs with CRVG. Based on some clinical similarities (although children do not develop the cutaneous lesions), the histologic and ultrastructural glomerular abnormalities, and the association with O157:H7, it was hypothesized that CRGV is caused by VT-producing *E. coli*. The role of O157:H7 is not completely clear, because the oral or intravenous (IV) inoculation of adult greyhounds with high doses of the VT-producing O157:H7 does not cause CRGV. Age, genetics, concurrent infection, or other factors may be involved. Anecdotally, it appears that the prevalence of CRGV has diminished dramatically, possibly because of better feeding practices.^{26,88,92}

37.2.2.7

Necrotoxicogenic *E. coli*

Cytotoxic necrotizing factors (CNFs) are protein toxins that were originally called “vir toxin.” CNF1 and CNF2 have been associated with diarrhea, bacteremia, and urinary tract infections (UTIs) in people. *E. coli* producing CNF1 have been isolated from stools of normal dogs and cats, as well as dogs (but not cats) with enteritis.^{9,103} Serogroups of necrotoxicogenic *E. coli*-1 (NTEC)-1 strains have been the same as those that

324

infect people.²² NTEC may have been responsible for rhabdomyolysis in a cat with chronic renal failure and an episode of acute enteritis.⁶⁹

325

37.2.3

Uropathogenic *E. coli*

Some strains of *E. coli* can cause extraintestinal infections, including UTIs, pneumonia, sepsis, and meningitis; these strains are designated *extraintestinal pathogenic E. coli* (*ExPEC*), in keeping with the terminology used for strains causing enteritis. This classification has some overlap, and some *E. coli* isolated from dogs with diarrhea have characteristics of uropathogenic and necrotoxicogenic strains.¹⁰³ (See the previous Systemic Infections section for an additional discussion of *E. coli* causing infections outside the urinary and GI systems.)

E. coli is the most common isolate from dogs with first-time and recurrent UTIs and the second most common isolate from dogs with uroliths.^{63,77} Some strains of *E. coli* express virulence factors that facilitate the colonization of the urinary system; uropathogenic *E. coli* strains are designated *UPEC*. The major determinant of their pathogenicity is the ability to adhere to the uroepithelium via adhesins such as type 1 pili or P fimbriae, the gene of which (*papG*) has been identified in canine isolates.^{54,56} After attachment, pili and endotoxin incite neutrophil migration and induce the release of cytokines, leading to an inflammatory response and characteristic signs of urgency, discomfort, and hematuria.

Exotoxins, especially hemolysins, may also be important in the development of clinical signs of lower UTIs. Iron acquisition is also an important virulence factor, as are bacterial capsules and antiphagocytic systems. Numerous virulence factors have been identified in canine and feline *UPEC* strains, including CNF1 and genes encoding adhesins, hemolysin, and aerobactin.^{28,127} The ability of some *UPEC* to actually invade uroepithelial cells has been reported in strains isolated from people, and it is possible that this characteristic may explain some relapsing UTIs in dogs and cats. *UPEC* are carried in the colon of many dogs; comparing phylogenetic background, O antigens, and extended virulence genotype, 54% of urinary isolates were also found in the gut. This is consistent with the idea that *UPEC* have a special type of pathogenicity, and UTIs are not the result of exposure to high numbers of “normal” *E. coli*.⁵³ Hemolytic *E. coli* have also been found in UTIs in cats.¹⁰⁸

Studies based on the identification of genes encoding adhesins, hemolysins, CNF1, and aerobactin suggest that canine uropathic strains may be similar if not identical to some human uropathic strains.⁵⁶ Similarly, *P. mirabilis* strains isolated from the urine of dogs have been characterized and found to be similar to human

Infectious Diseases of the Dog and Cat, 3rd Edition

uropathogenic *P. mirabilis* strains. The significance of these findings for people and dogs is not known.³⁴ ExPEC can also infect almost any anatomic site. Pneumonia, sepsis, and meningitis are some of the infections that have been observed. Multidrug-resistant strains have been isolated from animals with recurrent infections that have been treated with several types of drugs.¹⁰⁷

37.2.4 *Klebsiella* Infections

Klebsiella organisms, which are found in the nasopharyngeal and intestinal flora, can be associated with clinically significant infections of the GI and genitourinary tracts and systemic bacteremia. *Klebsiella* organisms have also been implicated in nosocomial infections in veterinary hospitals.³⁸

37.2.5 *Pseudomonas aeruginosa* Infections

P. aeruginosa is an environmentally stable organism that causes infection in animals whose immune systems or host defenses are impaired. Although it can be isolated from the upper respiratory, genital and GI tracts, and intertriginous areas of the skin, numbers of organisms are usually controlled by competition from normal bacterial flora. Inflammation or injury to these mucosal areas or chronic antibacterial therapy can lead to a proliferation of *P. aeruginosa*. In addition, open wounds or surgical incisions can become contaminated and subsequently infected with antimicrobial-resistant strains from the hospital environment. Defective flexible endoscopes that became contaminated were incriminated as a source of an outbreak in people.¹⁰⁰ *Pseudomonas* bacteria also have the ability to invade a healthy cornea in its warm, moist state. Through small scratches, the organism can enter the cell cytoplasm, where it rapidly replicates. However, some strains produce an exoenzyme toxin that kills epithelial cells and macrophages. In dogs with otitis externa, *P. aeruginosa* and *Proteus* organisms could be cultured from the ears but were not found in the ears of clinically healthy dogs.¹²⁶ *Pseudomonas* bacteria are also isolated from mixed infections in dogs.¹⁰² *P. aeruginosa*, which has few nutritional requirements, thrives in moist environments outside the host and creates microcolonies that allow it to grow on moist surfaces such as those in bath tubs and plumbing and drainage systems. Animals that are immunosuppressed or have implanted catheters or open wounds are particularly susceptible to contamination from these moist environments or surfaces. In hospital environments, many of the *P. aeruginosa* strains have acquired multidrug–antimicrobial resistance. Exposure to quinolones in vitro or in vivo causes *P. aeruginosa* from dogs to develop resistance more rapidly than other bacteria.^{15,106}

37.2.6 *Pasteurella* Infections

Pasteurella organisms are usually associated with the oral cavities of dogs and cats and are frequently found in wound infections caused by their bites (see Bite Infections, [Chapter 53](#)). Many *Pasteurella* spp. are covered with a layer of capsular polysaccharide, which gives rise to their specific serotypes. As with most gram-negative bacteria, they have cell-surface LPSs with endotoxic activities. Several outer membrane proteins are also involved in virulence. *Pasteurella canis* was isolated from newborn puppies with systemic infection.²¹ These organisms are susceptible to various commonly used antimicrobial drugs. Quinolones have been shown to exert a postantibiotic effect on isolates of *Pasteurella multocida* from cats.²⁷

Infectious Diseases of the Dog and Cat, 3rd Edition

37.2.7 *Citrobacter* Infections

Citrobacter freundii, a member of the bacterial family Enterobacteriaceae, is a ubiquitous bacterium in the environment. The GI tract is the likely source of systemic infection in dogs and cats. Neonatal or immunosuppressed animals develop enteritis with bacteremia, and the systemic infections often involve additional organs. Systemic spread can result in hepatitis, peritonitis, meningitis, interstitial pneumonia, and sepsis.³⁵

37.2.8 *Acinetobacter baumannii* Infections

The *Acinetobacter baumannii* bacteria, which is a pleomorphic rod, is a gram-negative, aerobic, oxidase-negative, catalase-positive, and nonfermentative bacterium. It is short and nonmotile during rapid growth and becomes more coccoid during static growth periods. It is a low-grade pathogen, producing endotoxin in vivo, adhesins, and some enzymes. Of most concern is its ability to develop and transfer antimicrobial resistance in a short time. Nosocomial infections with this organism have been recognized for many years in people; however, infections in hospitalized dogs and cats have been reported.^{12,32}

This ubiquitous organism can be isolated from food, water, and soil in the environment. In the hospital environment, it can contaminate surfaces; animals undergoing invasive procedures, such as placement of chest tubes, central venous lines, or indwelling urinary catheters, are most likely to be affected. Outbreaks can occur as the infection is transmitted to susceptible patients through the hospital environment, the hands of hospital staff members, or medical devices. Outbreaks in human hospitals suggest that airborne dissemination has a role in nosocomial infections, and air handling systems may become contaminated. Once animals become infected, they may shed the organism into the environment. Antimicrobial therapy selects for resistant isolates and increases the risk of developing resistant nosocomial infection. Use of cephalosporins has been a risk factor for these infections in people and animals.³² (See Chapter 94 for additional information on control of nosocomial infections.)

325

326

37.2.9 *Providencia alcalifaciens* Infection

Providencia alcalifaciens, a gram-negative member of the family Enterobacteriaceae, has been identified as a human enteric pathogen and is associated with being one cause of travelers' diarrhea. It is not a typical enteric resident of animals; however, environmental contamination through feces of infected people and from flies may spread the infection. In experimental oral infections of rabbits, the organism proliferated and colonized the intestinal tract, displacing the resident flora.² *P. alcalifaciens* was associated with diarrhea in pups raised in a low socioeconomic area with exposure to raw human sewage.⁷⁴ The litter of 2-week-old pups stopped nursing over a 2-day period, began vocalizing, and had yellow-green, blood-tinged diarrhea. Wright-stained fecal smears contained a homogeneous population of short bacilli, degenerate neutrophils, and desquamated epithelial cells containing the same bacteria. Dead pups had yellow pseudomembranous exudates throughout the small intestine. Microscopy revealed this symptom was associated with severe, diffuse superficial necrosis of epithelium. Large numbers of short, gram-negative bacilli were adhered to enterocytes.

Infectious Diseases of the Dog and Cat, 3rd Edition

37.2.10 *Serratia* Infections

Serratia organisms are gram-negative bacteria. Like *Pseudomonas* bacteria, they thrive in the environment and can grow in moist environments, even in the presence of antiseptic agents such as benzalkonium chloride. They have been linked to nosocomial infections associated with medical procedures in hospitalized dogs and cats³¹ (see [Chapter 94](#)).

37.2.11 *Enterobacter cloacae* Infections

As with *Serratia* bacteria, *Enterobacter cloacae* have been associated with nosocomial infections in dogs and cats⁷ (see [Chapter 94](#)).

37.3 CLINICAL FINDINGS

All of the bacteria discussed colonize normal tissues and maintain a commensal relationship in dogs and cats. Most of the bacteria are opportunists, requiring alterations in local or systemic defenses and immune function for disease to develop. However, disease cannot develop unless the colonizing strain carries at least some virulence factors. Examples of clinically significant infections with these organisms are listed in [Table 37-2](#).

Some important clinical associations have been reported. *E. coli* sepsis and lesions consistent with acute respiratory distress syndrome can develop in puppies with parvoviral enteritis.¹¹² *E. coli* and *Klebsiella* spp. neonatal septicemia have been identified in puppies with either signs of failure to gain weight, dyspnea, cyanosis, hematuria, and sloughing of extremities or acute death.⁸² *K. pneumoniae* has also been reported to cause severe enteritis and sepsis in adult dogs.⁹⁰ *Klebsiella* spp. produce urease, which splits urea into ammonia; this can damage the uroepithelium and alter urine pH, favoring the development of struvite uroliths. *Klebsiella* spp. are also associated with extensive, necrotizing, consolidating pneumonias. *Pseudomonas* spp. are pathogenic only when they colonize areas devoid of normal defenses. Debilitated patients are at risk for infection, as are those with malignancies, immunodeficiencies, urinary or IV catheters, traumatized tissues, or altered normal flora secondary to the administration of antibiotics. *Pseudomonas* spp. are also associated with rapidly progressive corneal ulcers caused by proteolytic enzymes secreted by the bacteria.

Cholestasis associated with nonhepatic bacterial infections—including *E. coli* UTIs and *E. coli*, *Klebsiella* spp., and *Proteus* spp. soft tissue infections—has been described in people. In dogs, it has been reported infrequently and associated with *E. coli* and gram-positive bacterial infections.¹⁰⁴ Characteristic findings include hyperbilirubinemia; slight increases in liver enzyme activities; bile retention within hepatocytes, Kupffer's cells, and canaliculi; and minimal hepatocellular inflammation or necrosis. The condition is considered a “functional” cholestasis (because no obstruction is present), resulting primarily from decreased excretion of conjugated bilirubin from hepatocytes to canaliculi; the prevalence and prognostic significance of this finding is not known for dogs or cats.⁶⁰

A. baumannii infections produce localized or systemic signs depending on the organ system of localization. Genitourinary, cutaneous, and respiratory signs are the most common, whereas systemic inflammatory responses are characteristic of dogs with sepsis.

Infectious Diseases of the Dog and Cat, 3rd Edition

Signs associated with *C. freundii* infections vary, as do those caused by *A. baumannii*. Mucohemorrhagic diarrhea has been observed in animals affected with extraintestinal signs, likely indicating the source of spread. Sepsis is more consistent in *C. freundii*-infected animals that are immunosuppressed.

37.4 DIAGNOSIS

Specimens such as urine, blood, exudates, spinal fluid, airway samples, and feces and equipment such as catheter tips should be submitted for culture in the routine manner. Special transport media are not necessary.

By direct microscopy the Enterobacteriaceae are seen as gram-negative, medium-size short rods that can be motile. Stained morphologic findings vary significantly in clinical specimens. *Klebsiella* spp. capsules are large and regular. The *Pseudomonas* bacterium is a motile rod and can be found as a single bacterium, in pairs, or in short chains. Capsules may be produced.

Enterobacteriaceae grow well on ordinary unenriched media. On blood agar, the bacteria look similar, typically appearing as circular, smooth colonies with distinct edges. *Klebsiella* spp. colonies are large and mucoid and tend to coalesce with prolonged incubation. *Proteus* spp. are actively motile, resulting in “swarming” on solid media. Some strains of *E. coli* produce hemolysis on blood agar. Selective media such as MacConkey's or triple-sugar iron agar contain specific dyes and carbohydrates, and may be used for rapid preliminary identification. The IMViC reactions (indole, methyl red, Voges-Proskauer, citrate) can be used to further differentiate among *E. coli*, *Klebsiella* spp., and *Proteus* spp.

Pseudomonas spp. are obligate aerobes that also grow on ordinary nutrient media. Some strains are hemolytic, and some produce a sweet or grapelike odor caused by the production of aminoacetophenone. *P. aeruginosa* forms smooth, round colonies that are fluorescent green, and various pigments can be produced. A single strain can form multiple colony types on the same plate, giving the impression that several species are present. *Pseudomonas* spp. can grow at 42°C, a characteristic that is used to differentiate it from other bacteria.

326

The metabolic characteristics of Enterobacteriaceae are commonly used in their identification. In general, they ferment glucose with the production of acid or acid and gas, are catalase positive and oxidase negative, and reduce nitrate to nitrite. Many biochemical tests can help to characterize carbohydrate fermentation patterns and the activity of amino acid decarboxylases and other enzymes. Several test kits are commercially available.

327

Several schemes have been developed to differentiate *E. coli* strains, including serotyping, biotyping, phage-susceptibility typing, electrophoretic typing of enzymes, colicin typing, and pulsed-field gel electrophoresis. Genetic methods have been used to determine sources of fecal pollution in the environment.⁷² These tests may not be available in general veterinary reference laboratories.

The routine culture and identification of *E. coli* from blood or deep tissue samples are all that is required to diagnose *E. coli* sepsis (see [Chapter 38](#) for the diagnosis of endotoxemia) and soft tissue infection. Quantitative urine culture is necessary to diagnose UTIs. Dogs and cats with diabetes mellitus, with hyperadrenocorticism, or those receiving glucocorticoids may have occult UTIs (i.e., no identification of bacteriuria and pyuria on sediment examination) and should have a urine culture to identify UTIs.^{30,71} Dogs with urolithiasis may also have occult UTIs. In one study, 18.5% of negative results of urine cultures from dogs with urolithiasis had positive culture results from either the urolith or those bladder mucosal biopsies. Swabs of bladder mucosa were no more sensitive than a routine urine culture.⁴²

Infectious Diseases of the Dog and Cat, 3rd Edition

Enteric pathogens can be differentiated from enteric commensals by evaluating cultured isolates for O, H, and K antigens and testing for production of enterotoxins. Several bioassays based on cell cultures have been described, as well as the enzyme-linked immunosorbent assay and other binding techniques. Cytotoxin (VT) assays can be performed on fecal specimens when EPEC and EHEC strains are suspected. Infected animals develop rising levels of VT-neutralizing antibodies, which can be identified serologically. Isolates can also be tested for toxin- or other virulence-encoding genes by DNA hybridization or PCR; the suggested PCR screening tests for *E. coli* isolates from dogs and cats include the *LT*, *STa*, *STb*, *SLT1*, *SLT2*, *CNF1*, *CNF2*, and *EAE* (attaching and effacing) genes.^{19,101} Normal dogs and cats may carry *E. coli* with these genes, but the bacteria do not always produce the gene product and may not be pathogenic; toxin must be identified in feces to ensure a correct diagnosis.⁵⁰ Histologic examination is necessary to describe attaching and effacing lesions.

Pseudomonas spp. are typically catalase and oxidase positive and split sugars by oxidation, not fermentation. They are citrate and indole negative and reduce nitrate. Strains can be identified by serotyping, immunotyping with cross-protection studies in mice, pyocin typing, or phage typing.

Additional descriptions of the isolation and identification of these bacteria can be found in veterinary microbiology texts, and the reader is encouraged to consult with their specific laboratory on questions regarding methodology and interpretation of test results.

37.5 PATHOLOGIC FINDINGS

ETEC typically attach to the brush border of enterocytes of the distal jejunum and proximal ileum but cause minimal histologic changes. EPEC colonize the small intestine and adhere to villi of epithelial cells, where they induce attaching and effacing lesions, destroying the brush border and forming microscopic pedestal-like structures on the surface of enterocytes. EHEC colonize the colon, also cause attaching and effacing lesions, and induce necrosis of the tips of villi. The lamina propria can be edematous and infiltrated with neutrophils, lymphocytes, plasma cells, and macrophages. Submucosal blood vessels may be occluded by thrombi. Fibrinonecrotic debris can form a pseudomembrane. The lesions of CRGV (putatively caused by EHEC O157:H7) involve the skin and kidneys and are primarily vascular. Cutaneous lesions include fibrinoid necrosis of small to medium arterioles and full-thickness necrosis of the epidermis. Renal changes are predominantly glomerular, with thrombotic microangiopathy and necrosis.

In soft tissue, gram-negative bacteria elicit an acute neutrophilic response, and the histopathologic findings of acute cystitis reflect this reaction. Granulomatous inflammation (nodular infiltrates of lymphoid cells and macrophages) can develop with chronic lower UTI. Polypoid changes can also complicate chronic lower UTIs and can only be differentiated from neoplasia by biopsy. Bacterial fermentation of glucose within a chronically inflamed and devitalized bladder wall can lead to emphysematous cystitis in dogs and cats with poorly controlled diabetes mellitus. Histologic findings associated with pyelonephritis include papillitis, pyelitis, and interstitial nephritis. Chronic pyelonephritis can lead to infarction, fibrosis, and the development of end-stage kidneys.

37.6 THERAPY

Therapy is based on the administration of appropriate antibacterial drugs, as well as debridement and surgical drainage where appropriate. The gram-negative cell wall confers some inherent resistance to antibacterial drugs, and appropriate dosages are important. Acquired resistance to antibacterial drugs is common and under the control of resistance (R) plasmids, which are transferred between bacteria by conjugation. Acquired resistance can also develop through other mechanisms, such as mutations in genes encoding the A subunit of DNA gyrase or genes

Infectious Diseases of the Dog and Cat, 3rd Edition

determining bacterial permeability, leading to resistance to fluoroquinolone antibiotics.¹¹⁷ Increased fluoroquinolone resistance over time has been observed in *E. coli* isolates from dogs with UTIs.¹⁶ Acquired antibiotic resistance varies greatly, and laboratory testing of isolates for specific susceptibility is always indicated.

Empiric recommendations for suspected soft tissue infections with the Enterobacteriaceae vary, and most are not substantiated by susceptibility data. However, the antibiotic susceptibilities of numerous isolates obtained from dogs in a teaching hospital are presented in Table 37-3. In general the Enterobacteriaceae are not susceptible to chloramphenicol, tetracycline, ampicillin, or trimethoprim-sulfonamide. Based on antibacterial susceptibility trends, it is rational to treat clinically stable animals that have non-life-threatening infections suspected to be caused by gram-negative rods with either amoxicillin-clavulanate or first- or second-generation cephalosporins until susceptibility results are known. Pending culture and susceptibility results, animals with life-threatening bacteremia should be treated with either amikacin, a third-generation cephalosporin, or enrofloxacin.

Renal excretion results in a high urine concentration of some antibiotics, which facilitates the management of lower UTIs caused by gram-negative rods. Lower UTIs caused by *E. coli* can usually be treated effectively with trimethoprim-sulfadiazine. *Klebsiella* infections can be treated effectively with cephalexin, and *Proteus* spp. infections can be treated with ampicillin. (See Chapter 91 for an additional discussion of UTI management.)

Data regarding changes in *E. coli* resistance patterns are conflicting. The patterns may depend on geographic location and antibiotic usage. In vitro, enrofloxacin and ciprofloxacin had additive effects against *E. coli* isolated

from dogs.⁶¹ An increase in enrofloxacin-resistant *E. coli* in teaching hospital and community uropathogenic isolates has been reported in California.¹⁶ Isolates were resistant to enrofloxacin and multiple antibiotics, including ampicillin, amoxicillin-clavulanate, chloramphenicol, cephalexin, tetracycline, and trimethoprim-sulfonamide. Several strains were identified, suggesting a collective increase in *E. coli* resistance in the population.¹⁶ Another large study in Illinois found that ExPEC susceptibility remained “fairly stable” from 1990 to 1998, with amikacin, gentamicin, norfloxacin, and enrofloxacin having the highest efficacy. Orbifloxacin and sulfamethoxazole-trimethoprim were less effective, whereas susceptibility to tetracycline fell from 80% to less than 50% during the study period.⁷⁹ Similarly, a large retrospective study in Scotland from 1989 to 1997 documented increasing *E. coli* resistance to amoxicillin, amoxicillin-clavulanate, and streptomycin but not to ampicillin, chloramphenicol, enrofloxacin, gentamicin, oxytetracycline or trimethoprim-sulfonamide. No increase in the proportion of isolates showing multiple drug resistance was found.⁷⁶

a Specific therapy should be based on sensitivity testing results.

b Data from Hirsh D, Jang SS. 1994. Antimicrobial susceptibility of selected infections bacterial. *J Am Anim Hosp Assoc* 30:487–494.

c See [Appendix 8](#) for additional information on each drug.

d Dose per administration at specified interval.

e Oral route not recommended for initial therapy of serious infections.

f High is generally greater than 80% to 90% unless it is a very resistant hospital strain.

g Little independent information exists regarding the clinical efficacy of marbofloxacin, difloxacin, or orbifloxacin for treating these bacteria in dogs or cats.

Therapy for *Pseudomonas* spp. infections can be difficult because natural and acquired resistance is common. The bacteria also have the ability to up-regulate impermeability to or active efflux of many antimicrobial drugs.⁶⁴ Furthermore, some hospital-acquired *P. aeruginosa* strains can be highly virulent. Gentamicin, amikacin, tobramycin, carbenicillin, ticarcillin, ceftazidime, or ciprofloxacin (isolates may be resistant to enrofloxacin) can be used for initial empirical therapy ([Table 37-4](#)); however, it is essential that antimicrobial susceptibility testing be performed for all suspected *P. aeruginosa* infections. Most *P. aeruginosa* bacteria can produce chromosomally mediated β -lactamases, which hydrolyze all penicillins except ticarcillin, and many isolates have plasmid-mediated resistance to other β -lactamases. Ticarcillin is much more active against *P. aeruginosa* than carbenicillin; however, cross-resistance occurs. Antipseudomonal cephalosporins are ceftazidime, cefoperazone,

Infectious Diseases of the Dog and Cat, 3rd Edition

and cefsulodin, which are all third-generation drugs. Some of the fourth-generation drugs such as cefepime are also antipseudomonals. Aztreonam is the only monobactam available to treat the bacteria; however, ceftazidime is more effective. Carbapenems such as imipenem and meropenem are very effective, and cross-resistance with other β -lactams does not usually occur. Of the quinolones, ciprofloxacin has the highest efficacy for treating *P. aeruginosa*; only a few of the newer quinolones have this activity. Many of the aminoglycosides are effective against this organism. In life-threatening situations in which susceptibility testing results are not yet available, *P. aeruginosa* infections should be treated with imipenem-cilastatin as a single agent or with either ticarcillin or carbenicillin in combination with an aminoglycoside. *Pseudomonas* spp. are usually resistant to penicillin, ampicillin, tetracycline, first- and second-generation cephalosporins, chloramphenicol, and trimethoprim-sulfadiazine. Most lower UTIs can be treated effectively with tetracycline. (The management of *Pseudomonas* otitis externa is discussed in [Chapter 85](#).)

37.7 PREVENTION

The Enterobacteriaceae are killed readily by sunlight and desiccation but not by freezing. *E. coli* can survive in feces, dust, and water at ambient temperature for months. Contaminated drinking water has been an important source of infection for people or pets. An improperly chlorinated swimming pool has also been a vehicle for transmission to people³³; the outbreak was suspected to have been caused by a person whose feet were contaminated with animal feces when the individual entered the pool. Fomite transmission may be important, and hand washing and disinfection of fomites are essential for prevention. Rabbits have been shown to be a reservoir

Infectious Diseases of the Dog and Cat, 3rd Edition

for enterohemorrhagic *E. coli*,³⁶ so people who handle rabbits might be at risk for acquiring infection, as may dogs and cats that prey on rabbits. *Pseudomonas* spp. are important nosocomial pathogens that survive well in hospital environments in locations such as water faucets, utensils, floors, instruments, humidifiers, baths, and respiratory care equipment. *Pseudomonas* spp. can also survive in disinfectant solutions, antiseptics, and liquid fluorescein drops. Appropriate management of IV and urinary catheters is extremely important in the prevention of nosocomial infection.⁶⁵

Orally administered autogenous vaccines have been reported to prevent and treat kennel-acquired enteric *E. coli* infections in dogs and cats, with significant decreases in morbidity and mortality; however, these are not available for general use.^{6,119,120}

37.8 PUBLIC HEALTH CONSIDERATIONS

Most *E. coli*, *Klebsiella* spp., and *Proteus* spp. are opportunistic pathogens; however, some pathogenic strains could be carried by dogs or cats and transmitted to people (or vice versa). In one study, seventeen uropathogenic *E. coli* isolates from dogs were characterized by phylogenetic background and virulence genotype and compared with human clinical isolates with similar serotypes. The genotypes of canine origin *E. coli* were similar to (and in some cases indistinguishable from) human ExPEC strains, suggesting that canine isolates, rather than being dog-specific pathogens, may pose an infectious threat to people.^{54,56} Furthermore, 30% of canine fecal samples collected from a residential neighborhood in St. Paul, Minn., contained ExPEC strains known to be virulent to humans.⁵⁵

R plasmids are transmitted between gram-negative organisms, and multiple drug resistance could be a human health problem. Twenty-one *E. coli* isolates from wounds, urine, and a veterinary teaching hospital intensive care unit environment had multiple drug resistance (to most cephalosporins, β -lactams and clavulanic acid, tetracycline, spectinomycin, sulfonamides, chloramphenicol, and gentamicin).⁹⁴ Thus it has been suggested that the use of fluoroquinolone and third-generation cephalosporins in veterinary settings be considered carefully and possibly even be restricted. The theoretical potential for animal owners (especially those who are immunocompromised), veterinarians, and technicians to be infected by resistant pathogens needs to be recognized.^{86,117}

38 CHAPTER 38 Endotoxemia

Stephen A. Kruth

38.1 ETIOLOGY

Clinically significant bacteremia in dogs and cats is expected to occur in a variety of infections (e.g., peritonitis, mastitis, prostatitis, pneumonia, pulmonary abscess, pyothorax, pyometra, pyelonephritis, intraabdominal abscess, biliary tract infections), as well as during dentistry. It probably also occurs during rectal palpation, intestinal endoscopy and surgery, and when indwelling venous or arterial catheters have been placed. Normally, circulating bacteria are cleared by the mononuclear-phagocyte system. Bacterial molecules are recognized by macrophages and other cells, which initiate a complex local inflammatory response, as well as up-regulating systemic host defenses, thus preparing the animal for the potential spread of infection. Typical clinical signs of bacteremia include altered body temperature, tachycardia, tachypnea, and neutrophilia or neutropenia; these signs are part of the systemic inflammatory response syndrome (SIRS). SIRS can be initiated by trauma, pancreatitis, and other insults in addition to infection and is characterized by a complex cytokine-mediated response. The host benefits if SIRS is controlled and balanced by antiinflammatory pathways. However, in some cases, bacterial virulence factors, inoculum size, co-existing disease, host genetic determinants, or any combination of these leads to the inappropriate, dysregulated generalized systemic response of severe sepsis, septic shock, and ultimately multiple organ dysfunction syndrome (MODS). The terminology referring to SIRS and sepsis was clarified in the 1990s in human medicine; relevant terms are defined [Table 38-1](#).

Endotoxemia is the best-studied cause of SIRS and its complications in people and horses. Endotoxin (lipopolysaccharide [LPS]) consists of a lipid A moiety (the toxic component) and polysaccharides (O antigens). LPS is released from the outer membrane of gram-negative bacteria when they lyse and is normally confined within the gut and portal circulation. Animals have evolved mechanisms that recognize and respond to LPS in tissues and fluids early in gram-negative infections, and *endotoxemia* occurs when SIRS develops in response to the presence of LPS. The source of endotoxin is usually a member of the Enterobacteriaceae family (*Escherichia* spp., *Klebsiella* spp., *Enterobacter* spp., *Proteus* spp.), as well as *Pseudomonas* spp. The term *endotoxemia* implies only that toxin is present in the blood; in some cases, bacteria are also present. In other cases, the bacteria remain compartmentalized in the gut or tissues, with only toxin being absorbed (i.e., it is common to have negative blood cultures in endotoxemia).

38.2 EPIDEMIOLOGY

The prevalence of naturally occurring endotoxemia in dogs and cats is unknown, even though the dog has been used for many years as a biomedical model of endotoxemia and SIRS for people, and the acute syndromes are well described. Risk factors for dogs include canine parvoviral (CPV) enteritis, gastric dilation or volvulus, pyometra, mastitis, other gram-negative infections, and heat stroke. Endotoxemia can develop when hepatic clearance of LPS is reduced, as in hepatic insufficiency and portosystemic shunts. Obstructive biliary disease may be a risk factor because bile salts bind endotoxin in the gut. Endotoxin may also play a significant role in the pathogenesis of severe acute pancreatitis in dogs.³⁴

Endotoxemia is recognized less commonly in cats. Risk factors for severe sepsis in cats include pyothorax, septic peritonitis, bacteremia secondary to gastrointestinal (GI) disease, pneumonia, endocarditis, pyelonephritis,

Infectious Diseases of the Dog and Cat, 3rd Edition

osteomyelitis, pyometra, and bite wounds.⁷ Endotoxemia is likely a component of some of these infections. Endotoxemia is also recognized as a cause of neonatal death in puppies and kittens.

Approximately 25% of individuals with gram-negative aerobic bacteremia develop endotoxic shock, with a 50% to 80% mortality rate. Predisposing conditions for endotoxic shock in those include diabetes mellitus, hepatic cirrhosis, burns, cancer, surgery, irradiation, cytotoxic drug therapy, administration of glucocorticoids, indwelling devices, and blood transfusions.

Uncomplicated SIRS-sepsis is not a negative prognostic finding if managed appropriately; however, the prognosis worsens as an animal develops severe sepsis, septic shock, and MODS.

Table 38-1 Definitions Associated with Systemic Inflammatory Response Syndrome (SIRS)

Septicemia	Systemic signs caused by the spread of microbes or their toxins via the blood stream
Sepsis	SIRS that has a proven or suspected microbial etiology; may be caused by circulating toxins; microbial invasion of the blood is not necessary
Severe sepsis	Sepsis with signs of organ dysfunction, hypoperfusion, or hypotension, including metabolic acidosis
Septic shock	Sepsis with hypotension that is not responsive to appropriate fluid therapy
Endotoxemia	SIRS associated with increased blood endotoxin levels
Multiple organ dysfunction syndrome (MODS)	Dysfunction of more than one organ, requiring intervention to maintain homeostasis

331

38.3 PATHOGENESIS

Endotoxin is released into the intestinal lumen or tissues when gram-negative bacteria lyse, as occurs with rapid bacterial replication or with bactericidal action of effective antibiotics. Within the intestinal lumen, most endotoxin is bound by bile salts and contained by the mucosal barrier; the small amounts absorbed into the portal circulation are cleared by hepatic macrophages. Endotoxin absorbed through the lymphatic system is cleared in regional lymph nodes. Thus endotoxin levels in the systemic circulation are usually extremely low to immeasurable. Clinical signs of endotoxemia occur only when binding and clearance mechanisms are overwhelmed.

Within hepatocytes, endotoxin interferes with transport mechanisms, causing functional cholestasis. Endotoxin can also directly activate complement via the alternative pathway. In terms of clinical signs, these effects are relatively minor; the more significant effect of endotoxin is its ability to stimulate macrophages and other cells to release a variety of proinflammatory and antiinflammatory cytokines.

In blood, endotoxin is bound by a specific carrier lipoprotein called lipopolysaccharide binding (LPB) protein (the canine molecule has been described and cloned³⁸); this complex binds to monocytes and macrophages via the receptor CD14, which amplifies the effect of endotoxin on the cell. The endotoxin-CD14 complex interacts with other cell surface receptors, called toll-like receptors, which trigger a signal transduction pathway, protein synthesis, and subsequent cytokine secretion. Soluble (free) CD14-endotoxin complexes bind to endothelial cells and induce a similar cytokine response. The endotoxin-triggered cytokine response is what leads to the clinical signs of SIRS.

Infectious Diseases of the Dog and Cat, 3rd Edition

The early macrophage response to endotoxin is characterized by release of multifunctional proinflammatory cytokines, especially interleukin-1 β (IL-1) and tumor necrosis factor- α (TNF- α). In dogs, TNF- α levels increase within 15 minutes of exposure to LPS, peak at 2 hours, and return to baseline levels in 4 hours. TNF- α mediates many immune and inflammatory functions, as well as further stimulating macrophages to secrete IL-1, IL-6, macrophage colony-stimulating factor, and granulocyte-macrophage colony-stimulating factor. IL-1 is released in similar burst fashion; it is a major co-stimulator of type 2 helper T (Th2) cells, stimulates the acute-phase response, induces fever, and has a multitude of other proinflammatory effects. Other cytokines, such as IL-6, IL-8 and interferon (IFN)- α , are becoming recognized as additional early mediators in SIRS-sepsis (see Tizard³⁶ for further discussion of the various cytokines involved in SIRS-sepsis). IL-1, TNF- α , and so forth are released early and transiently in response to endotoxin, before the animal is presented with clinical signs. Novel therapeutics directed toward these mediators have not demonstrated significant benefit in most human clinical trials. However, late mediators of SIRS, such as *high-mobility group 1 protein*, are now being described and may be more appropriate therapeutic targets.¹

The cytokine cascades increase the levels or activity (or both) of inflammatory phospholipid-derived mediators (prostacyclin, thromboxane, and platelet-activating factor),³⁷ coagulation factors, complement, reactive oxygen species, and nitric oxide (which is emerging as an important molecule associated with hypotension),^{11,22,24,33} endothelin-1 (a vasoconstrictor),²³ β -endorphin, histamine, serotonin, vasopressin, angiotensin II, and catecholamines. The biologic effects of these mediators include neutrophil activation, aggregation, and chemotaxis; platelet activation and aggregation; a procoagulable state; increased activity of plasma proteases; and vasodilation and potentially systemic hypotension, generalized endothelial inflammation, increased vascular permeability, and GI ulceration.^{21,25} Lysosomal enzymes such as elastase and chymotrypsin deplete fibronectin and activate blood clotting, triggering disseminated intravascular coagulation (DIC).

If the systemic inflammatory state progresses, structural and metabolic changes develop in vascular endothelial cells. Endothelial adhesion molecules are up-regulated, and neutrophils and platelets are sequestered in various organs. The endothelium also becomes more permeable, and plasma proteins move from the intravascular space to the interstitium, resulting in edema.

Concurrent with inflammatory mediator up-regulation, antiinflammatory mediators are secreted to balance and limit the inflammatory response. An insufficient or inappropriate antiinflammatory response can allow sepsis to progress.²¹

Until recently, the prevailing theory has been that sepsis is a result of a *cytokine storm*, leading to uncontrolled systemic inflammation. Studies now indicate that, for at least some patients, the hyperinflammatory state is followed by severe acute immunosuppression, caused by the apoptosis of B cells, CD4 T cells, and follicular dendritic cells. The mechanism of immunosuppression is not known; however, release of endogenous glucocorticoids may be an important contributor.¹⁶ Thyroid hormone production and secretion have been impaired in endotoxin-treated dogs.³¹

In summary, endotoxin acts as a signal to the immune system that gram-negative bacterial infection has occurred. A localized response along with a primed or controlled systemic response is beneficial, while an uncontrolled response leads to systemic inflammation, immunosuppression, severe sepsis, septic shock, and ultimately organ failure (Fig. 38-1).

331

Fig 38-1 Pathophysiology of endotoxemia. 1, Intracellular or extracellular gram-negative bacterial death leads to the release of endotoxin. 2, Endotoxin stimulates monocytes to release inflammatory cytokines, including TNF- α and IL-1 and a procoagulant (tissue factor, Factor III). 3, Monocytes are activated to release cytokines, which, in turn, stimulate CD4 T cells to release inflammatory or antiinflammatory mediators. The type of pathogen, size of the bacterial exposure, and the site of infection are factors that influence which pathway is stimulated. Monocytes, previously ingesting necrotic cells, release interleukins, which induce Th1 cells to secrete inflammatory cytokines (TNF- α , IFN- γ , and IL-2). Monocytes, previously ingesting apoptotic cells, release interleukins, which induce antiinflammatory Th2 cell activation with the release antiinflammatory cytokines, IL-10, and IL4, which suppresses monophage activation. 4, Endotoxin, IL-1, and TNF- α cause endothelial injury and the further release of inflammatory mediators (IL-1, TNF- α , IL-6, and nitric oxide [NO]) and procoagulatory tissue factor. 5, Tissue factor from damaged endothelium and activated monocytes initiates the coagulation cascade. Inflammatory cytokines IL-1 and TNF- α stimulate neutrophil chemotaxis. 6, The coagulation cascade, once activated, triggers the development of a fibrin clot. 7, Fibrinolysis is activated, converting plasminogen to plasmin, which leads to the breakdown of formed clots. Activated protein C (APC) has direct antiinflammatory and antiendotoxic properties at several sites in the pathway as designated by blue dashed lines. It blocks the production of cytokines by monocytes and the effects of endotoxin on cells. APC also blocks neutrophil adhesion. It inactivates factors Va and VIIIa, thereby preventing the generation of thrombin. In addition to inhibiting the coagulation pathway, APC blocks inhibitors of fibrinolysis thus accelerating the fibrinolytic pathway and clot dissolution. *PAI*, Plasminogen activator inhibitor; *TAFI*, thrombin activating factor inhibitor. (Courtesy University of Georgia, Athens, Ga.)

38.4 CLINICAL FINDINGS

38.4.1 Dogs

No clinical signs have been found that are pathognomonic for endotoxemia. Animals show either signs associated with infection (e.g., purulent vaginal discharge with pyometra, coughing with pneumonia, mastitis) or localizing signs such as inactivity and inappetence. Tachycardia, tachypnea, and fever are the clinical hallmarks of SIRS ([Table 38-2](#)). If a dog is progressing towards severe sepsis or septic shock, signs associated with the GI tract (the canine *shock* organ system) can develop, including vomiting or diarrhea, or both (with melena if GI bleeding secondary to ulceration or DIC occurs). In addition, portal hypertension, hepatosplanchnic pooling of blood, ileus, decreased jejunal absorption of water, electrolytes and glucose, increased colonic motility, and increased bacterial translocation have been described in experimental canine models. Cholestatic jaundice can develop and is not necessarily associated with a poor prognosis.

Table 38-2 Clinical Criteria for Diagnosis of Systemic Inflammatory Response Syndrome (SIRS)

CLINICAL PARAMETERS	DOGS	CATS
Heart rate	>120 bpm	<140 bpm or >225bpm
Respiratory rate	>40 brpm or PaCO ₂ <30 mmHg	>40 brpm
Temperature	<100.4° F or >104.0° F	<100.0° F or >104.0° F
Leukogram	>18,000 or <5000 WBC/μl	>19,000 or <5000 WBC/μl

bpm, Beats per minute; *PaCO₂*, arterial carbon dioxide pressure; *brpm*, breaths per minute; *WBC*, white blood cells.
Data from Brady CA, Otto CM. 2001. Systemic inflammatory response syndrome, sepsis, and multiple organ dysfunction, *Vet Clin North Am Small Anim Pract* 31:1147–1162.

The initial cardiovascular signs are associated with a hyperdynamic response, including brick-red mucous membranes, tachycardia, and bounding arterial pulses. Myocardial contractility is usually normal, and cardiac output is increased.³² Hours later, a hypodynamic phase can develop, with decreased central venous pressure, low systemic vascular resistance, decreased arterial blood pressures, pooling of blood in the viscera, and eventual myocardial failure. Cold extremities, pale mucous membranes, weak pulse, and prolonged capillary refill times can be seen. In model systems, dogs that survive endotoxic shock can have cardiovascular abnormalities that peak at 2 to 3 days and return to normal 7 to 10 days later. In some dogs, myocardial damage is progressive, and death from heart failure can occur up to 7 days following infusion of endotoxin.

Signs associated with an infected focus may be obvious or the focus may be occult, necessitating an aggressive diagnostic workup. Dogs may be presented for signs associated with either damage to intestinal barriers (gastric dilation or volvulus, CPV enteritis) or portal-systemic shunts.

Signs associated with MODS can be related to intestinal, hepatic, cardiovascular, renal, or respiratory insufficiency. Edema is associated with increased vascular permeability and hypoalbuminemia, and bleeding can occur if DIC is present.

Hematologic findings can include hemoconcentration, leukocytosis with left shift or leukopenia, toxic changes in neutrophils, and thrombocytopenia. Prolonged coagulation times, low antithrombin III levels, and elevated fibrin degradation products are consistent with DIC. Lactic acidosis caused by poor perfusion is an early finding. Serum biochemical abnormalities can include hypo- or hyperglycemia, hypoalbuminemia, and increased serum alkaline phosphatase (ALP) and alanine aminotransferase activities. Azotemia, casts, and proteinuria are consistent with acute renal failure. Organ failure can cause other clinical pathologic abnormalities, depending upon the organ system.

38.4.2 Cats

Endotoxemia is rarely reported and poorly described in cats. In a retrospective case series of cats with confirmed severe sepsis (9 of 29 cats had confirmed *Escherichia coli* or *Pseudomonas* spp. infections; endotoxin was not assayed), clinical signs included lethargy, pale mucous membranes, weak femoral pulses, tachypnea, hypothermia or fever, diffuse pain on abdominal palpation, bradycardia, and icterus (Table 38-3). Anemia, thrombocytopenia, neutrophilia with increased bands, hypoalbuminemia, and hyperbilirubinemia were the most frequent hematologic abnormalities (Table 38-4). Functional cholestasis was not identified histologically; thus icterus may have been caused by hemolysis.⁷ The lung is the feline shock organ, and pulmonary edema and respiratory failure may be the predominant signs in cats developing MODS.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 38-3 Clinical Findings of 29 Septic Cats^{a,b}

PERCENTAGE AFFECTEDMEDICAL PROBLEMS	
100%	Lethargy
100%	Pale mucosae
79%	Poor pulse
66%	Bradycardia <140 beats per minute
35%	Hyperthermia 38.9° C (102° F)
59%	Hypothermia <37.8° C (100° F)
72%	Tachypnea (>40 breaths per minute)
76%	Diffuse abdominal pain
72%	Icterus

a Uncommon pyrexia, tachycardia, moist gums.

38.5 DIAGNOSIS

A variety of assays have been described for the quantification of endotoxin in body fluids, with variations on the classical Limulus amebocyte lysate assay most commonly used in clinical research settings. These are specialized assays, notoriously difficult to standardize and not available for general veterinary clinical use. The interpretation of results is confounded by poor concordance with blood culture results.^{17,27,30} Improved assays are becoming available for clinical use, but these need to be validated and their utility determined.¹⁸ The diagnosis of endotoxemia remains presumptive in the majority of canine and feline clinical cases.

Assays for TNF- α , IL-1, and other cytokines are useful research tools but are also not generally available. Elevated cytokine levels are consistent with SIRS, for which endotoxin is only one stimulus. The diagnosis of sepsis is based on the identification of an infected focus in a patient with SIRS; clinical suspicion of sepsis depends on recognition of risk factors, along with the clinical signs outlined previously.

The diagnosis of severe sepsis or septic shock is dependent on hemodynamic and perfusion indices; these include rectal and toe web temperature, heart rate, mucous membrane color, pulse character, arterial blood pressure, and arterial blood gases, which should be determined at initial physical examination and then monitored. Serum electrolyte, glucose, urea nitrogen and creatinine levels, and liver enzyme activities should be determined, along with a complete blood count (CBC), platelet count, and coagulation testing. Culture specimens of wounds, urine, and blood should be taken before antibiotic therapy is initiated. For a review of specimen collection, see [Chapter 33](#).

a Brady CA, Otto CM, Van Winkle TJ, et al. 2000. Severe sepsis in cats: 29 cases (1986–1998), *J Am Vet Med Assoc* 217:531–535, with permission.

The infected site should be identified as soon as the animal is stable. Radiography of the thorax and abdomen, abdominal ultrasonography, echocardiography, or any combination of these tools may be helpful in locating sources of sepsis. Diagnostic peritoneal lavage, tracheal or bronchoalveolar lavage, arthrocentesis, cerebrospinal fluid collection, or any combination of these should be performed if indicated.

38.6 PATHOLOGIC FINDINGS

No specific gross or histopathologic findings that are diagnostic for endotoxemia have been found. Histologic findings associated with SIRS include widespread vascular endothelial injury, neutrophil margination, edema, and microthrombosis. The most important pathologic findings will be associated with the infected focus (CPV enteritis, pyometra, bacterial endocarditis).

Autopsy studies have not revealed why human patients with sepsis die, and discordance often occurs between histologic findings and the degree of organ dysfunction. The concept of *cell stunning* has been suggested in which sepsis activates defense mechanisms that cause cellular processes to be reduced to basic housekeeping roles. As discussed previously, some patients have widespread B-cell, CD4 T-cell, and follicular dendritic cell apoptosis, consistent with a state of severe immunosuppression.¹⁶ The exact cause of death in people with sepsis receiving supportive care remains elusive.

38.7 THERAPY

Current therapy of endotoxemia consists of aggressively managing SIRS and its complications while treating the infection with appropriate antimicrobials, drainage, and so forth, as outlined in Table 38-5. Treatment must be aggressive and instituted based on clinical signs and suspicion of sepsis because definitive diagnostic tests are not available. Because early treatment can be critical for survival, empiric therapy should be initiated as soon as clinical signs of SIRS are observed. Specific treatment for endotoxemia is more controversial because studies in people and animals have given variable outcomes. The discussion to follow is divided into routinely accepted therapy followed by a review of treatments specifically directed against endotoxemia. None of the measures aimed at endotoxin can be universally accepted for treatment of dogs and cats.

334

335

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 38-5 Therapeutic Recommendations for Endotoxemia in Dogs and Cats
CBC, Complete blood count; DIC, disseminated intravascular coagulation.

1. Establish central venous catheter.
2. Obtain laboratory specimens for CBC, biochemical profile, urinalysis.
3. Replace fluid volume within the first hour.
4. If blood pressure remains reduced, begin plasma or colloid.
5. Administer heparin as indicated to control hypercoagulability.
Low prophylactic doses in low grade DIC
Higher doses with acute or severe organ thrombosis
Low prophylactic doses plus plasma or whole blood in end-stage DIC
6. Administer parenteral antimicrobial therapy depending on source of infection. ^a
Skin: β -lactamase-resistant penicillin, first-generation cephalosporin
Soft tissue: β -lactamase-resistant penicillin plus clindamycin or metronidazole
Urinary tract: ampicillin plus aminoglycoside, third-generation cephalosporin
Pneumonia: macrolide plus second- or third-generation cephalosporin
Meningitis: third-generation cephalosporin
Intraabdominal: third-generation cephalosporin plus metronidazole or clindamycin
Uncertain site: ticarcillin-clavulanate, clindamycin and quinolone (possibly combined)
7. Consider oxygen delivery, increasing inspired concentration and reducing consumption.
8. Consider glucocorticoids at modest physiologic dosages.
CBC, Complete blood count; DIC, disseminated intravascular coagulation.

^a See Chapter 34 and Appendix 8 for information on drugs listed.

38.7.1 Routine Management

SIRS is managed supportively with an emphasis on maintaining tissue perfusion. Aggressive volume resuscitation is probably the most important intervention to minimize the time period of reduced organ perfusion. Intravenous access should be established, a urinary catheter placed, and a shock (volume replacement) dose of an isotonic crystalloid solution administered. If the animal does not respond adequately within the first hour, fresh or fresh-frozen plasma should be given along with a synthetic colloid such as hydroxyethyl starch. Colloids are more likely to stay in the vascular space longer than crystalloids and are more likely to prevent pulmonary edema, the most serious complication of fluid resuscitation. Fluid support should be aggressive and adjusted as dictated by the animal's response. Whole blood or erythrocytes should not be used

Infectious Diseases of the Dog and Cat, 3rd Edition

in septic shock unless the hemoglobin level is reduced below 10 g/dl. If blood pressure cannot be maintained, vasoactive agents such as dopamine or dobutamine should be infused. See Brady and Otto⁶ and Hardie¹⁴ for a more detailed review of hemodynamic resuscitation of septic dogs and cats. For drug dosages for this therapy, see [Table 38-6](#).

Table 38-6 Drug Dosages for Sepsis^a

DRUG ^b	SPECIES	DOSAGE ^c	ROUTE	INTERVAL (HOURS)
Volume Expanders				
Isotonic crystalloid solutions (Plasma-Lyte® 148, lactated Ringer's, normal saline)	D	≥90 ml/kg	IV	1 ^d
	C	≥60 ml/kg	IV	1 ^d
Colloids (fresh or fresh-frozen plasma, pentastarch, hetastarch 120, dextran 70)	D	20 ml/kg	IV	24
	C	10 mg/kg		
Sympathomimetic Drugs				
Dopamine	B	1–10 µg/kg	IV	1 min
Dobutamine	B	5–20 µg/kg	IV	1 min
Antibacterial Drugs^e				
Ampicillin	B	22 mg/kg	IV	8
Gentamicin	B	6 mg/kg	IV	24
Amikacin	B	20 mg/kg	IV	24
Cefazolin	B	5–15 mg/kg	IV	6–8
Cefoxitin	B	30 mg/kg once, then 15 mg/kg	IV	4
Ceftazidime	B	22 mg/kg	IV	6–8
Enrofloxacin	D	10 mg/kg	IV	24
	C	5 mg/kg	IV	24
Clindamycin	B	10 mg/kg	IV	8
Imipenem-cilastatin	B	5 mg/kg	IV	8

- b For additional information on each antibacterial drug, see [Appendix 8](#).
- c Dose per administration at specified interval.
- d Reassess perfusion and hemodilution after first hour before continuing.
- e Combination therapy is usually indicated until culture results are available. Choices include: ampicillin + amikacin or gentamicin, cefazolin + amikacin or gentamicin, ampicillin + ceftazidime, ampicillin + enrofloxacin, clindamycin + enrofloxacin. Single-agent therapy choices include cefoxitin, imipenem-cilastatin, or ticarcillin-clavulanate. Criteria include likely organism or

Infectious Diseases of the Dog and Cat, 3rd Edition

organisms based on infection site, knowledge of resistance patterns, severity of illness, signalment, renal or hepatic dysfunction, and cost.

Once fluid therapy has been initiated, infected sites should be cultured, drained, and débrided. Antibacterial therapy is one of the most important aspects of treatment. Antibiotic therapy should be directed toward the primary site of infection; however, with endotoxemia from any source, translocation of bacteria from the GI lumen to the portal circulation is increased, and antibiotic therapy should include drugs effective against anaerobes and Enterobacteriaceae. Chronic low-level endotoxemia can complicate portosystemic shunts and other forms of hepatic insufficiency. Lactulose and nonabsorbable antimicrobials such as neomycin potentially lower portal endotoxin levels by suppressing numbers of enteric bacteria.

Antimicrobial regimens are listed in [Table 38-6](#). Effective antimicrobial therapy, especially with bactericidal drugs such as cephalosporins and quinolones, theoretically might increase the release of endotoxin¹⁴; this was demonstrated in some experiments in vitro and in animals following intravenous or intraperitoneal administration of bacteria. Data are insufficient in veterinary medicine to make management recommendations concerning the avoidance of specific drugs in septic dogs and cats. In people treated with severe, naturally occurring gram-negative bacteremia, bactericidal antibiotics did not increase circulating levels of endotoxin, TNF- α , IL-6, or IL-8.¹⁹

Anticoagulant therapy has been used to modulate complications of sepsis because hypercoagulability and DIC are inevitable manifestations.^{8,43} DIC is treated with fluids and with plasma to replace the anticoagulants antithrombin 3, protein C, and thromboplastin, as well as depleted clotting factors.⁶ The use of heparin to treat DIC in sepsis remains controversial^{6,14}; however, it is the most practical means of anticoagulation therapy for veterinary patients. Depletion of antithrombin 3 with DIC has been of greatest concern given that it is important as a co-factor for heparin activity. Recombinant human antithrombin therapy has been implemented in the treatment of septic people; however, the effects were only demonstrable when the patients were also receiving heparin.⁴² Protein C, a potent anticoagulant, inhibits coagulation through Factors Va and VIIa and limits thrombin production in addition to activating fibrinolysis. Activated protein C has been shown to reduce mortality in people with sepsis.⁴

Patients receiving parenteral nutrition may develop bacterial infections associated with their catheter or as a result of their underlying disease. Thrombosis of large veins has been a frequent complication in human patients receiving parenteral nutrition that were concurrently injected with endotoxin.³⁹ Prolonged bowel rest and inclusion of lipids may enhance the coagulatory response to endotoxin. Prophylactic anticoagulation may be indicated in dogs and cats with predisposing hypercoagulation. For a summary of therapy in the various stages of DIC, see [Table 38-7](#).

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 38-7 Treatment of Various Stages of Disseminated Intravascular Coagulation in Dogs and Cats

STAGE	PLATELET COUNTS	COAGULATION TIMES	DOG	CAT
Early or low grade	L	Within reference interval	Prophylaxis Aspirin: 10–15 mg/kg/day Heparin: 100 U/kg SC every 8 hrs	Prophylaxis Aspirin: 25 mg/kg/day Heparin: 50 U/kg SC every 8 hrs
Acute or fulminant	LL	Slight prolonged	Heparin: 200–300 U/kg SC every 8 hrs	Heparin 100–150 U/kg SC every 8 hrs
End stage	L	Very prolonged or incoagulable	Heparin: 100 U/kg SC every 8 hrs or added to blood products consisting of whole blood or plasma transfusion	Heparin: 50 U/kg SC every 8 hrs or added to blood products (5 U/kg) consisting of whole blood or plasma transfusion

L, Low (<200,000 and >50,000); LL, very low (<50,000); SC, subcutaneous.

Glucocorticoids have been recommended to treat sepsis because they have effects against inflammatory cytokines and mediators. People with septic shock have shown a relative adrenal insufficiency as exhibited by marginally low levels of serum cortisol. At higher doses, benefits of glucocorticoids are unproven and potentially contraindicated; however, improved survival has been observed in people with septic shock when slightly supraphysiologic doses of 0.5 to 1 mg/kg were used.^{3,5}

Lazaroids are steroid compounds with free-radical scavenging and antioxidant properties. They decrease neutrophil migration and TNF- α production. These drugs have increased survival in animal studies with minimal toxicity in treated people. Pentoxifylline is a phosphodiesterase inhibitor and, among other influences, inhibits the release of TNF- α . Data on its beneficial effects in people are conflicting.

GI ulceration is a common complication of SIRS, and management should include an H₂ blocker, sucralfate, and misoprostol as necessary. Other complications such as noncardiogenic pulmonary edema, acute renal insufficiency, and cardiac failure should be managed as discussed in other sources. Nutritional support is important in animals with SIRS, and enteral alimentation is preferable to partial or total parenteral nutrition to maintain mucosal integrity and minimize bacterial translocation.¹⁴

38.7.2 Treatment of Endotoxemia

Specific therapy for endotoxemia has been investigated for many years in people and animals; however, the results of experimental and clinical studies are often contradictory. The utility of these interventions is not well established in septic dogs and cats, and the majority of substances are not currently available for use in veterinary practice; therefore they cannot be universally recommended. [Table 38-8](#) summarizes the mechanisms of these investigational modalities and their established efficacy.

336

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 38-8 Therapeutic Modalities Used in Treatment of Endotoxemia

DRUG	MECHANISM	CLINICAL AVAILABILITY	COMMENTS
Inhibitors of Inflammatory Cytokines			
TNF- α receptor fusion protein	Lowers TNF- α activity	Lenercept, Entanercept	Protects rats from shock and improves outcome in people
Antibody to TNF- α or TNF- α receptors	Interferes with TNF- α activity		
IL-1 or IL-1 receptor antagonist	Blocks IL-1 activity	Investigational	
Glucocorticoids	Antiinflammatory, inhibit TNF- α , IL1, nitric oxide synthesis, decrease release PAF	Many	Controversial results of benefits in sepsis. Low doses most benefit
Pentoxifylline	Phosphodiesterase inhibitor. Elevates intracellular cAMP, inhibits TNF release	Available	Conflicting benefits
PAF antagonists	Recruits neutrophils and platelets inducing endothelial cell and organ injury	Investigational	Reduce thrombocytopenia in dogs given endotoxin
PAF-AH	Inactivates PAF	Recombinant	Beneficial in preliminary studies in people
		Investigational	
Antiinflammatory Cytokines			
IL-10	Reduced proinflammatory cytokines	Investigational	Effective in treated mice
Proinflammatory Mediators, Immunostimulants			
IFN- γ	Reverses monocyte inactivation caused by sepsis	Available for people	No effect on infectious complications in people in controlled studies
G-CSF	Maintain neutrophil numbers and responses	Filgrastim	Conflicting results in people
Immunoglobulins	Increase resistance to bacterial toxins by unknown mechanisms	Human and equine lyophilized	Investigational for this problem
Anticoagulants			
Antithrombin	Natural inhibitor of thrombin and other procoagulant serine proteases	Investigational	No advantage over heparin
Heparin	Inhibits coagulation	Widely available	Helpful in reducing mortality
Activated protein C	Inhibits coagulation via factors IIa, Va and VIIa, and stimulates fibrinolysis	Drotrecogin- α	Increases survival in people but can cause hemorrhage
Lazaroids	Free radical scavengers, membrane stabilization	Available, expensive	Increase survival in experimental animals
NSAIDs and Arachadonic Acid Antagonists			
Prostaglandin E1 and PGI2 (prostacyclin)	Antagonize arachadonic acid and metabolites	Investigational	Not effective
Ibuprofen, etc.	Cyclooxygenase inhibitors	Widely available	No effect on shock or survival
Ketoconazole	Thromboxane synthetase inhibitor	Available clinically	Not effective in controlled studies
Methylxanthines	Improved hemodynamics, inhibit platelet aggregation, decreased mediators	Pentoxifylline	Conflicting data on efficacy
Antitoxins			

Infectious Diseases of the Dog and Cat, 3rd Edition

LPS elimination	Polymyxin B on blood filter absorbs endotoxin	Investigational use in people	Some favorable results
Bactericidal permeability-increasing (BPI) protein	Binds to lipid-A of gram-negative bacterial endotoxin	Available for people	Used in meningococcal sepsis people. Not effective in canine parvoviral infection
Salmonella endotoxin antisera	Binds gram-negative endotoxins	Septi-serum®	Some benefit in parvoviral enteritis in pups
LPS analogues and antibodies	Interfere with LPS action	Investigational in animals	Analogues effective in mice, antibodies effective in horses
Antioxidants			
Nitric oxide inhibition	Restores blood pressure but also increases pulmonary and systemic vascular resistance	Investigational and methylene blue	Some favorable response in small studies in people
N-acetylcysteine	Replenishes intracellular glutathione; scavenges oxygen radicals	Available	Variable efficacy
Selenium	Scavenger of oxygen free radicals via dependent glutathione peroxidase	Available	Improved outcome and less renal failure in people
<i>TNF</i> , Tumor necrosis factor; <i>IL</i> , interleukin; <i>PAF</i> , platelet activating factor; <i>cAMP</i> , cyclic adenosine monophosphate; <i>PAF-AH</i> , PAF-acetylhydrolase; <i>IFN</i> , interferon; <i>NSAIDs</i> , nonsteroidal antiinflammatory drugs; <i>LPS</i> , lipopolysaccharide; <i>G-CSF</i> , granulocyte colony-stimulating factor.			

Physical methods of decreasing LPS concentration in peripheral blood through hemofiltration have been described, including plasma exchange, extracorporeal activated charcoal hemoperfusion, and hemoperfusion or plasmapheresis over polymyxin B; these therapies are not generally available in veterinary medicine. Antibodies designed to bind LPS, lipid A analogues designed to competitively bind LBP and LPS receptors, and use of polymyxin B, which avidly binds lipid A, have been described, but their clinical utility appears to be low in people, likely because SIRS has already been initiated.²⁶

Bactericidal permeability-increasing (BPI) protein, a protein of neutrophil granule origin, binds lipid A, and the human recombinant amino-terminal fragment of BPI (rBPI₂₁) was investigated in a randomized, blinded, placebo-controlled trial in dogs with CPV enteritis. When examined, affected dogs had elevated endotoxin levels; rBPI₂₁ did not have a significant effect on outcome, duration of hospitalization, or plasma endotoxin levels.²⁸

Therapies designed to antagonize the cytokine and other mediators of SIRS have also been described and include IL-1 and TNF- α receptor antagonists, anti-TNF- α monoclonal antibodies, soluble TNF- α receptors, glucocorticoids, lizaroids, various nonsteroidal antiinflammatory drugs (NSAIDs), platelet-activating factor (PAF) blockers, inducible nitric oxide synthase inhibitors, and activated protein C, among others.

TNF- α has been identified as an important mediator in sepsis. It produces many of the acute pathophysiologic manifestations; however, administration of monoclonal anti-TNF- α antibody has not been beneficial in protecting people from complications of septic shock.

IL-1 acts synergistically with TNF- α and a receptor antagonist (IL-1RA), which is a naturally produced cytokine produced by macrophages, has shown variable efficacy on survival of septic people.²⁹

Trials in people using PAF-antagonists have not shown improved survival rates⁴¹; however, use of enzymes that degrade endogenous PAF have been more favorable.²⁰ Dogs given endotoxin had less thrombocytopenia and neutropenia when they were pretreated with a PAF antagonist.³⁷

Infectious Diseases of the Dog and Cat, 3rd Edition

Proinflammatory mediators, such as IL-10, and immunostimulants such as IFN- γ and granulocyte colony-stimulating factor have also been investigated in people.^{26,41,16} Some data suggest that some people respond to pretreatment or early treatment with IFN- γ .¹⁰ Because animals are evaluated clinically after inflammatory mediators have been released, the benefits of these drugs in clinical settings have been less than anticipated.

Prostaglandins and leukotrienes are increased in sepsis from activation of cyclooxygenase and lipooxygenase pathways. Natural inhibitors prostaglandin E1 (PGE1) and PGI2 (prostacyclin) have not been effective in therapeutic studies. Inhibitors of cyclooxygenase and thromboxane synthetase, such as ibuprofen or ketoconazole, have had variable effects in treating human sepsis depending on the study.⁴¹

Antitoxins can be used to neutralize cytotoxic intermediates released in endotoxemia. A salmonella endotoxin antiserum has been developed to treat endotoxic shock in horses and dogs. BPI protein is an endotoxin-binding protein that can damage the cell membrane of gram-positive and gram-negative bacteria. Recombinant BPI inhibits inflammation caused by bacterial Group B protective surface protein. Endotoxin was also removed from sera by extracorporeal perfusion through polymyxin B filters. 338 339

Antioxidants, such as N-acetylcysteine, have been variably effective in septic patients while selenium produced a beneficial response.^{2,13} Nitric oxide is increased in sepsis, and although inhibition increases blood pressure, vascular resistance and use of methylene blue have been favorable in small studies.

38.8 PREVENTION

Immunization against CPV and proper management of large- and giant-breed dogs to lessen the occurrence of gastric dilation or volvulus will help prevent endotoxemia of intestinal origin. Appropriate surgical technique and postsurgical management, avoidance of indiscriminant use of antimicrobials and glucocorticoids, and careful management of IV and urinary catheters will minimize iatrogenic and nosocomial infections. Aggressive infection control measures should be developed and implemented in intensive care facilities. Finally, animals at risk for endotoxemia, especially those with established infections, should be managed promptly and appropriately for the primary disorder and monitored for signs of SIRS.

39 CHAPTER 39 Enteric Bacterial Infections

39.1 CAMPYLOBACTER INFECTIONS

James G. Fox

39.1.1 Etiology

Campylobacter is a genus of gram-negative, slender, curved, motile rods (1.5 to 5 μm \times 0.2 to 0.5 μm) that are found singularly, in pairs, or in chains with three to five spirals (Fig. 39-1). The cells can also be curved, S shape, or gull shape. *Campylobacter* species have a single, nonsheathed polar flagellum and microaerobic growth requirements. *Campylobacter jejuni* is the organism routinely associated with diarrheal disease in dogs, cats, and people as well as other domestic, wild, and laboratory animals. *Campylobacter coli*, distinguished from *C. jejuni* on the basis of hippurate hydrolysis, is also isolated from diarrheic animals and people. Other intestinal catalase-negative campylobacters, *Campylobacter upsaliensis* and *Campylobacter helveticus*, have been being isolated more frequently from asymptomatic and diarrheic dogs and cats. * Table 39-1 summarizes the features of these *Campylobacter* species.

* References 99, 117, 145, 184, 383, 381, 400.

39.1.2 Epidemiology

Privately owned adult dogs and cats generally have a lower isolation rate of *C. jejuni* than strays or those maintained in kennels or catteries, laboratories, and animal shelters.¹⁴⁷ It has been isolated from 21% and 29% of diarrheic cats and dogs, respectively, compared with 4% of clinically healthy cats and dogs.⁸² In other studies the isolation rate from feces of mature dogs and cats with and without diarrhea has varied from 0% to 50%.⁴²⁷ Prevalence of *C. jejuni* in clinically normal dogs in one report was significantly greater ($p < 0.05$) in dogs younger than 6 months old, dogs living in high-density and cohabitation housing conditions for long periods, and the autumn months.⁴⁵⁴ Cats less than 1 year old had a higher (30%) isolation rate of *Campylobacter* spp. compared with cats older than 1 year (3%).^{31a}

In a 6-year study, 64 of 227 commercially reared cats without clinical signs of diarrhea had microaerobic bacteria isolated from their feces.⁴⁰⁰ All the isolates were initially identified as *Campylobacter*-like organisms (CLOs) based on biochemical and phenotypic characteristics. DNA extractions from 51 of these isolates were subjected to the polymerase chain reaction (PCR) using primers specific for *Helicobacter* spp. and *Campylobacter* spp. Of the isolates, 92% (47 isolates) were positive for *Campylobacter* spp., 41% (21 isolates) were positive for *Helicobacter* spp., 33% (17 isolates) were positive for both genera, 59% (30 isolates) were positive only for *Campylobacter* spp., and 8%⁴ were positive only for *Helicobacter* spp. Sixteen of the 47 *Campylobacter*-positive cultures were positive for more than one species of *Campylobacter*. Based on a species-specific PCR assay, 83% of the isolates were identified as *C. helveticus*, 47% of the isolates were identified as *C. upsaliensis*, and 6% of the isolates were classified as *C. jejuni*. This study demonstrated that biochemical and phenotypic characteristics of microaerobic organisms in cat feces were insufficient to characterize mixed *Helicobacter* and *Campylobacter* infections. The finding of *C. helveticus* in a high percentage of the cats confirms the findings of a previous study in England in which the organism was cultured from the feces of healthy cats.⁴²³ Others have observed a high prevalence of *C. upsaliensis* and *C. helveticus* in

340

Infectious Diseases of the Dog and Cat, 3rd Edition

rectal swab specimens from dogs and cats and the lack of correlation between serotypes and genotypic analysis.³¹¹

Investigators in the Netherlands have documented a 26% prevalence of multiple *Campylobacter* species in *Campylobacter*-containing feces of dogs.²⁴³ Using multiple isolation methods (different antibiotic-supplemented media plus filtration), selecting 12 suspicious colonies per plate, and rapidly processing the samples, the authors were able to identify *C. jejuni*, *C. upsaliensis*, and *Campylobacter lari*. In two samples, all three species were isolated, whereas in the other four fecal samples, two species of *Campylobacter* were identified. Interestingly, none of the dogs infected with multiple species of *Campylobacter* had diarrhea.²⁴³ This asymptomatic characteristic was also true for cats harboring multiple species of *Campylobacter* and *Helicobacter*.⁴⁰⁰

Fig 39-1 Scanning electron microscopy view of *Campylobacter jejuni* adhered to chick embryo cell (×15,900).

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 39-1 Comparative Features of *Campylobacter* Species That Infect Dogs or Cats

CAMPYLOBACTER ORGANISM	MORPHOLOGIC AND DISTINGUISHING FEATURES	HOSTS	CLINICAL FEATURES
<i>C. jejuni</i> ; <i>C. coli</i>	Slender, curved, motile rods; found singularly, in pairs, or in chains with three to five spirals; curved S or gull shape; single, polar, nonsheathed flagellum; <i>C. coli</i> : hippurate negative	Dogs, cats, ferrets, cattle People	Neonates—diarrhea, adults— asymptomatic Diarrhea, systemic manifestations
<i>C. upsaliensis</i>	Catalase negative	Dogs, cats People	Asymptomatic Diarrhea, abscess, placental damage
<i>C. lari</i>	Grows at 42°C	Dogs People	Asymptomatic Bacteremia, urinary tract infections
<i>C. helveticus</i>	Catalase negative	Cats	Asymptomatic

Alterations in *Campylobacter* may occur with changes in intestinal microflora. In dogs, fecal *Campylobacter* species counts increased in a majority of dogs fed a probiotic containing *Enterococcus faecium*, whereas counts of *Salmonella* were higher and those of *Clostridium* species were lower.⁴⁶² Feeding of probiotics containing *E. faecium* favors the adhesion and colonization of *C. jejuni* and the dissociation from and reduction of *Clostridium perfringens* in the canine intestine.³⁷⁰

Puppies and kittens appear more likely to acquire *C. jejuni* and show clinical disease, probably because of a lack of previous exposure and development of protective antibody. Studies of pups show that shedding of *Campylobacter* species ranges from less than 5% to as high as 90%.

As with most enteric microbial pathogens, fecal-oral spread with foodborne and waterborne transmission appears to be the principal avenue for infection. Suspected sources of *Campylobacter* infection include contaminated meat products, particularly poultry and unpasteurized milk. Asymptomatic carriers can shed campylobacters in their feces for prolonged periods and directly infect other animals or contaminate food products or water. Nosocomial infection of hospitalized animals occurs, as does exposure through other pets in a household (e.g., ferrets, hamsters, birds, rabbits) and rural farm animals that may shed the organism.

39.1.3 Pathogenesis

The severity of the disease depends on the number of organisms ingested by the host as well as previous exposure and development of protective antibody. Other enteric pathogens, such as parvovirus and coronavirus, *Giardia* organisms, or *Salmonella* organisms, may play a synergistic role.^{45,384} Environmental, physiologic, and surgical stresses may also exacerbate the severity of the disease. Various virulence factors, such as enterotoxins, cytotoxins, or adherence or invasion properties, are expressed by different *C. jejuni*-*coli* isolates. A cytotoxin referred to as *cytolethal distending toxin* has been identified in *C. jejuni*, but its role in production of intestinal disease is not known. However, in vitro the cytotoxin causes distension of cell lines and cell cycle arrest in the G₂M1 phase in the cell cycle. Blood and leukocytes in the feces, congestion, edema, mucosal ulcers, and occasional sepsis in people suggest that the organism can be invasive. Experimental challenge in laboratory animals also indicates that the organism can be isolated from blood several days after challenge

340

341

Infectious Diseases of the Dog and Cat, 3rd Edition

inoculation. Experimental infections of puppies and kittens with strains isolated from people with diarrhea are less severe than those observed in the people from which the organisms were isolated. Animals appear to be more resistant or better adapted to the pathogenic effects of various different *C. jejuni* isolates and usually only develop watery mucoid diarrhea.^{278,360,362}

39.1.4 Clinical Findings

39.1.4.1 Dog

In many cases, dogs are asymptomatic carriers of *Campylobacter* species. The clinical syndrome occurs most frequently in dogs younger than 6 months. Animals may be more susceptible to clinical disease when stressed by hospitalization, concurrent disease, pregnancy, shipment, or surgery. *Campylobacter*-associated diarrhea has a wide clinical spectrum in dogs as well as people, ranging from mild, loose feces to watery diarrhea to bloody mucoid diarrhea. Acute campylobacteriosis that develops in puppies and some adult dogs is manifest by mucus-laden, watery, or bile-streaked diarrhea (with or without blood and leukocytes) for 5 to 15 days, partial anorexia, and occasional vomiting.^{142,144,146} Elevated temperature and leukocytosis may also be present. In certain cases, diarrhea can be chronic and last 2 or more weeks, can be intermittent, or in some cases can be present for several months.¹¹⁴ In people, *C. jejuni* can cause extraintestinal complications such as arthritis, meningitis, myocarditis, cholecystitis, and abortions. *C. jejuni* has been isolated from two dogs with bacteremia and cholecystitis.³³⁵ Clinical signs included anorexia, fever, and icterus. Ultrasonography showed a fluid-filled, abnormally thickened gallbladder wall in both dogs. *C. jejuni* and *Campylobacter fetus* are also recovered from the bile of people with cholecystitis, although infrequently.^{165,471} Insofar as *Helicobacter* species are present in liver and bile of various hosts (see Intestinal and Hepatic Helicobacters section in this chapter), detailed biochemical and phenotypic descriptions are necessary to fully characterize and validate whether microaerophilic organisms isolated from the hepatobiliary tract of dogs are *Campylobacter* or *Helicobacter* species. *Campylobacter*-associated abortion has also been noted in dogs, although it is infrequent.

39.1.4.2 Cat

In cats, clinical signs of campylobacteriosis are poorly documented in the absence of other pathogens. As with dogs, campylobacteriosis is usually asymptomatic. If clinical signs are evident, the animal generally is younger than 6 months. In a prevalence survey of 159 cats from pounds, 17 shed *C. jejuni* in the feces, but of these only 2 had bloody, mucus-laden diarrhea. *Giardia* species were present in both, combined with *Iso spor a* species in one cat and *Toxocara* species in the other. Another cat concurrently infected with *Salmonella* species and *C. jejuni* was depressed and anorectic but not diarrheic. Culture results from the two cats' feces after antibiotic therapy and clinical improvement were negative for *C. jejuni*.¹²⁹ Chronic diarrhea in another cat that had serum antibodies to *C. jejuni* plus positive culture results for the organism abated when treated with chloramphenicol. *C. jejuni* could not be recultured from the stool after therapy.¹³²

Infectious Diseases of the Dog and Cat, 3rd Edition

39.1.5 Diagnosis

39.1.5.1 Microscopic Examination

Rapid presumptive diagnosis is possible using either dark-field or phase-contrast microscopy. Fresh fecal samples are examined for curved bacteria with the characteristic darting motility of *C. jejuni*. This method is especially sensitive in people (and perhaps dogs and cats) during the acute stage of clinical diarrhea. With Gram stain, faintly staining, gram-negative, gull-wing-shape slender rods are apparent. Maintaining the safranin counterstaining improves their visualization.²⁹⁶ However, based on morphology alone, these organisms could also be enteric helicobacters. Presence of fecal leukocytes should be ascertained, because leukocytes may be found in enteritis caused by natural or experimental infections with *C. jejuni*.

39.1.5.2 Cultural Identification

Rectal swab specimens can be obtained, or fresh feces can be collected. For diagnosis of *C. jejuni* cholecystitis and bacteremia, appropriate diagnostic testing, including abdominal ultrasonography, gallbladder aspiration with bile culture, and blood culture, should be performed.³³⁵ Transport of fecal specimens usually does not present isolation difficulties because *C. jejuni*-coli remain viable in feces at room temperature for at least 3 days and at refrigeration temperatures for at least 1 week. However, higher rates of isolation can be achieved with shorter time delays.

Swabs obtained from fresh feces are streaked onto *Campylobacter* blood agar plates (Campy-BAP, Scott Laboratories, Fiskeville, R.I.), which are then placed in an oxygen-reduced atmosphere. The standard method for culture uses commercially available selective medium that inhibits fecal flora; however, it may not be necessary for isolating thermophilic *Campylobacter* strains from acute cases of enteritis. Similarly, broth enrichment procedures have not been more effective than direct plating on Campy-BAP for isolation of *C. jejuni* from canine feces.

Plates are incubated at 37° C to 42°C and examined at 72 to 96 hours. Colonies composed of curved gram-negative rods are round, raised, translucent, and sometimes mucoid. Isolates are identified as *C. jejuni* on the basis of positive oxidase and catalase reactions, susceptibility to nalidixic acid, resistance to cephalothin, and inability to grow at 42°C under aerobic conditions. *C. upsaliensis* and *C. helveticus* are catalase negative, and isolation is enhanced by selective filtration of feces to be cultured through a 0.45-μ filter.¹⁷¹ Investigators in South Africa have published results for a protocol that has been in use in their diagnostic laboratory since 1990 and allows primary isolation of multiple species of *Campylobacter* and *Helicobacter* from the diarrheic specimens of individual children.^{258,259} Filtrates are plated onto antibiotic-free blood agar plates and incubated in an H₂-enriched atmosphere. These authors not only documented an increase in the number of CLOs isolated but also were able to culture *C. upsaliensis* for the first time. They have reported a 16.2% prevalence of multiple species of CLOs based on primary isolation, biochemical characterization, and serologic confirmation. They frequently recovered between two and five species of CLOs from one stool sample, with *C. jejuni* (different serotypes), *C. coli*, *C. upsaliensis*, *Helicobacter fennelliae*, and *Helicobacter cinaedi* being commonly isolated.²⁵⁸ Additional analysis using the filtration isolation technique with cat and dog feces may yield prevalence rates for mixed *Helicobacter* and *Campylobacter* infections even higher than those reported recently in cats.⁴⁰⁰

Infectious Diseases of the Dog and Cat, 3rd Edition

Various procedures have been used, especially during outbreaks, to identify different serotypes of *C. jejuni-coli* by using thermostable and thermolabile surface antigens.³⁰² Isolates from people and various animal species have shown that extensive serologic heterogeneity exists within *C. jejuni-coli*. Many of the isolates frequently found in diarrheic and normal dogs and cats have had serotypes frequently encountered in human patients.¹³³ For example, serotype 4 (commonly associated with outbreaks of *C. jejuni*-associated diarrhea in people) was also a common serotype isolated from commercially reared beagles.^{133,443} Plasmid characterization, restriction enzyme analysis, and ribotyping can also be used for strain identity, but these techniques require specialized methodologies. The technique of restriction enzyme analysis of whole genomic DNA allowed verification of *C. jejuni* zoonotic transmission to personnel in vivaria caring for wild-caught coyotes.¹⁵²

39.1.5.3 Serologic Testing

Various techniques can detect serum antibodies to various antigens of *Campylobacter*. A specific bactericidal assay has been used to demonstrate a rising antibody titer in people and animals. Other serologic assays, such as the enzyme-linked immunosorbent assay (ELISA), have been developed to survey human populations during outbreaks of campylobacteriosis and ascertain previous exposures to the organism. Unfortunately, no systematic studies have been performed in dogs and cats to ascertain the importance of antibody titers as an indicator of infection in animals with or without diarrhea.

39.1.5.4 Pathologic Findings

Gross visible findings in naturally and experimentally infected canine neonates are abnormally fluid colonic contents as well as thickening, congestion, and edema of the colonic mucosa.⁶⁸ Microscopically, the colon and cecum show decreases in epithelial cell height, brush borders, and numbers of goblet cells. Hyperplasia of epithelial glands results in a thickened mucosa. Subepithelial congestion, hemorrhage, and inflammatory infiltrates have also been seen. Findings in adult animals inoculated with *C. jejuni* were similar to those in some dogs with natural campylobacteriosis: stunting of intestinal villi, infiltration of lamina propria with inflammatory cells, and hyperplastic Peyer's patches.²⁷⁸ Naturally occurring intestinal lesions in adult dogs have consisted of mucosal hyperplasia in the colon characterized by immature hyperchromatic, hyperplastic epithelial cells with a high mitotic index, and deep and irregular crypts.¹⁴² With Warthin-Starry stain, CLOs have been demonstrated attached to but not within colonic epithelium. However, in experimentally produced *C. jejuni* colitis in macaques, intraepithelial invasion of *C. jejuni* was demonstrated by electron microscopy (EM).³⁷⁸ A relative increase had been noted in the number of lymphocytes infiltrating the lamina propria. Ileal lesions consisted of focal, shallow crypts and blunt, irregular villi, which occasionally fused. Mild congestion and dilatation of lacteals has been found. Stunting and fusing of intestinal villi and mononuclear cell infiltrates in lamina propria have also been noted in subacute stages of parvovirus infection and in a dog with protracted *Campylobacter*-associated diarrhea.⁷⁵ Experimentally, selected strains of *C. jejuni* produce hepatitis in mice, and the organism has been isolated from inflamed livers of dogs.

39.1.6 Therapy

The efficacy of antibiotic therapy and treatment of *Campylobacter*-associated diarrhea in the dog and cat is not known—nor is it known whether antibiotics effectively alter the course of enteric disease. However, in some dogs and cats with severe diarrhea, antibiotic therapy may be warranted. Antibiotic treatment of infected

Infectious Diseases of the Dog and Cat, 3rd Edition

animals may be instituted to minimize exposure to people and other pets in the household. Fortunately, strains of *Campylobacter* isolated from animals and people are susceptible to several antimicrobial agents (Table 39-2). Erythromycin, the drug of choice for *Campylobacter*-induced diarrhea in people, may also be effective in the treatment of the disease in animals. Treatment of clinically affected cats and dogs has resulted in resolution of the illness and elimination of the organism as determined by *Campylobacter*-negative fecal culture results. However, failure to eliminate *C. jejuni* with oral erythromycin from ferrets housed in a research environment has also been noted.¹²⁸ Erythromycin can also cause gastric irritation and vomiting in some animals.

Chloramphenicol has been given with mixed results to treat *Campylobacter*-associated diarrhea in dogs and cats. Treatment in dogs has resulted in abatement of clinical signs. However, the same organism has been reisolated after therapy has been completed. It is possible that these dogs developed an antibiotic-induced carrier state (as occurs in enteric *Salmonella* infections), experienced a protracted period of *Campylobacter* shedding, or became reinfected. Clinical improvement was noted in a diarrheic cat treated with chloramphenicol, and fecal culture results after completion of the treatment were negative for *C. jejuni*. *C. jejuni*-associated bacteremia and cholecystitis have been successfully treated with IV cefoxitin, a second-generation cephalosporin, or oral erythromycin (see Table 39-2) for 21 days, which resulted in complete resolution of all clinical and laboratory abnormalities.³³⁵

Several other antibiotics are active against *Campylobacter* strains isolated from dogs and cats. These strains show in vitro susceptibility to furazolidone as well as gentamicin, neomycin, clindamycin, and tetracycline. However, resistance in many strains to various tetracyclines and kanamycin is caused by plasmids that confer resistance and are transmissible within *C. jejuni* serotypes. Antimicrobial agents that are usually ineffective include penicillin, ampicillin, polymyxin B, trimethoprim, and vancomycin. In vitro resistance also develops to metronidazole and sulfadimethoxine.¹³⁹ Many *Campylobacter* strains produce β -lactamase, which accounts for the resistance to penicillin and ampicillin. Before therapy is instituted, isolation and sensitivity tests should be done. Some animals continue to shed the organism despite antibiotic therapy. Quinolone antibiotics may be useful in eliminating *C. jejuni* and *C. coli* in asymptomatic carriers, but drug resistance can develop to this class of antibiotics.

39.1.7 Public Health Considerations

Although *C. jejuni*-*coli* exist as commensal gastrointestinal (GI) microflora of domestic animals, they are a leading cause of enteric disease in people. The infectious dose of *C. jejuni* for humans is as low as a few hundred organisms. The disease is often severe in people and in addition to diarrhea may be characterized by vomiting, fever, and abdominal discomfort. When dogs or cats are the incriminated reservoirs for human infection, they usually have been recently acquired from pet stores or kennels and have had diarrhea. However, asymptomatic dogs and cats can also be a source of infection to people. A survey conducted in Seattle, Washington, indicated that 6% of sporadic *C. jejuni* infections were linked to exposure to diarrheic kittens.¹³ Another study reported that 30% of the cases in university students were associated with healthy cats.¹²² Risks from pet exposure have been very high among infants and children.^{446,497} Other nonpet sources of exposure risk include contact with cattle or chickens, eating salad vegetables, swimming in natural water sources, and drinking natural bottled mineral water.^{11,104,393a} These are all risks associated with fecal contamination in the environment. In all studies a consistent risk factor for acquiring *C. jejuni* enteritis has been the consumption of unpasteurized milk or raw or undercooked meat, particularly chicken or foods that have contacted this meat during preparation.^{11,122} Nevertheless, veterinary practitioners should alert owners of the zoonotic implication of *Campylobacter* infection for other household members and stress the importance of exercising appropriate

Infectious Diseases of the Dog and Cat, 3rd Edition

hygienic measures, especially when pets have diarrhea. An alarming concern is that *Campylobacter* strains worldwide from human and animal patients are developing increased antibacterial resistance to drugs such as the quinolones.^{276,409,440,319a} Presumably, this has been linked to the use of these drugs in animal husbandry situations. An additional zoonotic risk is the development of Guillain-Barré syndrome, a polyradiculoneuritis in people, which may occur after infection with *C. jejuni*. The GM, gangliosides of peripheral nerves, share epitopes with lipopolysaccharides of these bacteria.^{309,332,}

Table 39-2 Drug Therapy for Nonenteric Salmonellosis and Other Enteric Bacterial Infections in Dogs and Cats

DRUG ^a	SPECIES	DOSE ^b (mg/kg)	ROUTE	INTERVAL (HOURS)	DURATION (DAYS)	INDICATED INFECTIONS
Erythromycin	D	20	PO	12	5–21	Campylobacteriosis, nongastric

b Dose per administration at specified interval.

c Monitor for renal failure.

Infectious Diseases of the Dog and Cat, 3rd Edition

d Other quinolones such as ciprofloxacin, difloxacin, or marbofloxacin, are alternatives, although dosages vary.

C. jejuni has been linked to immunoproliferative small bowel disease, also known as α -chain disease in people.²⁶⁵ This disease is a form of lymphoma that arises in small intestinal tissue. Interestingly, early forms of the disease respond to antibiotics, similar to *Helicobacter pylori*-associated mucosa-associated lymphoid tumor (MALT) lymphoma, which has tumors that regress in responsive to antibiotic therapy.

C. upsaliensis has been isolated from a person with bloody diarrhea as well as his pet dog, which also had diarrhea. The plasmid profile of the two strains were identical, suggesting that *C. upsaliensis* infection may also be a zoonosis.¹⁷¹ *C. upsaliensis* was isolated from the blood and fetoplacental tissue of a woman with diarrhea who was 18 weeks pregnant and had been in contact with a cat that had a similar strain of *C. upsaliensis* isolated from its feces, also suggesting zoonotic transmission.¹⁸¹ Others have also reported *C. upsaliensis* gastroenteritis in people who have had contact with pets.³⁴⁵ Human and canine isolates of *C. upsaliensis* have distinct ribotypes and plasmid profiles, suggesting that host-specific genotype differences may exist among strains of *C. upsaliensis*.⁴²⁴ However, these analyses or other molecular fingerprinting techniques must be used on suspected pet-associated *C. upsaliensis* zoonoses before the definitive transmission can be defined.

39.2 GASTRIC *HELICOBACTER* INFECTIONS

James G. Fox

39.2.1 Etiology

Gram-negative, microaerophilic, curved to spiral-shape bacteria isolated from gastric mucosa of people and animals have created a great deal of interest because of their causal role in gastric disease.²⁶⁷ The genus *Helicobacter* includes 24 formally named species as well as other unnamed closely related organisms.* Once considered a predominantly sterile organ protected from microbial colonization by low gastric pH, the euchlorhydric stomach is now known to be colonized with gastric bacteria belonging to the newly named genus *Helicobacter* (Table 39-3 and Fig. 39-2), whereas the hypochlorhydric stomach is resistant to their replication. These organisms possess a high level of urease activity that allows them to survive in an acidic environment. The type species *H. pylori* colonizes the stomach of 20% to 95% of human adult populations worldwide (see Fig. 39-2, A).¹⁷² *H. pylori* causes persistent, active, chronic gastritis and peptic ulcer disease in people and has been linked to the development of gastric adenocarcinoma and gastric mucosa-associated lymphoma.³⁴¹ *H. pylori* has also been isolated from inflamed gastric tissue of cats in a commercial cattery and can experimentally infect cats.^{188,349}

344

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 39-3 Comparative Features of Gastric *Helicobacter* Species That Infect Dogs and Cats

GASTRIC <i>HELICOBACTER</i> ORGANISM ^a	MORPHOLOGIC AND DISTINGUISHING FEATURES	HOSTS	CLINICAL FEATURES
<i>H. pylori</i>	Small (2–4 μ); curved to spiral shape	People, nonhuman primates	Gastritis, peptic ulcer; gastric neoplasia, also asymptomatic
<i>H. (Flexispira) rappini</i> (Lockard type 1)	Fusiform shape; entwined with multiple periplasmic fibers; multiple bipolar sheathed flagella	Cats Sheep People and animals Dogs	Gastritis in catteries Abortion, hepatic necrosis Intestinal disease Asymptomatic, gastric and fecal isolate
<i>H. felis</i> (Lockard type 2)	7–10 μ long; superficial periplasmic fibers; sparse; exist singly or in groups; multiple bipolar flagella with sheaths	Cat, dogs, people	Cultured from stomach, subclinical (histologic) gastritis
<i>H. bizzozeronii</i> (Lockard type 3, <i>Gastrospirillum hominis</i> , <i>H. heilmannii</i>)	7–10 μ long; tightly spiraled; no periplasmic fibers and difficult to culture deep in gastric glands and parietal cell canaliculi	Dogs, cats, people, swine, nonhuman primates	Common gastric colonizer Inflamed gastric tissue of people mucosa-associated lymphoid tumor (MALT) in people
<i>H. salomonis</i>	5–7 μ long by 0.8–1.2 μ wide; tufts of sheathed flagella at each end; not as tightly spiraled as in <i>H. bizzozeronii</i> ; isolated from glands of corpus of stomach	Dogs	Subclinical

^a Previously used terms for organisms are in parentheses.

Other gastric helicobacters have been linked to gastritis in various mammalian hosts.^{*} Many of these infected animals have asymptomatic gastric inflammation. Additional species of gastric *Helicobacter* have been isolated from stomachs of various mammalian hosts, including dogs (*Helicobacter rappini*, *Helicobacter felis*, *Helicobacter bizzozeronii*, *Helicobacter heilmannii*-like, *Helicobacter salomonis*, *Helicobacter bilis*), cats (*H. felis*, *H. heilmannii*-like, *Helicobacter pametensis*), ferrets (*Helicobacter mustelae*), cheetahs (*Helicobacter acinonychis*), dolphins, whales, harp seals (*Helicobacter cetorum*), and nonhuman primates (*H. heilmannii*-like). (See Table 39-3 and Fig. 39-2 for a summary of the gastric helicobacters infecting dogs and cats.)

Historically, these *Helicobacter* organisms in dogs and cats have been described histologically as gastric spirilla.¹²³ Three morphologically distinct forms have been described in dogs and cats.^{274,480,481} More than one of these morphologic types of bacteria can be seen in the stomach of one animal. Lockard type 1 is a bacterium with multiple bipolar, sheathed flagella entwined with periplasmic fibers, which appear to cover the entire surface of the organism (see Fig. 39-2, B). A similar organism was isolated from aborted ovine fetuses and was classified as *Flexispira rappini*.^{242,331} This bacterium, classified as a *Helicobacter* species based on 16S RNA sequencing, has been isolated from the feces of asymptomatic mice, dogs, and cats as well as from the stomach of dogs.^{274,391} *Helicobacter bilis*, a member of the *Flexispira* taxa associated with hepatitis and inflammatory bowel disease (IBD) in mice, has also been cultured from the stomachs of dogs. Lockard type 2 also has

Infectious Diseases of the Dog and Cat, 3rd Edition

periplasmic fibers, but they are most sparsely distributed on the organism and can appear singly or in groups of two, three, or four. This organism has been cultured from the feline stomach and has been named *H. felis* (see Fig. 39-2, C).³⁴⁴ The third type of organisms, called *gastrospirilla*, are the bacteria most commonly found in mammalian stomachs. These are also very tightly spiraled, but they have no periplasmic fibrils. On the basis of morphologic characteristics, it appears that the Lockard type 2 organism primarily is restricted to cats and dogs, whereas type 3 has been seen in cats, dogs, nonhuman primates, cheetahs, swine, and people. The type 3 bacterium has been given various names in different hosts, including *Gastrospirillum hominis*, and *H.*

heilmannii.^{191,412} *H. heilmannii* is a provisional name given to closely related or perhaps identical organisms that have not yet been cultured on artificial media. These organisms (see Fig. 39-2, D) are morphologically similar to *H. bizzozeronii* (see Fig. 39-2, E) found in the gastric mucosae of nonhuman primates, dogs, cats and pigs. *H. bizzozeronii* has also been cultured from the inflamed gastric tissue of people.¹² EM shows that this organism lacks periplasmic fibers, unlike *H. felis*. This morphologic distinction is confounded with the observation of two gastric *Helicobacter*-like organisms (GHLOs). These GHLOs from canine stomachs lacking periplasmic fibers had genetic analysis compatible with *H. felis*.⁹³ *H. salomonis* (see Fig. 39-2, F) is a gastric helicobacter with unique molecular characteristics that has been isolated from dogs.^{191,219} Because of the difficulty in cultivating these organisms to determine their phenotypic properties, *H. bizzozeronii* and *H. salomonis* from dogs are the only formally named gastric helicobacters based on defined biochemical and genetic analyses.¹⁹⁰

* References 123, 192, 316, 328, 499.

39.2.2 Epidemiology

Although infected animals and people mount a significant systemic IgG response to gastric organisms, the antibodies are not protective and the organisms persist in the mucous layer or closely adhere to the gastric epithelium, protected from the gastric acidic milieu. The mechanisms of transmission are poorly understood. Gastric helicobacters have specific enteric tissue tropism and colonize only gastric and not intestinal epithelium. Fecal-oral transmission has been suggested, and gastric helicobacters have been isolated from feces of animals and people.³⁴² *H. mustelae* was isolated from feces of ferrets, particularly when ferrets had drug-induced hypochlorhydria.¹⁴⁸ *H. pylori* has been isolated from feces of children from a third-world country as well as from infected adults from a more developed country.^{236,450} In pups, experimentally inoculated gastric helicobacters have been acquired during the lactation period, and puppies have infected each other.¹⁹⁰ Gastric helicobacters have been isolated from the environment in surface waters,¹⁹⁵ likely a result of fecal contamination. Indirect transmission in this manner might result in more widespread dissemination. One concern is that helicobacters are more resistant than coliforms to chlorination.

345

Oral-oral transmission is more likely and is supported by clinical observations of people being infected by exposure to gastric secretions,³⁴² isolation of *H. pylori* from dental plaque and tissue, and nosocomial infection from improper disinfection of gastric pH probes and endoscopic equipment. Similar transmission routes are also probable for gastric *Helicobacter* in animals. Vomitus containing gastric *Helicobacter* is another likely source for transmission.¹¹¹ Cats naturally infected with *H. pylori* were screened by culture and PCR for the organism in salivary secretions, gastric juices, gastric tissues, and feces.¹⁴⁹ *H. pylori* was cultured from salivary secretions (50%) and gastric fluid samples (91%) from cats. A PCR product specific for an *H. pylori* surface protein was amplified in 42% of feline dental plaque specimens and 80% of feline fecal specimens. Isolation of *H. pylori* from feline mucosal secretions suggests a zoonotic risk exists from personnel handling of *H. pylori*-infected cats in vivaria.¹⁸⁸ In comparison, *H. pylori* infection was not detected in stray cats,⁹⁶ which may reflect an anthroponosis in the closed commercial cattery where *H. pylori* was present in 100% of the animals. Additional studies using molecular, cultural, and histologic techniques are needed to ascertain whether *H. pylori* naturally colonizes dogs and cats.

346

The prevalence of gastric *Helicobacter* spp. infections in clinically healthy colony-raised dogs and cats in high population densities routinely approaches 100%, indicating the organisms' unique ability to colonize the stomach of numerous hosts selectively and efficiently.⁴⁰⁴ In laboratory-reared beagles, *H. felis* and other spiral helicobacters were observed in high numbers in the gastric glands of the fundic-pyloric junction and the cardia. These organisms were associated with lymphoid hyperplasia and parietal cell degeneration.^{197,274} In pet dogs and cats a series of gastric biopsy samples were examined for the presence of GHLOs.²⁰⁰ GHLOs were observed in 82% of dogs and 76% of cats; the bacteria were present in the mucus of foveolar epithelia, gastric pits, and parietal cells. More lymphoid follicles are found in the stomachs of older random-source cats with high numbers of GHLOs in their gastric mucosae than in younger cats with lower numbers of GHLOs.³³⁶

Infectious Diseases of the Dog and Cat, 3rd Edition

39.2.3 Pathogenesis

Because gastric helicobacteriosis is widespread but the clinical disease is less common, host factors are likely responsible for adverse outcomes caused by infection. Chronic or chronic active gastritis resulting from oral inoculation of *Helicobacter* species has been experimentally produced in people, germ-free pigs and dogs, specific-pathogen-free (SPF) cats, mice, and nonhuman primates with *H. pylori*; in ferrets with *H. mustelae*; in kittens with *H. acinonychis* and *H. heilmannii*; and in germ-free dogs, SPF dogs, mice, and rats with *H. felis*.¹²³ The *H. pylori*-associated gastritis in people consists of polymorphonuclear cells as well as mononuclear cell infiltrates and is classified as active chronic gastritis. Persistent *H. pylori* infections in people (particularly children) and the domestic cat also are often characterized by lymphoid aggregates and gastric lymphoid follicles.^{130,189} Inflammation and associated lymphoid follicles were primarily located in the antrum, which corresponded to the heaviest concentration of *H. pylori*.¹⁸⁸ Ultrastructurally the organisms were numerous in the gastric mucus, were less frequently adhered tightly to gastric epithelia, and formed pedestals between bacterial membranes and the epithelial microvilli.¹⁸⁸

In the past, gastric lymphoid elements were considered a normal histologic finding in dogs and cats. However, experimental and clinical evidence suggests that they are the result of host responses to *Helicobacter* antigens.⁴⁰⁷ The presence of GHLOs is often associated with a reduction in mucous content of surface epithelia, occasional intraepithelial leukocytes, and some degenerating glands. The gastritis observed in dogs and cats with non-*H. pylori* helicobacters is generally mild. Eosinophils in gastric mucosae of animals can also be a major component of the inflammation, particularly in the acute phase of the infection.^{130,268,365} Neutrophils and eosinophilic infiltrates, interepithelial globule leukocytes, epithelial dysplasia, and up-regulation of certain mucosal proinflammatory interleukins (IL-1 β and IL-8), and interferon- γ (IFN- γ) are noted in *H. pylori*-infected cats but not in uninfected control cats.^{103,406,432} Despite the inflammatory and infiltrative changes, mild gastritis caused by *H. felis* in cats did not alter gastric secretion.⁴⁰⁷ In dogs with naturally acquired gastritis, mucosal pathology was related to cytokine mRNA expression with neutrophils to IL-8 and IFN- γ , macrophages and lymphocytes to IFN- γ , and fibrosis to INF-1 β .^{492a}

The degree of GHLO colonization and lymphoid follicles correlated well in cats but not in dogs. If the number of GHLOs in dogs was classified as high, then lymphoid follicles were more likely to be present. In high-grade GHLO infections, glandular degeneration was more pronounced in cats than dogs.²⁰⁰ The majority (91%) of naturally infected pet cats had gastric helicobacters.³¹⁶ All cats had mild to moderate gastritis in the antrum or body, regardless of the presence or density of bacteria. In other naturally infected cats, infected sick cats had a higher degree of pyloric but not fundic inflammation than healthy infected cats and uninfected cats.⁴³³ In dogs²⁶¹ the severity of gastritis correlated with infection but not with the clinical sign of vomiting. In other studies,⁹² 100% of laboratory and shelter dogs and 67% of pet dogs were colonized with GHLOs that were morphologically consistent with *H. heilmannii* or *H. felis*. Regardless of the colonization intensity, all dogs had mild to moderate gastritis, and *H. pylori* was not isolated.

Experimentally, *H. felis* infection in dogs for 26 weeks did not correlate with number of *H. felis* observed and degree of inflammation or number of affected lymphoid follicles.⁴⁰³ Furthermore the gastric secretory axis was not perturbed in *H. felis*-infected dogs or dogs naturally infected with GHLOs.⁴⁰⁵

Infectious Diseases of the Dog and Cat, 3rd Edition

Competitive inhibition may occur in gastric helicobacteriosis; the colonization by one organism suppresses proliferation of other helicobacters. *H. pylori*-infected cats did not have large gastric spiral organisms colonizing the gastric mucosa. When 6-week-old pups with gastric *H. salomonis* were experimentally infected with *H. bizzozeronii*, infection by *H. salomonis* was suppressed.¹⁹⁰ This phenomenon has also been suggested to account for the rare occurrence of concurrent infection in people and nonhuman primates with large gastric spiral organisms and *H. pylori*.^{86,87,196,267,429} Experimental inoculation of the feline *H. pylori* strain into naive cats without gastric infection caused by GHLOs confirmed that *H. pylori* produces a persistent gastritis identical to that noted in cats naturally infected with *H. pylori*.¹³⁰ *H. pylori* was isolated on serial biopsies and at necropsy 7 months after inoculation from all cats.¹³⁰ Additional studies are required to ascertain whether duodenal and gastric ulcers have an infectious component in dogs and cats.¹³⁴

39.2.4 Clinical Findings

Although gastric helicobacters produce gastritis in people and animals, they usually cause asymptomatic infection in their hosts. The reason most infected individuals remain asymptomatic but some have more serious disease is unclear.^{92,188} However, clinical signs in pet animals attributable to *Helicobacter*-associated gastritis do occur.^{492a} Signs include chronic vomiting, weight loss, and in some cases, severe emaciation or diarrhea.^{93,200} Vomiting in dogs with chronic superficial gastritis attributed to gastric spiral organisms has been characterized as intermittent, consisting of mucus or gastric secretions, sometimes containing bile. Pica, belching, anorexia, and weight loss also are occasionally noted. Signs attributed to gastric helicobacteriosis have been based on finding these organisms in gastric biopsy samples from animals with GI illness. Because these organisms can be present in clinically healthy animals, the direct cause-and-effect relationship to clinical illness cannot always be ascertained.³¹⁹

346

347

Fig 39-4 *Helicobacter* organisms visible on Giemsa stain of smear made from gastric biopsy forceps (×1000). (Courtesy University of Georgia, Athens, Ga.)

39.2.5 Diagnosis

As in people a diagnosis of chronic gastritis in animals cannot be made by gross visual endoscopic examination of the gastric mucosa (Fig. 39-3). Cytologic examination of impression smears made from gastric biopsies can reveal the presence of spiral bacteria (Fig. 39-4); however, their role if any in the inflammatory process cannot be determined. Histologic evaluation of gastric biopsy samples using a special silver stain or modified Giemsa stain to reveal the presence of GHLOs is required (Fig. 39-5). A definitive diagnosis requires culture and isolation of the specific species of *Helicobacter*. Unfortunately, *H. bizzozeronii* is the most common spiral organism in dogs and cats, and it has been extremely difficult to culture on artificial media.¹⁹¹ *H. felis* is also difficult to isolate. In practice, histologic findings of inflammatory changes accompanied by gastric spiral organisms on the gastric mucosa or in the gastric mucous layer have been used for diagnosis. *H. felis* cannot be distinguished from *H. heilmannii* by histologic examination; EM and molecular evaluation are necessary. Cytologic examination of gastric biopsy specimens in dogs has proven equal to or better for detecting infection than histologic examination or the rapid urease test.¹⁹² For cytologic information, mucus covering the gastric mucosa is collected with a cytology brush during endoscopic examination and before lavage. It is smeared on a slide, dried, and preferably stained with May-Grünwald and Giemsa. The numbers of organisms can be evaluated. However, no information regarding inflammatory changes in the stomach can be obtained.

Fig 39-5 *H. pylori* in crypt of cat stomach (Warthin-Starry stain, $\times 1000$).
(Courtesy Elizabeth Howerth, University of Georgia, Athens, Ga.)

Helicobacter organisms are difficult to recognize histologically with hematoxylin-eosin stains. Silver (Warthin-Starry, Genta, or Steiner methods) and immunohistochemical stains are needed to identify these organisms. In infected cats, reactive inflammation varies in intensity and location within the stomach. *H. heilmannii*-like infected cats have had moderate lymphoid follicular hyperplasia and mild inflammatory infiltrates composed of lymphocytes, plasma cells, and macrophages in the mucosae.³⁹⁰ *H. pylori*-infected cats have more severe inflammatory lesions in the pyloric mucosae with additional inflammatory cells such as neutrophils and eosinophils. In addition, diffuse fibrosis and atrophy of the pyloric mucosae were observed.³⁹⁰

Because oral bacteria and bacteria refluxed from the duodenum (e.g., Enterobacteriaceae, diphtheroids, streptococci, and anaerobes) may overgrow the fastidious *Helicobacter* species, selective media are available for isolation. Media consist of *Brucella* agar with 10% horse blood containing vancomycin (10 mg/L), polymyxin B (2500 U/L), and trimethoprim (5 mg/L). Fresh media are recommended for optimal growth. Various *Helicobacter* spp. have different antibiotic susceptibilities, and selection of the type and quantity of antibiotics in culture media may determine success of isolation. Helicobacters, like campylobacters, require special environmental and cultural conditions for their growth. The organisms are thermophilic and grow at 37°C, with some species growing at 42°C. Growth on chocolate or blood agar takes 3 to 5 days. For *H. bizzozeronii*

Infectious Diseases of the Dog and Cat, 3rd Edition

isolation, incubation requires 5 to 10 days.¹⁹¹ Helicobacters do not grow under aerobic or anaerobic conditions but achieve optimum growth in high humidity with microaerobic conditions.

Table 39-4 Comparison of Techniques to Diagnose Gastric Helicobacter Infection

TECHNIQUE	ADVANTAGES	DISADVANTAGES
Invasive		
Endoscopy	Provides biopsies for histopathologic confirmation	Requires anesthesia
	Allows detection of ulcers and neoplasia	Is invasive and expensive
	Permits culture and susceptibility testing	Has prolonged culture (~2wk) with low sensitivity
	Allows for biopsies and rapid urease-based tests	Yields false positives with bacterial overgrowth
Rapid urease test	Analyzes biopsy specimen quickly (<3 hr)	Yields false negatives with antacids May indicate false-positive strains with other urease-producing organisms
Touch cytology	Allows identification of organism's morphology and numbers	Occasionally indicates false-negative strains Provides no information regarding inflammation in gastric mucosae
Histopathology	Allows observation of gastric pathologic changes	Inflammation not always correlated with clinical signs
Culture	Provides specific identification about infecting strain	Is difficult and prolonged and may be impossible for many helicobacters
Polymerase chain reaction (PCR)	Allows rapid detection and classification of organism	Positive indicates live or dead organisms, not clinical disease
Electron microscopy	Allows for morphologic differentiation of species	Is an expensive research tool
Noninvasive		
Serologic testing	Is minimally invasive with low exposure	Does not allow visualization of lesions or identification of organisms
	Allows retrospective evaluation	Is not reliable in animals
Urea breath test	Is useful for monitoring Is minimally invasive and provides rapid results	Does not allow visualization of lesions or identification of organisms
Urea blood test	Is minimally invasive and allows evaluation of therapy	Gives false negatives during therapy Does not allow visualization of lesions or identification of organisms
Stool antigen testing	Is noninvasive and convenient	Requires fecal specimen
Salivary IgA testing	Is noninvasive and convenient	Requires fecal specimen Has low accuracy and specificity
PCR of tissue or secretions	Allows rapid detection and classification	Is a research tool that is expensive and has limited availability
		Does not distinguish between live and dead organisms
		Close similarity of currently used genes

Infectious Diseases of the Dog and Cat, 3rd Edition

A comparison of the advantages and disadvantages of diagnostic modalities for gastric helicobacteriosis is summarized in Table 39-4. Isolation of helicobacters is enhanced by proper processing of gastric tissue. Mincing the gastric tissue with sterile scalpel blades or using a tissue homogenizer enhances isolation. If immediate processing of the biopsy sample is not possible, the tissue can be placed in sterile 30% glycerol in *Brucella* broth at 4°C for at least 5 hours. Specimens in this media can also be frozen at –80° C for longer periods for subsequent culture of the biopsy sample or transport of previously characterized organisms.

A provisional diagnosis of gastric helicobacters takes advantage of a biochemical feature of these organisms: the ability to produce large quantities of urease. Gastric biopsy samples can be placed in a urea broth containing a pH indicator (phenol red) and a preservative (sodium azide). Rapid urease test kits are available commercially (CLOtest, Kimberly-Clark Healthcare, Roswell, Ga.) and can be used very effectively and economically in dogs.⁵⁰⁰ A positive result correlates with the presence of gastric spiral organisms but does not definitively determine their pathogenic potential. Another urease test for people (that has been perfected only in research animals), is the urea breath test, which measures expired radiolabeled carbon dioxide, a by-product of a carbon-labeled urea test meal that is ingested by the patient.⁴⁷⁶

Serologic assays are being used to diagnose *H. pylori* infection in people and *H. mustelae* infection in ferrets, and *Helicobacter* spp. infection in dogs,^{134,421,434} and cats.⁴³³ However, they do not provide a routine, reliable, noninvasive diagnostic test for gastric *Helicobacter* infection in dogs and cats. ELISA analyses of serum and mucosal secretions from cats naturally infected with *H. pylori* revealed an *H. pylori*-specific IgG response and elevated anti-*H. pylori* IgA levels in salivary and local gastric secretions.¹⁴⁹ This assay probably cannot be used clinically in cats because of the high prevalence of the large spiral GHLOs in pet cats and the cross-reactive antigens shared by these bacteria and *H. pylori*.

In a survey of 101 dogs a combination of ELISA and immunoblotting using ureA, ureB, and heat shock protein antigens appeared to be a highly specific and moderately sensitive indicator of GHLO infection.⁴³⁴ However, the degree of seropositivity assessed by ELISA was not related to degree of gastric helicobacter-colonization density, degree of mucosal inflammation, or presence of lymphoid follicles.

In a study of 17 of 45 cats naturally infected with *H. heilmannii* (9 of 17), *H. felis* (4 of 17), both infections (3 of 17), and unclassified *Helicobacter* species (7 of 17), antibody titers to high molecular cell-associated protein fraction of *H. felis* were higher for infected cats regardless of the infecting species.⁴³³ Neither age nor clinical signs affected the results of the assay. A weak correlation was observed between the level of the titer and degree of inflammatory and lymphoid changes in the stomach.

Stool antigen tests have been used as a noninvasive method to detect and monitor *H. pylori* infection in people; however, as with antibody measurements, cross-reactivity in animal infections is anticipated. Similarly PCR, using 16S ribosomal RNA (16S rRNA) primers, has been used to detect and specifically identify corresponding helicobacter in gastric biopsies and the feces of dogs.⁴⁰¹

39.2.6 Therapy

Therapy for gastric *Helicobacter* spp. infections has become somewhat controversial as newer information has been discovered. These organisms may cause subclinical infections in the majority of people and animals. Very few controlled studies in dogs and cats document the benefits of therapy. For people, treatment to eradicate *H. pylori* is beneficial for those with peptic ulcers or gastric lymphoma or requiring long-term treatment with

Infectious Diseases of the Dog and Cat, 3rd Edition

nonsteroidal antiinflammatory drugs.³⁴³ Unfortunately for people, limited studies indicate that treatment may increase the risk of esophageal cancer or worsen gastroesophageal reflux. However, this data requires confirmation in large controlled clinical trials. Antimicrobial resistance is another concern because it rapidly develops against drugs such as clarithromycin.³⁵⁵

Table 39-5 Therapeutic Options for Gastric Helicobacteriosis

DRUG TYPES	THERAPEUTIC CHOICES
Antisecretory agents	1. Bismuth
	2. H ₂ antagonist
	3. Proton pump inhibitor
Antimicrobials	1. Metronidazole and amoxicillin
	2. Metronidazole and tetracycline
	3. Metronidazole and clarithromycin
	4. Amoxicillin and clarithromycin
	5. Clarithromycin
	6. Amoxicillin or clarithromycin and metronidazole and tetracycline

Various clinical trials using different antisecretory and antimicrobial drug combinations have been used in people to treat *H. pylori* infections (Table 39-5). Most regimens combine two to three antibacterial agents (including bismuth-containing drugs) with antisecretory drugs such as proton pump inhibitors (PPIs). Increased pH inhibits helicobacters and improves the efficacy of the antimicrobial agents. A triple-therapy regimen consisting of amoxicillin and an imidazole (either [1] metronidazole or tinidazole or [2] a tetracycline and metronidazole) and a macroclide (clarithromycin) in combination with bismuth subsalicylate given for 2 to 3 weeks has proved to be the most efficient in eradication of *H. pylori*. Indeed, this antimicrobial regimen, plus antisecretories such as ranitidine, has proved successful in treating patients with *Helicobacter*-induced gastric and duodenal ulcers. In studies comparing this treatment with ranitidine alone, ulcers not only healed faster, but the recurrence was also significantly less than in those receiving only antibiotics. Therapy regimens using PPIs (e.g., omeprazole) in combination with antibiotics (e.g., amoxicillin) also have shown considerable efficacy in eradicating *H. pylori*. Antisecretories likely improve the effect of antimicrobials by increasing gastric pH, which inhibits helicobacters and improves antibiotic activity. Whether antimicrobial therapy should be instituted in domestic dogs and cats with gastritis or ulcer disease has not been consistently evaluated. Many protocols have been adapted from treatment of *H. pylori* in people. Suggested combination drug regimens based on those that are effective for *H. pylori*-infected people⁴⁷⁶ with dosages for dogs and cats are listed in Table 39-6. Studies in ferrets indicate that the triple therapy consisting of amoxicillin, metronidazole, and bismuth subsalicylate three times a day for 3 to 4 weeks has successfully eradicated *H. mustelae* from ferrets.³³⁶ Omeprazole given to ferrets once daily effectively induces hypochlorhydria and can be given in conjunction with antibiotics to treat *H. mustelae*-associated duodenal or gastric ulcers. Clarithromycin and ranitidine bismuth citrate combinations have also been effective in treating these infections when the appropriate dosages were used.²⁸⁵ Cases of acute bleeding ulcers must be treated as emergencies, and fluid and blood transfusions are essential.

Infectious Diseases of the Dog and Cat, 3rd Edition

Because GHLO infections are so common in clinically healthy dogs and cats, the decision to treat should be based on evidence of gastric lesions with compatible clinical illness. The duration of treatment of dogs and cats with helicobacteriosis has not been extensively substantiated. Cats naturally infected with *H. pylori* have received a 21-day course of oral amoxicillin, metronidazole, and omeprazole.³⁵⁰ All six treated cats were culture negative at several sites (saliva, gastric juice, and gastric mucosa) for *H. pylori*. However, as determined by PCR, 2 and 4 weeks after treatment the majority of cats had gastric biopsy samples positive for *H. pylori*.³⁴⁹ Six weeks after treatment, all six cats had *H. pylori*-negative cultures for samples from several gastric sites taken at necropsy, and only one cat had *H. pylori* cultured from gastric juice. PCR analysis revealed that five of six cats still had *Helicobacter* DNA present in plaque, saliva, and gastric biopsy samples using *Helicobacter*-specific 26 kDa primers. However, it is known that these primers amplify DNA of other *Helicobacter* species. It is likely though not proven that the PCR helicobacter primers were amplifying DNA from enteric helicobacters present in the cats. In pet dogs with histologic GHLO gastritis, treatment in combination for 10 days with amoxicillin, tetracycline, metronidazole, and omeprazole, most dogs tested helicobacter-negative and had resolving gastrointestinal signs.¹⁹³ However, no change in the histologic lesions was found, and all dogs checked months later had a reoccurrence of infection. GI signs did not return. Reoccurrence is most likely in dogs that have intimate contact with other dogs.⁵⁰⁰

Table 39-6 Therapy for Gastric Helicobacteriosis in Dogs and Cats

DRUG ^a	SPECIES	DOSE ^b	ROUTE	INTERVAL (HOURS)	DURATION (DAYS) ^c
Coating Agents					
Bismuth subsalicylate ^d	D	0.5–2 ml/kg	PO	4–6	14–28
	C	0.5–1 ml/kg	PO	4–6	14–28

a See Appendix 8 for additional information.

Infectious Diseases of the Dog and Cat, 3rd Edition

- b Dose administration at specified interval.
- c Treatment duration in people has taken up to 8 weeks for successful resolution.
- d Bismuth subsalicylate, original formula (Procter Cinnatic OH). Dose is 17.5 mg/kg when using other products. Salicylate compounds must be used judiciously in cats, and other substitutes such as bismuth subcitrate should be considered.
- e Metronidazole resistance has been noted with increasing frequency in people with *H. pylori* infections.^{144a} A combination regimen of metronidazole (30 mg/kg/day), spiramycin (15,000IU/5kg/day), and omeprazole (1 mg/kg) for 7 days has been used in dogs.²⁶⁴
- f Ranitidine bismuth citrate (*Tritec*, Glaxo, SmithKline, Research Triangle Park NC) and clarithromycin have been used as a combined bimodal therapy with high efficacy in experimentally infected ferrets.²⁸⁵
- g Cimetidine inhibits absorption of ketoconazole; metoclopramide inhibits cimetidine absorption. Other than ranitidine, similar drugs include nizatidine and roxatidine.
- h Not as a bolus but by slow infusion.
- i Available as 20-mg capsule; maximum dose for dog is 20 mg. Granules must be fractionated and placed in gelatin capsules for lower doses. Alternative drugs include lansoprazole, pantoprazole, esomeprazole, and rabeprazole.
- j Must avoid using within 2 hr of administering many of the oral drugs because it interferes with their absorption.

Treatment with amoxicillin, metronidazole, and famotidine resulted in clinical improvement in over 90% of 63 dogs and cats colonized with GHLOs and when reexamined by endoscopy, they were reportedly negative.⁷⁸

Unfortunately the diagnostic test used to assess the presence of GHLOs was not stated, nor was the time interval of the endoscopy after treatment specified. Another study, using amoxicillin, metronidazole, and famotidine for 2 weeks, indicated that at 28 days after treatment the urea breath test was still positive in most dogs.⁶⁹ Similar poor results have been documented in cats with azithromycin, tinidazole, bismuth, and ranitidine or with clarithromycin, metronidazole, bismuth, and ranitidine for 4 to 7 days.³¹⁸ The less-than-favorable results of all these studies makes uniform recommendations of treating infected cats and dogs unlikely.

In people with severe GHLO infection (i.e., *H. heilmannii* or *H. felis*), bismuth subsalicylate, amoxicillin, tetracycline, and metronidazole in various combinations successfully eradicated GHLOs from the gastric mucosa with resolution of gastritis.^{196,451} Antimicrobial therapy has also been used successfully to treat GHLO-induced MALT lymphoma in humans.^{33a} In two separate reports, prolonged treatment with bismuth subsalicylate (4 weeks) or bismuth subcitrate (8 weeks) also successfully eradicated the GHLOs from patients.^{196,310} No systematic antibiotic trials have been conducted in dogs and cats to test for efficacy in eradicating either *H. heilmannii* or *H. felis* from gastric mucosa.

39.2.7 Public Health Considerations

Because *H. heilmannii* (which is currently classified as *H. bizzozeronii* in dogs) and to a lesser extent *H. felis* colonize a small percentage of people with gastritis and no environmental source for these bacteria has been recognized, pets have been implicated in zoonotic transmission. In one report of *H. heilmannii* infection in a child, the child's household had two cats. A gastric biopsy from one cat indicated it was infected with gastric

Infectious Diseases of the Dog and Cat, 3rd Edition

spiral organisms that had morphologic characteristics similar to those detected in the child's stomach.²⁶⁶ In another report, a girl who moved to a rural environment developed an 18-month history of epigastric pain, nausea, vomiting, and anorexia. Antral active chronic gastritis associated with *H. heilmannii* was confirmed.⁴⁵¹ Institution of various anti-*Helicobacter* antimicrobial treatments was only temporarily successful. The girl had two dogs—one that frequently licked the girl's face and had chronic intermittent vomiting and another that was asymptomatic. The symptomatic dog had active chronic gastritis associated with large numbers of *H. heilmannii*, whereas the asymptomatic dog had mild gastritis associated with fewer *H. heilmannii*. The girl and the dogs were simultaneously placed on a 6-week course of amoxicillin and bismuth. The symptoms in the dog resolved, but the girl required additional therapy with omeprazole. Although DNA analysis of the *H. heilmannii* strains was not performed to confirm the organism's identity, the zoonotic association is highly suggestive. Multiple *H. heilmannii* strains were found in a person with gastric ulcers, and one genetic strain was identical to one derived from his cat.⁸¹ Another child who acquired an *H. heilmannii* infection had a strain that matched the isolate from a cat.⁴⁶⁹

In Germany a survey of 125 individuals infected with GHLOs provided information in a questionnaire regarding animal contact. Of these patients, 70.3% had been in contact with one or more animals, compared with 37% of the clinically healthy control population.⁴²⁹ More than three times as many male patients had GHLOs than female patients. Because *H. bizzozeronii* and *H. felis* can be cultured on artificial media, a comparison is needed among the various species infecting animals and their genetic markers. A researcher performing physiologic studies with cat stomachs developed an acute gastritis presumably resulting from *H. felis* on the basis of EM.²⁶⁰ Similar gastric spiral bacteria were demonstrated in gastric mucosa of cats being used by this scientist.

If *H. pylori*, as demonstrated in commercially reared cats,^{149,188} is isolated from pet cats, the zoonotic potential of helicobacteriosis from cats would obviously increase substantially. *H. pylori* infection is an important cause of human gastritis, peptic ulcer disease, MALT lymphoma, and gastric adenocarcinoma. Most epidemiologic studies do not incriminate pet contact with *H. pylori* human infection. Cats can be experimentally infected with certain strains of *H. pylori*, and they develop persistent gastritis.³⁴⁹ However, cats tested generally have rare evidence of infection.⁹²

In serologic studies of people with *H. pylori* infection, owning pets was inversely related to *H. pylori* IgG antibody titers; however, pet ownership in these studies was associated with a higher socioeconomic status.^{111,172} Furthermore, pet ownership was not segregated by whether the pets were dogs or cats, the number and age of pets, or the length of pet ownership. In another study, even though the number of patients with pets was small, exposure to cats or dogs in the preceding year was not statistically associated with *H. pylori* infection.⁴⁷⁰ An epidemiologic survey conducted in Germany did not show an increased risk of *H. pylori* because of cat ownership.¹⁹ In a serologic survey measuring antibodies to *H. pylori*, lower socioeconomic status—not pet ownership or day care attendance—was associated with seropositivity.⁴²¹ In a survey of male employees in England, pet ownership as a child was marginally associated with current *H. pylori* infection; however, overcrowding plus person-to-person contact was found to be the major risk factor.⁴⁷⁹ In veterinarians, no serologic evidence for increased risk of exposure was found.³¹⁷ Only one study suggested an epidemiologic risk. IgG anti-*H. pylori*-seropositive farm workers were more likely to report more contact with cats than dogs.⁴⁴⁹

Infectious Diseases of the Dog and Cat, 3rd Edition

39.3 INTESTINAL AND HEPATIC *HELICOBACTER* INFECTIONS

James G. Fox

39.3.1 Etiology

In addition to their association with the gastric mucosae, an increasing number of other *Helicobacter* species have been isolated from the lower intestinal tract of mammals and birds (Table 39-7). Some of these (e.g., *H. cinaedi*, *H. fennelliae*, and *H. rappini*) have been linked to proctitis, colitis, and septicemia in immunocompromised people.^{239,455} In addition, *H. hepaticus* and *H. bilis* have been isolated from livers of mice with hepatitis and hepatocellular carcinoma as well as from intestines of asymptomatic mice sampled from United States and international sources.^{137,153} *H. bilis* also has been isolated from a gastric sample of a dog and *H. canis* from the liver of a dog with hepatitis.^{92,138}

One of these gram-negative spiral organisms with sheathed bipolar flagella was given the name *H. canis group* because it has a weak DNA homology to *H. cinaedi* and *H. fennelliae* but is phenotypically distinguishable from these organisms by its morphologic characteristics (Fig. 39-6); it is also resistant to polymyxin B and unable to reduce nitrate. Like *H. hepaticus*, *H. bilis*, and *Helicobacter pullorum*, the marked resistance of *H. canis* to bile probably enables the organism to colonize the liver.^{137,153,425,426}

Also of interest is the isolation (on the basis of cellular fatty acid analysis) of *H. cinaedi* from the feces of dogs and a cat.²³⁹ *H. cinaedi* was isolated from a rhesus monkey with colitis and hepatitis as well from rhesus monkeys without diarrhea.^{110,140} *H. fennelliae* has also been identified in the feces of a dog and macaque monkey. Like *H. cinaedi*, *H. fennelliae* (previously known as *Campylobacter fennelliae*, or CLO-2) was first isolated from gay individuals who were infected with human immunodeficiency virus (HIV) and had colitis and proctitis.⁴⁵⁵ However, unlike *H. cinaedi*, this enteric *Helicobacter* species does not often cause bacteremia in adult humans.^{237,321}

351

352

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 39-7 Comparative Features of Intestinal and Hepatic *Helicobacter* Species That Infect Dogs and Cats

HELICOBACTER ORGANISM	MORPHOLOGIC AND DISTINGUISHING FEATURES	HOSTS	CLINICAL FEATURES
<i>H. cinaedi</i> and <i>H. fennelliae</i>	Single bipolar, sheathed flagella; catalase positive	Dogs and cats Nonhuman primates and people Hamsters	Fecal isolate Experimental and natural infection (<i>H. cinaedi</i>) Often asymptomatic, colitis and proctitis if immunosuppressed, diarrhea and septicemia in immunocompetent hosts
<i>H. canis</i>	Sheathed, bipolar flagella; resists bile; resists polymyxin B; cannot reduce nitrate	Dogs, cats People	Liver with multifocal hepatitis Diarrhea or asymptomatic
<i>H. marmotae</i>	Single bipolar flagella; catalase positive	Cats, woodchucks	Asymptomatic in cats, hepatitis in woodchucks
<i>H. rappini</i>	Fusiform—slightly spiral periplasmic fibers	Cats, dogs, people	Asymptomatic, hemorrhagic enteritis

Fig 39-6 Scanning electron microphotograph of *H. canis*. (Courtesy M.H. Stoffel, University of Bern, Bern, Switzerland.)

* References [127](#), [137](#), [153](#), [397](#), [426](#), [425](#).

39.3.2 Epidemiology

On the basis of biochemical, phenotypic, and 16S rRNA analyses, *H. canis* was isolated from Bengal cats with and without chronic diarrhea.¹¹⁷ Because the cats were coinfectd with other potential pathogens, including *C. helveticus*, and because *H. canis* was isolated from nondiarrheic cats, the causal role of *H. canis* in producing

Infectious Diseases of the Dog and Cat, 3rd Edition

the diarrhea could not be proved. Isolation of *H. canis* in cats raises the possibility that *H. canis*, like *H. hepaticus* and *H. bilis* in mice, can cause inflammation of the colon, particularly in hosts with immune dysregulation. Additional studies are needed to determine the importance of *H. canis* as a primary enteric pathogen in cats and the role of cats in the possible zoonotic spread of *H. canis* to people.

In epidemiologic studies regarding incidence of CLOs in 1000 dogs, 4% of the animals had an organism, which was later identified as *H. canis*, isolated from their feces.^{49,425} The organism was also isolated from the feces of a child with gastroenteritis during a similar survey of children to determine prevalence of CLOs.⁵¹

On the basis of 16S rRNA data, *H. canis* has also been identified from the liver of a puppy diagnosed as having an active, multifocal hepatitis.¹³⁸ Determining whether this organism is capable of experimentally inducing hepatitis in dogs or occurs as a natural liver infection in people requires additional study. The pathogenic potential is strengthened by isolation of *H. canis* from a bacteremic person³³¹ and by studies that demonstrate that *H. hepaticus*, an intestinal *Helicobacter* of mice, can experimentally induce hepatitis in both inbred and germ-free mice.^{143,154,477} *H. hepaticus* can also cause liver tumors in susceptible strains of mice.

The entire genome of *H. hepaticus* has been sequenced recently.⁴³⁷ It is anticipated that by analyzing this sequence data, a great deal will be learned about how this organism (as well as other enterohepatic helicobacters) exerts its pathogenic potential on its hosts.

In the 6-year study of 64 of 227 commercially reared cats, microaerobic bacteria were isolated from their feces. All the isolates were initially identified as CLOs based on biochemical and phenotypic characteristics. DNA extractions from 51 of these isolates were subjected to PCR using primers specific for *Helicobacter* species and *Campylobacter* species. Of the isolates, 92% (47 of 51 isolates) were positive for *Campylobacter* spp., 41% (21 of 51 isolates) were positive for *Helicobacter* spp., 33% (17 of 51 isolates) were positive for both genera, 59% (30 of 51 isolates) were positive only for *Campylobacter* spp., and 8% (4 of 51) were positive only for *Helicobacter* spp.

The 1.2-kb PCR products of the 16S rRNA genes of 19 *Helicobacter* species isolates were subjected to restriction fragment length polymorphism (RFLP) analysis. Of the five different RFLP patterns obtained, two clustered with *Helicobacter (Flexispira)* taxon 8, one clustered with *H. bilis*, one clustered with *H. canis*, and the remaining pattern was closely related to a novel *Helicobacter* strain isolated from a woodchuck. The sequence data for the 16S rRNA genes of 10 *Helicobacter* species validated the RFLP-based identification of these isolates.

352

353

Woodchucks (*Marmota monax*) have a high incidence of hepatocellular carcinoma (HCC) associated with chronic infection with woodchuck hepatitis virus and serve as a model of hepatitis B virus–associated HCC in people. To determine whether woodchucks harbor a *Helicobacter* species that might play a role in potentiating hepatic inflammation or neoplasia, a study was undertaken to determine whether the woodchucks' livers were infected with a *Helicobacter* species.¹⁵¹ A 1200-base pair *Helicobacter* species-specific sequence was amplified from 14 liver samples. Southern hybridization confirmed the specific identity of the PCR products. A urease-, catalase-, and oxidase-positive bacterium was isolated from one liver sample from a woodchuck with a positive liver tumor. By 16S rRNA analysis and biochemical and phenotypic characteristics, the organism was classified as a new *Helicobacter* species. Subsequently, four additional bacterial strains isolated from feces of cats and characterized by biochemical, phenotypic, and 16S rRNA analysis were determined to be identical to the woodchuck isolate. The new helicobacter was named *Helicobacter marmotae*.¹⁵¹

Infectious Diseases of the Dog and Cat, 3rd Edition

Given that cats are often diagnosed with chronic cholangiohepatitis of unknown etiology, it will be interesting to ascertain whether this new *Helicobacter* species causes liver disease in cats and other mammals.^{161,39a}

39.3.3 Pathogenesis

The normal ecologic niche of certain helicobacter species is the lower intestine; the mechanism by which they colonize the liver is unknown. Like another intestinal enteropathogen, *Salmonella typhi*, the organisms may gain access to the liver by initial enterocyte or M cell uptake in the intestine and spread to the liver via the portal circulation. The bacteria may then be discharged from the liver into the biliary tract.²⁰⁸ Alternatively, helicobacters may migrate retrograde from the lumen of the gut into the bile duct. Whether the presence of intestinal parasites facilitates the ability of *H. canis* (and other helicobacters) to colonize the liver and cause hepatitis is unknown. Organisms with *H. bilis* morphologic characteristics have been noted previously in bile canaliculi of rats experimentally infected with *Fasciola hepatica*.¹²¹ In addition, *Flexispira (H.) rappini* has been associated with abortion in sheep, necrotic hepatitis in the aborted fetuses, and intestinal disease in animals and people. Experimentally, *H. rappini* causes similar abortions and necrotic hepatitis in guinea pigs.^{21,242,374} It is conceivable but certainly has not been proven that puppies can be infected in utero; however, its importance as a pathogen in pet animals has not been determined.

Pigtail macaques (*Macaca nemistrina*) were experimentally challenged orally with *H. cinaedi* and *H. fennelliae*.¹¹⁵ Although infection occurred in these monkeys and caused abnormal feces and focal large-bowel lesions, only one of five monkeys infected with *H. fennelliae* had acute proctitis, and *H. cinaedi* induced only lymphoid hyperplasia.¹¹⁵

39.3.4 Clinical Findings

It is not known whether intestinal *Helicobacter* can cause primary diarrheal disease in immunocompetent companion pet animals or only those that are immunocompromised. *H. hepaticus* and *H. bilis* are increasingly linked to severe IBD and colon cancer in immunocompromised mice,^{101,135} and select germ-free mice inoculated with the organism develop segmental enteritis.^{137,143,154} A 4-month-old British Blue cat developed hemorrhagic enteritis and died. The animal was heavily colonized with spiral to fusiform bacteria in the stomach, small intestine, and cecum. A robust inflammatory response in lamina propria of stomach and intestine was noted. Immunohistochemistry using antihelicobacter antibody indicated that these spiral organisms were strongly positive. EM showed that these organisms had a morphology similar to *H. rappini*.²⁴¹ If helicobacters are determined to be a common cause of hepatitis and enteritis in dogs and cats, appropriate liver function tests as well as microaerobic culture of liver and intestinal biopsies should provide insight.

39.3.5 Diagnosis

Many hospital laboratories have difficulty isolating helicobacters. For example, because of the slow growth of *H. cinaedi*, laboratory diagnosis is unlikely if blood culture procedures that rely on visual detection of the culture media are used.^{239,240} In a retrospective study of people with *H. cinaedi*-associated illness, most of the patients had the organism isolated from blood using automated blood culture system.²⁴⁰ Dark-field microscopy or use of acridine orange staining of blood culture media rather than Gram stain increases the likelihood of seeing the organism. Likewise, fecal isolation is difficult; selective antibiotic media are required, and recovery

Infectious Diseases of the Dog and Cat, 3rd Edition

is facilitated by passing fecal homogenates through a 0.45- μ filter.^{164,398} In addition, some strains of *H. cinaedi* and *H. fennelliae* are inhibited by concentrations of cephalothin and cefazolin used frequently in selective media for isolation of enteric microaerophilic bacteria.²³⁹ These organisms also require an environment rich in hydrogen for optimum in vitro growth. *H. canis* can be distinguished from *H. fennelliae* by its ability to grow at 42°C, its failure to produce catalase, and its marked tolerance to bile.

For the best recovery of *Helicobacter*-like organisms (HLOs), fecal samples should be placed in glycerol medium for transportation. Higher hydrogen levels (5% to 10%) are required for optimal *Helicobacter* species isolation. Unfortunately, this atmosphere is not available in the commercially available diagnostic kits used for *Campylobacter* isolation.

Microaerobic conditions were maintained in vented GasPak jars (Becton Dickinson, Franklin Lakes, N.J.) without a catalyst by evacuation to -20 mm Hg and then repressurization with a gas mixture consisting of 80% nitrogen, 10% hydrogen, and 10% carbon dioxide to yield a final oxygen concentration of 5%.¹⁴⁵

Identification of multiple species of microaerobic bacteria in the feces of an animal poses a diagnostic challenge, particularly when these microaerobes grow on similar media in comparable atmospheric conditions. Primary isolation of these microaerophilic bacteria may be misleading because *Helicobacter* species may be present in smaller numbers and grow at a slower rate than *Campylobacter* species. The similar phenotypic traits and biochemical profiles of these genera also complicate the diagnosis. Using *Campylobacter* and *Helicobacter* genus-specific PCR assays allow distinction between the two genera. The PCR-RFLP assay was also useful for *Helicobacter* species identification.

39.3.6 Pathologic Findings

Although the normal ecologic niche of *H. canis*, *H. hepaticus*, and *H. marmotae* is the crypts of the intestine, these organisms can also colonize the liver. The best characterized liver lesion caused by a *Helicobacter* is *H. hepaticus*-associated hepatitis in A/JCr mice. In infected mice the organism causes a multifocal hepatic lesion with cholangitis and vasculitis, which progresses in severity to include bile duct hyperplasia, hepatomegaly, oval cell hyperplasia, hepatocellular proliferation and—in aged male A/JCr, B6C3F1, AXB mice—hepatoma or hepatocellular carcinoma.^{137,143,477} The *H. canis*-associated liver lesion noted in a young dog consisted of an acute multifocal necrotizing hepatitis.¹³⁸ Interestingly, HLOs were present at the periphery of the hepatic lesion and appeared to be located in bile canaliculi. This pattern of colonization is also noted in *H. hepaticus*- and *H. bilis*-infected livers.^{137,143,153,472}

353

Isolation of "*H. rappini*" from the blood of experimentally infected guinea pigs 1.5 weeks after inoculation indicates the ability of these organisms to cause bacteremia.⁴⁶ For example, *H. rappini*-like organisms were recently isolated from a 9-year-old child with bacteremia and pneumonia.⁴⁴⁵ In addition the observation of translocation of *H. rappini*-like organisms in enterocytes of cotton-top tamarins (*Saquinus oedipus*) with ulcerative colitis or mice coinfecting with *Serpulena hyodysenteriae* supports this viewpoint.^{59,210}

354

Several recent studies have been undertaken to determine whether *Helicobacter* species are associated with cholecystitis and other hepatobiliary diseases in people. In these studies the presence of *Helicobacter* species detected specific DNA by PCR and sequencing.^{23,136,150,324-326} The difficulty in obtaining gallbladder and liver tissues from selected populations highlights the need for noninvasive serologic assays to determine the prevalence of hepatic *Helicobacter* organisms in various biliary and hepatic diseases of people and animals.

Infectious Diseases of the Dog and Cat, 3rd Edition

To date, none of these studies have reported that they have been able to culture *Helicobacter* from bile or liver. Additional studies using specific and sensitive detection methods are needed to ascertain the association of *Helicobacter* infection with hepatobiliary diseases in different human populations as well as dogs and cats.

Enterohepatic helicobacters cause IBD and lower bowel cancer in immunodysregulated mice. In addition, multiple new *Helicobacter* species have been isolated from rhesus monkeys and cotton-top tamarins with chronic debilitating colitis.^{100,141,389} It will be interesting to ascertain whether chronic colitis and lower bowel cancer in dogs and cats is related to *Helicobacter* infection.¹¹⁷

39.3.7 Therapy

Antimicrobial susceptibility testing of *H. cinaedi* indicates that tetracycline, chloramphenicol, and various aminoglycosides should be effective in treating infections with *H. cinaedi*.²⁴⁰ (See Table 39-2 for appropriate dosage information.) Apparent relapses of *H. cinaedi* bacteremia have occurred in people treated with ciprofloxacin despite its previous use to successfully treat *H. cinaedi* infection. The development of in vitro resistance of *H. cinaedi* isolates to ciprofloxacin suggests that fluoroquinolones should be used with caution.^{239,240}

H. rappini-like organisms isolated from a child with bacteremia and pneumonia was successfully treated with erythromycin.⁴⁴⁴ Recurrent *H. rappini*-associated bacteremia over a period of several months, despite several courses of antibiotics, has also been noted in two patients with prolonged cellulitis and X-linked agammaglobulinemia (XLA).

One patient was first diagnosed as having *H. rappini* at age 4. In vitro antibiotic testing using E-test strips indicated the bacteria were resistant to ampicillin, azithromycin, ceftriaxone, chloramphenicol, ciprofloxacin, and clindamycin.⁴⁸⁷ The organism was sensitive to imipenem, metronidazole, minocycline, and rifampin and showed intermediate sensitivity to doxycycline. Based on these findings the patient was initially treated with doxycycline and metronidazole with noted clinical improvement of the cellulitis. However, blood cultures remained positive, and treatment was changed to oral amoxicillin-clavulanate, minocycline, and rifampin.⁴⁸⁷ Initial improvement was again noted, but symptoms recurred. IV gentamicin and imipenem were then initiated and continued for 5 months. This regimen resolved the systemic infection, and follow-up blood cultures were normal.⁴⁸⁷

In the second case of XLA, the patient's symptoms began when he was 6 months old. He had been diagnosed as having pyoderma granulosum with nonhealing skin ulcers and swelling of the leg at age 17. One year later, he developed pyrexia and was treated with IV gentamicin, metronidazole, and vancomycin. The fever resolved and the skin ulcers healed but after treatment was terminated, the lesions recurred. Three years later, his clinical signs had not improved. Blood samples were taken, and *H. rappini*-like organisms were cultured on several occasions. Magnetic resonance imaging also indicated that the patient had osteomyelitis. Surgical bone debridement of the affected bone was performed, and *H. rappini*-like organisms were cultured from these sites. Treatment with IV imipenem and gentamicin successfully resolved the fever and macular rash; gradual improvement of the ulcers was also noted. Gentamicin was discontinued (because of hearing loss) and replaced by IV meropenem. After 9 months of IV antibiotics the ulcers regressed and therapy was discontinued. These two cases of XLA highlight the apparent susceptibility of a B-cell (humoral) immunodeficiency in people to *H. rappini*-like infections. The resultant intravascular and intralymphatic infections in people are difficult to treat

Infectious Diseases of the Dog and Cat, 3rd Edition

with antibiotics. If these clinical signs are present in dogs and cats, clinicians should attempt to ascertain whether helicobacters are associated with the disease syndrome.

39.3.8 Public Health Considerations

Because *H. cinaedi* has been isolated from normal intestine flora of hamsters, it was suggested that pet hamsters could serve as a reservoir for transmission to people.¹⁶⁴ *H. cinaedi* was isolated from the blood and feces of a neonate with septicemia and meningitis.³³³ The mother of the neonate had worked with hamsters during her first two trimesters of pregnancy and had a diarrheal illness during the third trimester. The newborn was likely infected during the birthing process, although this was not proven. Additional studies are needed to confirm the zoonotic risk of handling *H. cinaedi*-infected hamsters and possibly other animals as well.¹⁶⁴

H. rappini was first reported in two people with chronic diarrhea and their pet dogs.²¹ *H. rappini*-associated cellulitis ensued after a cat scratch; perhaps the patient had *H. rappini* colonization his bowel, and the organism gained access to the blood via translocation. Nevertheless, zoonotic transmission of this organism is possible.^{21,374,416}

Even though *H. canis*, *H. cinaedi*, *H. fennelliae*, and *H. rappini* have been isolated from dogs, cats, and people, additional investigations are needed to ascertain whether these helicobacters in dogs and cats constitute a potential reservoir for zoonotic transmission to people. Although *H. canis* and *H. pullorum* have been isolated from children and adults with gastroenteritis and diarrhea, evidence that either organism can cause hepatitis in people is indirect. *H. canis* has been isolated from the blood of people, which increases the likelihood that liver infection with *H. canis* in people also occurs.^{83,331} In addition a patient with *H. pullorum*-associated diarrhea had persistent increases in liver enzymes as well as hepatomegaly on abdominal ultrasonography.⁵⁰ With the use of appropriate diagnostic media and microaerobic culture conditions, various other *Helicobacter* species will also be isolated from people with hepatitis and companion animals.

39.4 ANAEROBIOSPIRILLUM INFECTION

Craig E. Greene

Similar to *H. rappini* and *H. cinadei*, the motile, spiral-shaped anaerobic bacteria *Anaerobiospirillum thomasi*, *Anaerobiospirillum succiniciproducens* and other *Anaerobiospirillum* spp. have been implicated as a cause of diarrhea with or without bacteremia in people. They are not isolated from feces of clinically healthy people but are commonly found in feces of clinically healthy dogs and cats.²⁸⁴ In fact the organisms were first isolated from the pharynx and fecal contents of beagle dogs.⁷⁷ In one puppy with bloody diarrhea, spiral bacteria consisting of *C. upsaliensis*, *H. cinaedi*, *H. rappini*, and two *Anaerobiospirillum* species were isolated.³⁰³ Organisms closely related to *A. succiniciproducens* were identified in intestinal lesions of 6 cats with ileocolitis.^{77a} Vomiting, diarrhea, or signs not related to the GI tract were observed. As with *Campylobacter* infections, the risk of people developing *Anaerobiospirillum* infection from their diarrheic dogs or cats is great, and some instances have been reported.^{168,282-284,445} These organisms can be distinguished from other spiral bacteria by genetic and ultrastructural methods.

39.5 SALMONELLOSIS

Craig E. Greene

39.5.1 Etiology

Salmonella are primarily motile, non-spore-forming, gram-negative bacilli of the family Enterobacteriaceae. Members of the genus *Salmonella* are ubiquitous pathogens that infect a wide variety of mammals, birds, reptiles, and even insects. Although they are primarily intestinal parasites, they can cause systemic disease and be isolated from other organs and blood. Salmonellae from animals have important public health implications because they are capable of causing mild to severe gastroenteritis in people.

The taxonomy of salmonellae has undergone many changes, with classification schemes being based on biochemical or serologic differences. Because the salmonellae are related, they are thought to belong to a single species: *Salmonella enterica*. The practice of substituting serotype names as species is commonly accepted. The more than 2400 serotypes of *S. enterica* are identified by agglutination reactions of their somatic (O) and flagellar (H) antigens. The species (serotypes) recognized to be of major pathogenic significance in veterinary and human microbiology include *S. ser choleraesuis*, *S. ser arizonae*, *S. ser enteritidis*, and *S. ser typhimurium*. *S. ser typhi*, which is extremely important as the cause of typhoid fever in people, is not normally pathogenic for animals; it is of little if any zoonotic importance. *S. ser enteritidis* has been further divided into more than 1700 bioserotypes, each with a distinguishing name such as *S. enteritidis dublin*. Although taxonomically incorrect, the species name is often omitted in favor of using the bioserotype alone (e.g., *S. dublin*).

Some species of salmonellae show a preference for certain animal hosts, and each domesticated farm animal species appears to have an adapted *Salmonella* species: horse—*Salmonella abortus equi*, cow—*S. dublin*, sheep—*Salmonella abortus ovis*, pig—*Salmonella choleraesuis*, and fowl—*Salmonella pullorum* and *Salmonella gallinarum*. Rarely, *S. choleraesuis* and *S. dublin* produce disease in people or other animals.

The remaining serotypes of *Salmonella* show little or no specific host adaptation and are equally pathogenic for people and other animals. Many have been isolated from vertebrates and invertebrates and the environment. These *Salmonella* serotypes or individual isolates of certain serotypes vary widely in their ability to infect and produce disease within a given animal host, and more virulent serotypes appear to be able to multiply intracellularly. Muroid and encapsulated strains are more pathogenic than other strains; *S. typhi*, which produces prolonged and systemic infections in its human hosts, is noted for these features. The species most commonly isolated from diseased animals and people is *S. typhimurium*.

39.5.2 Epidemiology

39.5.2.1 Source of Infection

In nature, most serotypes of *S. typhimurium* are ubiquitous and readily transmitted among animals and people and the environment (Fig. 39-7). The most common source of infection, which occurs through the GI route, is contact with contaminated food, water, or fomites. Airborne transmission, which produces respiratory infection, may occur occasionally because the organism is able to survive on dried airborne particles in the absence of organic material.

Infectious Diseases of the Dog and Cat, 3rd Edition

Salmonellae can survive for relatively long periods outside the host. Finding *Salmonella* in the environment usually indicates direct or indirect fecal contamination. A large portion of the aquatic biosphere is now contaminated with *Salmonella* organisms, probably as a result of pollution of streams and lakes with untreated sewage, garbage, and other refuse. Fish and shellfish living in previously infected waters are microbiologic monitors, because they can harbor the organisms in their digestive tracts for extended periods after direct isolation from the water is no longer possible. Dogs and cats may acquire an infection by drinking contaminated water, although this is less of a problem in areas where pets drink from chlorinated municipal water supplies. Environmental contamination from carrier dogs was suggested in one dog that may have acquired its infection while on exercise walks.³⁸⁷

Another source of infection for dogs and cats as well as for their human owners is contamination of food. This was a major problem in the past because pets were fed uncooked or unprocessed foods. Meat and meat by-products, especially those from contaminated horse meat, were the foods most commonly incriminated. Isolation of *Salmonella* from infected animals has been most common from swine, cattle, turkeys, and horses (in that order). *S. typhimurium* was by far the most common isolate. Meat from clinically healthy animals intended for human consumption is not sterile and frequently can contain enteropathogens. Bacterial microflora are deposited on the meat during processing. Racing greyhounds and working sled dogs are frequently fed diets containing raw meat because it is believed they need it to increase their endurance; some people want to provide uncooked meat diets for their pet animals as well.⁵³ Racing sled dogs are fed diets that are extremely palatable and have a high caloric content. These diets generally comprise high-fat commercial food supplemented with raw or partially cooked beef, horse, lamb, fish, or fat.⁵³ Carnivores in zoos being fed raw, meat-based diets are commonly exposed to and shed salmonellae in their feces.⁶⁶ Pet dogs fed pieces of whole, raw chicken meat and vegetables (a current trend involving a “natural” diet) had a 30% prevalence of salmonellae in their feces; no salmonellae were isolated from control animals fed commercially prepared food diets.²²³ Salmonellae were isolated from 80% of the purchased raw chicken being fed to the animals. In other surveys, salmonellae have been found in 20% to 35% of poultry carcasses intended for human consumption.^{25,54} Raw, dehydrated, or improperly cooked cat or dog food products prepared from contaminated sources have a higher prevalence of contamination than pelleted and heat-processed foods, which are less likely to be infected because they are adequately sterilized during preparation. Imported commercial dog chews made from animal hides have been found to contain *Salmonella* organisms.⁴⁹⁵ Animal-derived dog treats sold in the United States were found to contain various *Salmonella* isolates, some of which were multidrug-resistant strains.⁴⁹⁰ Even commercially processed foods can become contaminated if they are exposed to infected mammals, birds, reptiles, amphibians, or insects or to unsanitary conditions. Salmonellae can multiply quickly in moistened food left at room temperature. Supplementation of processed foods with uncooked food scraps or meat by-products is another common source of infection. In the United States, raw meat (*4-D meat*) used to feed racing greyhounds is highly contaminated with *Salmonella*.^{63,430,494}

Contaminated fomites such as food dishes, hospital cages, endoscopic equipment, and bathtubs can spread the disease throughout a veterinary hospital. Salmonellae can occasionally be transmitted through	355
contaminated pharmacologic or diagnostic preparations of animal origin, such as pancreatic extracts, liver extracts, bile salts, gelatin, vitamins, and hormonal extracts. Free-roaming dogs and cats have ample opportunity for exposure to <i>Salmonella</i> because they are carnivorous and occasionally coprophagous. Such animals may be infected with and shed numerous strains simultaneously. ^{48,438,481,501} Cats may have greater resistance to infection than dogs, as suggested by the less frequent isolation of <i>Salmonella</i> from cats.	356

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 39-7 Epidemiology of salmonellosis. (University of Georgia, Athens, Ga.)

Infected animal handlers may also be a source of *Salmonella* infection in a hospital, kennel, or cattery. Human infections with nontyphoid salmonellae are usually self-limiting, and shedding of the organism is usually not a persistent problem. Animal infections are more important in maintaining the organism in animal-holding facilities. Human carriers chronically infected with salmonellae that cause typhoid fever pose no health hazard for animals.

39.5.2.2

Prevalence

Salmonellosis in dogs and cats is more common than the prevalence of clinical disease suggests, with numerous serotypes being isolated from each species. The frequency of fecal isolation from clinically healthy or hospitalized dogs is reported to be 1% to 36% and from healthy cats is 1% to 18%. The actual prevalence of infection is probably higher than that estimated from fecal swab culture results and routine isolation procedures, because culture of intestinal lymph node specimens taken at necropsy yields a much higher prevalence of *Salmonella* organisms. The prevalence is probably decreasing because more pets are now fed commercially processed foods. *Salmonella* infection is still a problem in zoologic gardens where exotic carnivores are fed raw-meat diets.
